Netter's Internal Medicine

2nd Edition

By **Marschall S. Runge**, MD, PhD, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC, USA; and **M. Andrew Greganti**, MD, University of North Carolina at Chapel Hill School of Medicine, Chapel Hill, NC, USA

I. Common Clinical Challenges

1. Practicing in the Modern Environment - Patient Safety, Medical Errors, Malpractice (NEW)
2. Screening - Health Promotion and Disease Prevention/Wellness Examination" (NEW)
3. Diagnostic Testing: The Example of Thromboembolism (PE/DVT)
4. Obesity
5. Evaluation and Treatment of Chronic Pain
6. Chronic Fatigue Syndrome
7. Poisoning and Drug Overdose

II. Disorders of the Upper Respiratory Tract and Oropharynx

8. Pharyngitis
9. Rhinosinusitis
10. Rhinitis: Allergic and Idiopathic
11. Common Oral Lesions (Title Change)
12. Acute Otitis Externa
13. Acute Otitis Media
14. Hoarseness
15. Vocal Cord Dysfunction (NEW)
16. Neck Masses in Adults

III. Disorders of the Respiratory System

17. Cough
18. Community-Acquired Pneumonia
19. Pleural Effusions and Pneumothorax
20. Asthma
21. Bronchitis: Acute and Chronic (NEW)
22. Chronic Obstructive Pulmonary Disease
23. Restrictive Lung Disease, Including Interstitial Lung Disease (NEW)
24. Environmental Lung Diseases (NEW)

IV. Disorders of the Cardiovascular System

25. Hypertension
26. Hypertension Secondary to Renovascular Diseases
27. Hypertension Secondary to Diseases of the Adrenal Gland
28. Angina Pectoris
29. Myocardial Infarction
30. Electrocardiography and Functional Testing (NEW)
31. Peripheral Vascular Disease
32. Congenital and Valvular Heart Disease
33. Cardiomyopathies (NEW)
34. Heart Failure
35. Hypercholesterolemia: Evaluation and Treatment
36. Cardiac Arrhythmias
37. Atrial Fibrillation (NEW)
38. Syncope (NEW)

V. Disorders of Endocrinology and Metabolism

39. Diabetes and PreDiabetes: Diagnosis and Treatment
40. Prevention and Treatment of complications of Diabetes
41. Hypothyroidism
42. Thyrotoxicosis
43. Hyperparathyroidism
44. Disorders of the Adrenal Cortex
45. Pituitary Diseases
46. Hirsutism
47. Hypogonadism in the Male
48. Osteoporosis
49. Paget 's Disease of Bone

VI. Disorders of the Gastrointestinal Tract

50. Gastroesophageal Reflux Disease
51. Peptic Ulcer Disease
52. Helicobacter Pylori Infection and Associated Disorders
53. Gastrointestinal Bleeding (NEW)
54. Cholelithiasis
55. Pancreatitis
56. Diarrhea: Acute and Chronic
57. Constipation
58. Common Anorectal Disorders and Colonic Diseases
59. Irritable Bowel Syndrome
60. Inflammatory Diseases of the GI Tract
61. Esophageal Disorders: Dysphagia (NEW)
62. Diseases of the Liver - Non-Alcoholic Fatty Liver Disease, Drug Induced Liver Diseases, and Abnormal Liver Function Tests (NEW)
63. Viral Hepatitis: Acute and Chronic Disease

- 64. Cirrhosis
- 65. Celiac Disease

VII. Disorders of Coagulation and Thrombosis

- 66. Hypercoagulable States
- 67. Deep Venous Thrombosis and Pulmonary Embolism
- 68. Disseminated Intravascular Coagulation
- 69. Anticoagulation Management: Periprocedural, During Pregnancy, Supratherapeutic Levels/Complications of Therapy (NEW)
- 70. Bleeding Disorders

VIII. Hematologic Disorders

- 71. Anemias
- 72. Bone Marrow Failure States
- 73. Blood Component Therapy
- 74. Malignant Lymphomas
- 75. Leukemias
- 76. Multiple Myeloma/Monoclonal Gammopathy of Unknown Significance (NEW)
- 77. Hematopoietic Stem Cell Transplantation

IX. Oncologic Disorders

- 78. Lung Cancer
- 79. Colorectal Cancer
- 80. Breast Cancer
- 81. Prostate Cancer
- 82. Upper Gastrointestinal Tract Cancer
- 83. Skin Cancer
- 84. Cancer of the Oral Cavity and Oropharynx
- 85. Cervical Neoplasia
- 86. Testicular Cancer (NEW)
- 87. Thyroid Cancer (NEW)
- 88. Palliative Care for Patients with Advanced Cancer

X. Infectious Diseases

- 89. Fever of Unknown Origin
- 90. Septicemia
- 91. Staphylococcal Infections
- 92. Cellulitis (NEW)
- 93. Endocarditis
- 94. Meningitis
- 95. Septic Arthritis (NEW)
- 96. Osteomyelitis (NEW)

- 97. Catheter Infections (NEW)
- 98. Influenza
- 99. Infectious Mononucleosis
- 100. Herpes Simplex Virus Infections
- 101. Varicella-Zoster Infections
- 102. Encephalitis (NEW)
- 103. Pulmonary Tuberculosis
- 104. Fungal Infections (NEW)
- 105. Parasitic Infections
- 106. Malaria
- 107. Infectious Diseases in Travelers

XI. Sexually Transmitted Diseases

- 108. Acquired Immune Deficiency Syndrome (AIDS)
- 109. Nongonococcal Urethritis and Mucopurulent Cervicitis
- 110. Gonorrhea
- 111. Pelvic Inflammatory Disease (NEW)
- 112. Genital Warts
- 113. Syphilis

XII. Disorders of the Reproductive System

- 114. Contraception (NEW)
- 115. Common Problems in Pregnancy
- 116. Diabetes in Pregnancy
- 117. Menstrual Disorders
- 118. Endometriosis
- 119. Menopause
- 120. Erectile Dysfunction

XIII. Neurologic Disorders

- 121. Disorders of Consciousness: Persistent Vegetative State, etc. (NEW)
- 122. The Radiculopathies: Cervical, Lumbar, Spinal Stenosis (NEW)
- 123. Peripheral Neuropathy
- 124. Migraine Headache
- 125. Stroke and Transient Ischemic Attacks
- 126. Vertigo
- 127. Sleep Disorders
- 128. Epilepsy
- 129. Tremor
- 130. Parkinson's Disease
- 131. Bell's Palsy
- 132. Trigeminal Neuralgia
- 133. Multiple Sclerosis

134. Myasthenia Gravis

XIV. Disorders of the Kidney and Urinary Tract

- 135. Urinary Tract Infection
- 136. Bladder Function Disorders
- 137. Microscopic Hematuria (NEW)
- 138. Urinary Stone Disease (Nephrolithiasis)
- 139. Chronic Kidney Disease
- 140. Acute Renal Failure
- 141. Glomerulonephritis
- 142. Nephrotic Syndrome

XV. Disorders of the Immune System, Connective Tissue and Joints

- 143. Osteoarthritis
- 144. Low Back Pain in Adults
- 145. Fibromyalgia/Regional Pain Syndromes (NEW)
- 146. Gout
- 147. Calcium Crystal Diseases
- 148. Autoinflammatory Syndromes (NEW)
- 149. Vasculitis
- 150. Polymyalgia Rheumatica and Giant Cell Arteritis
- 151. Systemic Lupus Erythematosus
- 152. Antiphospholipid Syndrome (NEW)
- 153. Rheumatoid Arthritis
- 154. Scleroderma
- 155. Spondyloarthropathies
- 156. Polymyositis and Dermatomyositis (NEW)

XVI. Ocular Diseases

- 157. Myopia and Common Refractive Disorders
- 158. Common Eye Diseases (NEW)
- 159. Glaucoma
- 160. Diabetic Retinopathy

XVII. Psychiatric Disorders

- 161. Personality Disorders (NEW)
- 162. Anxiety and Panic
- 163. Depression
- 164. Grief
- 165. Posttraumatic Stress Disorder (PTSD) (NEW)
- 166. Obsessive-Compulsive Disorders
- 167. Schizophrenia

- 168. Emotional and Behavioral Problems Among Adolescents and Young Adults

- 182. End of Life Decision Making (NEW)

Practicing in the Modern Environment: Improving Outcomes and Patient Safety

Introduction

In this first decade of the 21st century, medicine in the United States remains a learned profession. Patients, and the public at large, continue to hold doctors in relatively high regard. Physicians preside over an ever-expanding array of diagnostic and therapeutic tools that are more targeted and therefore more successful, and many tests and procedures are less invasive than those available in the past. In general, the care available to individuals has never been more potentially powerful or more efficacious.

At the same time, Americans have lately become much more conscious of practitioners' imperfections, and they are especially aware of the shortcomings of the system that they must navigate to obtain care. The public now knows that the health care system often falls short of its potential; that medical care sometimes causes avoidable harms; and that the system includes wide variations in practice and cost without apparent differences in benefit to patients. Caregivers, and the organizations in which they practice, are increasingly tasked to demonstrate that their respective practices meet available standards and avoid potential harms.

As doctors well know, we remain limited in our ability to collect valid and reliable data and to appropriately compare different types of practice behaviors and different types of patients. Just as important, reimbursement models are fundamentally misaligned from the goals of optimizing performance and patient safety. Public and private pressures to change practice are, for now, modest, and physicians will face these demands while continuing to cope with others that at times will seem more pressing—such as billing regulations, staff shortages, and declining income. Despite these additional pressures, scrutiny of physician

practice by the government, by payors and their customers (employers), and by the public is here to stay.

Before the mid-1990s, payors, policy makers, and the profession gave scant attention to the shortcomings of the health care system. To be sure, the U.S. tort system has long permitted compensation for individual victims of negligence. For a plaintiff to be compensated, a defendant must be judged as failing to meet a standard of care and therefore blamed for “more likely than not” causing harm. Medicine weathers periodic crises of rising insurance premiums, and a few states have enacted reforms, but the U.S. malpractice system remains fundamentally unchanged in structure, and it has contributed little if anything to the real evolution of the scrutiny of clinical practice.

The attention to the quality and safety of medical care is the result of several other trends. From roughly the 1960s to the 1980s, what we now call health services researchers gradually standardized the methods for evaluating the structure of health care delivery models, the processes of care delivery, and clinical outcomes. Advances in information technology have gradually brought the computing power to apply these methods for evaluating care, processes, and outcomes. Federal support for the

evaluation of medical practice was boosted by the creation in 1990 of the Agency for Health Care Policy and Research (now the Agency for Health Research and Quality). Meanwhile, a multitude of groups—from employers who fund health insurance, to federal and state governments who also pay for an increasing share of health care, to managed care insurers and coalitions of consumer groups—all have steadily turned more of their attention to the quality of health care services and to the value of the services received in proportion to their cost.

Most recently, the medical profession has aggressively (if somewhat belatedly) lent its voice to the need for systemic change in the way doctors, hospitals, and others provide medical care. The Institute for Healthcare Improvement (IHI) is a private not-for-profit organization founded in 1991 by a pediatrician, Donald Berwick, MD, and has always included physicians in its leadership. IHI began as a lonely voice within the health care professions advocating for fundamental changes in care delivery. Over the ensuing years, IHI has been joined by a growing chorus of voices from “official” medicine, including many specialty societies, the American Medical Association, and the Institute of Medicine (IOM). Indeed, the IOM’s serial reports on the flaws and the potential for improvements to the health care system represent a watershed in both raising national consciousness about these matters and stimulating real movement toward change, both within the profession and in public policy.

In this decade, widespread measurement of care has become a reality. The Joint Commission (TJC) has adopted a broadening set of performance measures that hospitals are required to collect and report. The data are posted to a public website. The Centers for Medicare and Medicaid Services (CMS) has now joined TJC in this effort; as of 2005, hospitals that wish to receive their full annual inflation update from CMS must report their performance measures. CMS has proposed the long-anticipated conversion of its program from “pay for accurate reporting” to “pay for performance,” with some fraction of a hospital’s payments adjusted according to its success in improving care as determined by these measures. The Leapfrog Group, a consortium of large employers founded in 1998 to press for changes in health care delivery, has its own scorecard to track hospitals’ performance. Participation in the Leapfrog survey is voluntary, but payors and the public increasingly look to this data set for information about hospital performance. The Leapfrog and the TJC/CMS instruments measure processes (e.g., whether a hospital ensured that an aspirin was prescribed after an acute myocardial infarction) as opposed to clinical outcomes (e.g., the proportion of patients with a prior acute myocardial infarction who have a second heart attack). Process measures tend to be easier to track because they typically represent a behavior that is occurring at a snapshot in time, whereas outcomes may take much longer to assess. It is also easier to achieve expert consensus on the validity of a process

measure. Process measures also avoid the complications of socioeconomic mix of the population and severity adjustment. Hospital-based measures of outcomes tend to be reported to discipline-specific or specialty-specific national databases, or as research findings. Examples include the Vermont-Oxford database for neonatal care, the Society for Thoracic Surgeons database, and data sets collected by hospital-sponsored groups such as the University Health-System Consortium.

Physician-specific measurement has been slower to take shape in the United States but is now emerging as another important component of the field. CMS initiated in 2006 a voluntary reporting system for a finite set of process measures in the doctor’s office. In December 2006, President Bush signed the Tax Relief and Health Care Act of 2006, mandating establishment of a physician quality reporting system and authorizing a payment incentive (at least initially). At this time, physician participation in the CMS quality reporting initiative is still voluntary, but beginning in the second half of 2007, physicians who share data about their care of certain conditions will receive a 1.5% financial incentive from Medicare. Private insurers have also initiated a few programs to encourage individual physicians to report data about their practice. An example is the Bridges to Excellence program, which offers bonus payments to doctors who meet standards for the care of several chronic diseases. Efforts to more closely align provider payments with quality and safety measures remain the exception but will continue to expand.

Other important contributors to the movement toward transparency and accountability in the health care system have focused less on tying performance to accreditation or payment, and more on emphasizing peer-stimulated and evidence-supported incremental change. A prominent example is the 2005 IHI 100,000 Lives Campaign. Participating hospitals (3,000 ultimately enrolled) and their medical staff volunteered to commit resources to implement a series of practices that the medical literature has unequivocally shown will reduce in-hospital deaths. The IHI evidence suggests that most hospitals were successful in improving clinical outcomes and safety in one or more of the six suggested interventions. Most participants continue to work on these interventions. In December 2006, the IHI launched a new drive to reduce avoidable morbidity in hospitalized patients. Another organization, the National Quality Forum (NQF), has focused on creating, codifying, and disseminating standards of clinical practice that represent the best clinical evidence (and expert consensus). The NQF serves a valuable function by accelerating the endorsement of consensus-based national standards for measurement and public reporting of data about specific clinical diagnostic and therapeutic interventions. Other groups, such as Leapfrog, TJC, CMS, and specialty societies, can adopt these standards rather than having to create their own and can thereby focus on helping providers to improve care.

Although the ultimate impact of the initiatives outlined on the quality of care rendered to individual patients remains to be established, few can dispute that the central goal of improving our health care delivery system is worth any effort required. The hesitancy of some providers to embrace and participate in quality-enhancing initiatives often reflects the time constraints of a busy clinical practice rather than a lack of interest. To deal with the realities of the modern time- and resource-constrained clinical practice environment, policymakers must acknowledge the need for clinicians to have more infrastructure support to comply with new guidelines. In many cases, that will require an increase in hospital and professional fees to cover the additional overhead costs.

This website reviews the requirements, expectations, and general organization of this program.

EVIDENCE

1. Committee on Quality of Health Care in America, Institute of Medicine: *Crossing the Quality Chasm: A New Health System for the 21st Century*. Washington, DC, National Academy Press, 2001.

An excellent summary of the state of the health care system at the start of this century, and still the definitive consensus summary of the fundamental changes that physicians and health care organizations can make to improve care. The document’s Six Aims for Improvement are the most widely cited definition of quality: health care should be safe, effective, patient centered, timely, efficient, and equitable.

2. U.S. Department of Health and Human Services: Hospital Compare—A quality tool for adults, including people with Medicare. Available at: <http://www.hospitalcompare.hhs.gov/>. Accessed February 4, 2007.

This consumer-friendly website provides data submitted by more than 90% of U.S. hospitals, allowing the viewer to make comparisons among these hospitals.

Overview of Preventive Medicine

Introduction

High-quality health care requires not only treatment of medical conditions but also attention to effective preventive care. Prevention is defined as the reduction of risk for future adverse health events. A number of disparate services are regarded as prevention, including immunizations, screening, individual and group interventions for lifestyle change, and prophylaxis. As many as 50% of deaths in the United States are potentially preventable with current knowledge.

Like other medical care, preventive services can cause harm as well as benefit. Unlike treating serious medical problems, the risk that is addressed by prevention is small when seen in individual terms. For example, the probability of an asymptomatic 50-year-old woman having breast cancer detectable by her next mammogram is 4 to 5 in 1000, and the probability that her life will be extended by this mammogram is less than 1 in 1000. But, because so many people are involved, the absolute number of lives affected by preventive care can be large. For example, the lives of some 10,000 women each year in the United States either are or could be extended by breast cancer screening. Thus, it is most useful to think of the benefits and harms of prevention in terms of a practice's total patient population. High levels of participation are needed to maximize the number of patients who benefit.

For many health conditions, there is no effective prevention strategy yet available. This is sometimes frustrating and can lead proponents to recommend various untested or less than adequately tested preventive services. Because these services may ultimately be shown to lead to net harm rather than net benefit, and because performing ineffective services may take time and effort away from more effective services, it is important for clinicians to utilize two criteria to prioritize preventive services that

(1) address an important health condition for the specific patient, and (2) have been shown to lead to more benefit than harm.

Although clinicians may be overwhelmed by the number of *proposed* preventive care services, only a limited number of these services actually meet these criteria. Analyzing the tradeoffs between benefits and harms for each service is complex, however. We suggest that clinicians closely follow the recommendations of the U.S. Preventive Services Task Force (USPSTF), a nonfederal panel of prevention experts, to help understand which preventive services to prioritize. For immunizations, the best recommendations are those by the Advisory Committee on Immunization Practices (ACIP), convened by the Centers for Disease Control and Prevention (CDC).

The next section briefly discusses the “prevention strategies” available to clinicians. The following sections discuss common conditions and proposed preventive services, examining which meet our criteria and should be prioritized by clinicians. Table 2-1 gives an overview of suggested priority preventive services for adults. Table 2-2 gives some selected services that should not be prioritized, and Table 2-3 provides some that should not be provided at all unless there are special circumstances.

Table 2-1 Priority Preventive Services for Adults

Priority Health Problem	Priority Population	Effective Service/Comments
Immunization-preventable disease	All ages	Various immunizations; see: http://www.cdc.gov/nip/recs/adult-schedule.htm
Tobacco-related problems (e.g., CVD, lung cancer, emphysema)	All ages	Screening and appropriate counseling of current smokers, plus preventive counseling of adolescents
Cardiovascular disease	Smoking and blood pressure screening at all ages; focus lipid screening on men ages 45 years and older; women ages 55 years and older; focus screening for diabetes on people with hypertension or dyslipidemia	Screening for and appropriately treating CVD risk factors: dyslipidemia, smoking, blood pressure, diabetes Note that aggressiveness of treatment depends on the level of global CVD risk No need to screen people for diabetes who do not have hypertension or dyslipidemia
Cardiovascular disease	Focus on men ages 45-75 years and women ages 55-75 years	Low-dose aspirin for people with more than 10% 10-year risk
Rupture of abdominal aortic aneurysm	Current or previously smoking men ages 65-75 years	Abdominal ultrasound, screen once only unless abnormal No need to screen nonsmokers and women
Colorectal cancer	Men and women, ages 50-75 years if healthy	Screening with one of four approaches: home fecal occult blood (FOBT) cards done annually; sigmoidoscopy every 5 years; both FOBT and sigmoidoscopy; colonoscopy every 10 years
Breast cancer	Women ages 50-75 years; women ages 40-50 years who have considered pros and cons of screening	Mammography and clinical breast examination by a health care provider every 1-2 years (note: women over age 50 years with a negative and no abnormal mammogram within the previous 2 years can be screened every 2 years)
Cervical cancer	Sexually active women under age 65 years with an intact cervix	Papanicolaou smear every 3 years unless recent positive test No need to screen women without a cervix, women not sexually active, women older than 65 years if previous negative screening
Depression	All adults	Two-question screening test: (1) "Over the past 2 weeks, have you felt down, depressed, or hopeless?" (2) "Over the past 2 weeks, have you felt little interest or pleasure in doing things?" Diagnostic interview and appropriate treatment/follow-up needed for positive screening test
Falls and fractures	Men and women ages 65 years and older	Screen for adequate vitamin D intake and counsel if too low Screen for previous falls and assess fall risk factors if positive Minimize psychoactive drugs Screen people ages 65 years and older for osteoporosis and appropriately treat people in osteoporotic range No need to screen people younger than 65 years unless they have important risk factors
Automobile crashes	All adults	Screen for alcohol misuse and counsel if detected Counsel to wear lap and shoulder restraints
Obesity	All adults	Screen for obesity by calculating BMI and for level of physical activity Discuss diagnosis of obesity and low physical activity with patient and consider approaches for change, including referral to intensive community programs
Sexually transmitted infections (e.g., chlamydia and gonorrhea)	Sexually active women ages 15-26 years and older women with risk factors	Screen and appropriately treat: (1) chlamydia in all groups meeting criteria; (2) gonorrhea, focusing on women living in high-prevalence areas
HIV	All ages	Screen and appropriately treat: patients who ask about screening; patients with any risk factors; patients who live in areas with average or high levels of HIV infection The only people excluded are people without risk factors living in low-risk areas
Visual problems	Adults ages 65 years and older	Screen by asking about visual function and by Snellen chart; refer to ophthalmologist if positive
Hearing problems	Adults ages 65 years and older	Screen by whispered-voice test or HHIE questionnaire; refer for audiology if positive

BMI, body mass index; CVD, cardiovascular disease; HHIE, Hearing Handicap Inventory for the Elderly; HIV, human immunodeficiency virus.

Table 2-2 Preventive Services That Should Not Be Prioritized*

Preventive Service	Population	Comments
Routine prostate-specific antigen and digital rectal exam to screen for prostate cancer	Adult men	May discuss with men ages 50-70 years and provide to those who understand pros and cons and still want to be tested
Routine total-body skin exam for melanoma	Adults	Should refer for suspicious lesions detected in usual exam for other reasons
Routine examination of the oral cavity for oral cancer	Adults	Should refer for suspicious lesions detected in usual exam for other reasons
Routine screening for family/domestic violence	Adults	Should maintain a high index of suspicion in women with depression or vague symptoms
Routine screening for dementia/cognitive impairment	Adults	Should maintain a high index of suspicion in people with cognitive change or poor judgment
Routine screening for glaucoma	Adults	Should maintain a high index of suspicion in older, African American men with eye complaints
Routine screening for thyroid dysfunction	Adults	Should maintain a high index of suspicion in older women with nonspecific complaints

* Note that all these suggestions refer to usual-risk people with no known symptoms. They do not refer to people at high risk or with special-risk situations. People with symptoms should be examined and tested appropriately—this is not screening.

Table 2-3 Preventive Services That Should Generally Not Be Provided*

Preventive Service	Population
Urine analysis for blood to screen for bladder cancer	Adults
Supplements for beta carotene, vitamins E, A, and C	Adults with normal diet
Postmenopausal hormone therapy	Postmenopausal women
Screening ECG, exercise ECG, coronary calcium, ankle-brachial index for existing coronary heart disease or risk for future coronary heart disease	Adults
CA-125 and ultrasound to screen for ovarian cancer	Adult women
Ultrasound or CT to screen for pancreatic cancer	Adults
Testicular examination to screen for testicular cancer	Adult men
Routinely teaching breast self-examination to screen for breast cancer	Adult women
Routine urinalysis to screen for asymptomatic bacteriuria	Adults
Routine screening for hepatitis C	Adults
Routine chest x-ray or spiral CT to screen for lung cancer	Adults
Duplex carotid ultrasound for carotid artery stenosis	Adults
Whole-body CT scan	Adults

* Note that all these suggestions refer to usual-risk people with no known symptoms. They do not refer to people at high risk or with special-risk situations. People with symptoms should be examined and tested appropriately—this is not screening. CT, computed tomography; ECG, electrocardiography.

Prevention Strategies

Immunizations

Six immunizations are currently recommended by the ACIP for routine use in adults:

- Tetanus, diphtheria booster every 10 years (for people ages 19 to 64 years, at least one booster should be tetanus, diphtheria, and acellular pertussis)
- Influenza (inactivated intramuscular) vaccine once each year for people ages 50 years and older (and special groups under age 50 years; live vaccine [FluMist] can be offered to healthy, nonpregnant patients ages 5 to 49 years)
- Pneumococcal vaccine once after age 65 years (and special groups under age 65 years)
- Measles, mumps, and rubella if born in 1957 or afterward and not previously immunized

- Varicella for people born in 1966 or afterward who have never had varicella infection or previous immunization
- Human papillomavirus vaccine for females ages 9 to 26 years

Another vaccine approved by the Food and Drug Administration is a high-potency varicella vaccine for adults age 60 years and older to prevent herpes zoster. Other vaccines (e.g., hepatitis A and B and meningococcal vaccine) are recommended for special groups. The complete ACIP adult immunization recommendation table can be accessed from the CDC website.

Screening

Screening is a widespread strategy that is often misunderstood. We are screening all the time. The “annual physi-

cal” is actually a series of screening questions, examinations, and tests—searching for disease (or risk factors) in people with no recognized symptom or sign of the condition. The basic idea of screening is that earlier treatment may lead to better health than later treatment (after symptoms or signs appear). The problem is that, as intuitive as this idea seems, it is only sometimes correct. Sometimes, in fact, screening can lead to more harm than benefit.

There are at least three ways that screening can lead to harm: through adverse effects of (1) the screening test itself; (2) false-positive screening tests; and (3) detection of conditions that require surveillance or treatment but would never have progressed to cause clinical problems (sometimes called *pseudodisease*).

Adverse Effects of Screening Tests

Most screening tests have few adverse effects. Some tests, however, can cause complications. A study published in 2006, for example, found a serious complication rate of 5 per 1000 people receiving a colonoscopy. Any complication of screening tests must be counted against the number of people whose lives are extended by screening.

Adverse Effects of False-Positive Tests

Because screening is conducted in people who have a small (though not zero) risk for a condition, most screening tests result in more false-positive results than true-positive results. For example, less than 10% of “positive” mammograms lead to a diagnosis of breast cancer; more than 90% are falsely positive. People with false-positive screening tests often experience considerable anxiety until they have a negative confirmatory test. If the confirmatory test is itself not completely sensitive (e.g., prostate biopsy for an elevated prostate-specific antigen screening test), this anxiety can be prolonged. In addition, if the confirmatory test carries some discomfort or risk (e.g., laparoscopy for a positive ovarian cancer screening test or lung biopsy for a positive spiral computed tomography screening test), then the person with a false-positive screening test has a higher probability of being harmed. These possible harms must be counted against the number of people whose lives are extended by screening.

Adverse Effects of Detection of Pseudodisease

Studies of large groups of people tell us that some conditions detected by screening would never cause clinical problems for the patient. Some of these conditions include in situ cancers (e.g., ductal carcinoma in situ of the breast), “pre” conditions (e.g., “prediabetes” or “prehypertension”), benign conditions that only sometimes progress (e.g., colonic polyps or cervical intraepithelial neoplasia type I or II), or slowly progressive conditions (e.g., many prostate cancers). Detection of such conditions often leads to increased anxiety for the patient. Even more concerning, because we are often unable to determine which people

with these conditions will suffer clinical problems and which will not, we usually subject most or all to treatment. For those who would never have had clinical problems, this amounts to overtreatment and may cause undue suffering from adverse treatment effects (e.g., radical prostatectomy for prostate cancer, leading to impotence or incontinence).

Lifestyle Change

Such lifestyle issues as tobacco use, obesity, lack of physical activity, alcohol abuse, not using car restraints or bicycle helmets, and unsafe storage of firearms contribute to many deaths in the United States. Changing such unhealthy lifestyles would have potentially large benefit for the health of the public. Studies are clear that, properly done, counseling by clinicians can help patients stop smoking cigarettes and reduce problematic alcohol intake. Changing such behaviors as physical inactivity and unhealthy weight gain, however, is more difficult to accomplish in the context of a clinical office visit. Growing evidence suggests that broader programs that target groups with behavioral and social interventions as well as information can have positive effects on unhealthy lifestyles. Such programs may be developed and offered within the community or by health plans. Clinicians should consider referring appropriate patients to these programs. Appropriate patients would include those who have an interest in changing lifestyle. Clinicians can use motivational interviewing techniques to encourage patients to make these changes.

Prophylaxis

Prophylaxis is intervening with a treatment such as medication to prevent an adverse health event. Examples include “treatment” of hypertension and hyperlipidemia to prevent cardiovascular events. Many considerations are relevant in trying to maximize benefit and minimize harm from prophylactic interventions. Some of these include the following:

- At what level of risk to begin treatment
- How intensively to treat
- What should be the target of treatment
- What are the adverse effects of the treatment

In general, people at higher risk have more to benefit and can be treated more aggressively. Often, however, our approaches to defining an individual at sufficiently increased risk to warrant treatment are inadequate. Also, the safety of prophylactic interventions is an important limitation to widespread use of prophylaxis. If even a small percentage of the large number of treated people suffer an adverse effect of the treatment, this may outweigh any benefit. This is the case, for example, for tamoxifen prophylaxis to prevent breast cancer for most women.

Common Conditions and Proposed Preventive Services

Note that the recommendations below are for usual-risk patients, not for patients with special conditions at very high risk.

Cardiovascular Disease

A small number of preventive activities, widely performed, could effectively reduce the large burden of cardiovascular disease. These include appropriate treatment of risk factors, counseling for smoking cessation, and aspirin prophylaxis. The approach begins with an assessment of a patient's "global cardiovascular risk." People at high global risk should be offered aggressive risk factor control (see USPSTF recommendations on hypertension, lipids, aspirin, and smoking cessation). People at even moderate risk should still consider aspirin, smoking cessation, and moderate control of other risk factors. The most important risk factors to consider are those in the Framingham model: blood pressure, cholesterol, smoking, diabetes, age, and gender.

In addition to prevention of coronary artery disease and stroke, a single screening for large (>5.5 cm) abdominal aortic aneurysm (AAA) among men ages 65 to 75 years who have ever smoked could reduce the number of deaths from AAA rupture.

Cancer

The cancers that cause the largest number of deaths in the United States are lung, colorectal, breast, and prostate. Screening is clearly effective in reducing mortality for colorectal and breast cancers. The most effective way to reduce mortality for lung cancer is smoking cessation. We do not yet have a clearly effective way to reduce mortality from prostate cancer. Trials of screening are underway but will not be completed for another several years.

There are four effective ways to screen for colorectal cancer: home fecal occult blood test (FOBT) cards done annually; flexible sigmoidoscopy every 5 years; both FOBT and sigmoidoscopy; and colonoscopy every 10 years. The ideal approach is the one that the patient is most comfortable with.

Optimal breast cancer screening includes both screening mammography and clinical breast examination. Women over age 50 years who have had no abnormal screening test in the past several years may be screened every other year. Women in their 40s may be given the option of screening, although the benefit from screening is small at that age.

In addition to these cancers, screening for cervical cancer is clearly effective. A woman who has had her cervix removed for nonmalignant reasons need not be screened. Women with repeated negative screening tests can be

screened every 3 years rather than annually. Women with recent negative screening tests need not be screened after age 65 years.

Depression

Brief screening for depression, coupled with evaluation and possible treatment of people who are found to be depressed, is effective in improving the quality of life. Asking two questions ("Over the past 2 weeks, have you felt down, depressed, or hopeless?" and "Over the past 2 weeks, have you felt little interest or pleasure in doing things?") is sufficient to detect many cases of subclinical depression.

Injury Prevention

Clinicians should consider three major areas in preventing injuries: prevention of falls and bone fractures; prevention of motor vehicle crashes; and prevention of domestic violence.

Multifactorial risk assessment and control programs and exercise interventions effectively reduce falls in older people. These programs assess such issues as postural hypotension, gait unsteadiness, psychotropic medication use, strength, nutrition, and auditory and visual problems. Routinely asking about previous falls and targeting more intensive examinations for those who have a recent fall is also a reasonable strategy.

Screening women older than 65 years for osteoporosis is another important strategy. Bisphosphonate therapy of women with osteoporosis reduces fractures. Because of the low fracture risk, screening younger women—unless they have special risk factors—is not indicated.

Use of car lap and shoulder restraint systems reduces motor vehicle crashes. These are most widely used when they are automatic and require no individual decision. Clinician counseling can reduce inappropriate alcohol use; clinicians should screen for this problem.

The evidence is insufficient to determine whether screening for family and domestic violence is useful; we don't recommend it at this time. However, being alert to the sometimes subtle signs and symptoms of family violence can help find women who are being abused physically or emotionally. Women who are found to be suffering domestic violence should be given information about local resources for assistance.

Lifestyle-Related Problems

Obesity and physical inactivity are major and growing problems in our society. Intentional weight reduction and increased physical activity are associated with reductions in diabetes risk, hypertension, and mortality. Although brief counseling infrequently affects these lifestyles, more intensive programs that include behavioral and social com-

ponents can be effective. We recommend that clinicians familiarize themselves with community and health plan programs for obese and physically inactive patients and refer appropriate patients to these programs.

Sexually Transmitted Infections

Women at increased risk for chlamydia and gonorrhea infection should be screened. For chlamydia, this includes women ages 15 to 25 years and older women with behavioral risk factors such as multiple sexual partners. For gonorrhea, this includes younger, sexually active women living in high-risk areas.

The recommendation for screening for human immunodeficiency virus (HIV) infection includes more people now than in the past. This is because of both the availability of tests with very few false-positive results and the availability of effective treatment. Screening now should be considered for men and women who have other sexually transmitted infections, have behavioral risk factors (e.g., men who have sex with men, multiple sexual partners), or live in high or moderate prevalence areas.

Substance Abuse–Related Problems

Alcohol misuse is common and an important cause of morbidity and mortality in our society. Screening and brief counseling and follow-up for alcohol misuse in office settings have been shown to reduce alcohol consumption.

Tobacco use causes more than 400,000 deaths each year in the United States. Screening and brief counseling for smoking cessation increases long-term quit rates. Use of such adjunctive treatments as nicotine replacement and bupropion treatment can reduce quit rates further.

Vision and Hearing Problems

People over age 65 years frequently develop problems with vision and hearing. These problems may develop so slowly that patients are not aware that they are present. Thus, simple screening with questions about function (including the Hearing Handicap Inventory for the Elderly questionnaire for hearing), brief testing of visual acuity, and the whispered-voice test for hearing can detect people who would benefit from referral for further evaluation.

What Not to Do

If clinicians focus primarily on getting the previously described services done, they will be making an important contribution to the health of their patients. Other services may be highly recommended by others but frequently either cause important injuries or are backed by insufficient evidence of benefit. Table 2-3 gives a selected list of commonly discussed services that we recommend *not* be generally provided unless there are special circumstances.

The Health Maintenance Examination (“Annual Physical”)

Much of the periodic health maintenance examination is screening. This examination is an insufficient approach to delivering preventive care for at least two reasons: (1) many people do not get a periodic exam, and (2) some services, such as controlling blood pressure, elevated lipids, and counseling for smoking cessation, cannot be effectively delivered in a single visit. In addition, the usual activities on this visit—a comprehensive review of systems and a complete physical examination—are poor screening tests for many patients.

On the other hand, a focused examination that takes into account the problems for which a patient is at highest risk, and the most effective preventive services for reducing that risk, can be an efficient way of delivering some preventive services to some people. This type of visit can also have other benefits, including developing the patient-clinician relationship and helping the patient understand better how to use the health care system.

Conclusion

Although preventive care is not the panacea that some have suggested, it can make a substantial contribution to the health of patients. It is best to know one’s patients well: what are the health conditions for which they are at greatest risk? Then it is important to understand the science of prevention: what services can most effectively reduce that risk?

In the past, some have used a haphazard approach of delivering prevention to each patient, emphasizing whatever is “hot” and interesting (and there is time for). We prefer instead a thoughtful, proactive approach of determining ahead of time what you will recommend for each patient, and then finding systematic approaches within the practice to make sure all patients receive good information and encouragement to adhere to the preventive services that are appropriate for them. This approach is likely to help keep your patients healthy as long as possible.

Diagnostic Testing: The Example of Thromboembolism (PE/DVT)

Introduction

Testing is a strategy to improve diagnostic certainty. It is necessary because of the statistical improbability of any disease presenting according to classic descriptions. The diagnostic certainty needed by a clinician depends on the seriousness of the illness in question and the hazards of therapy—the notion of an action threshold. For example, a benign illness with a benign therapy (acetaminophen for viral pharyngitis) requires little certainty to take action, whereas a more serious disease, thromboembolism (pulmonary embolism and deep venous thrombosis [PE/DVT]), with a more hazardous therapy requires greater diagnostic certainty.

Typically, clinicians ask whether a test was positive or negative so that they can “rule out” or “rule in” a disease. Tests, however, are not dichotomous variables; they convey increasing levels of information the further they deviate from “normal.” For example, a patient with 4-mm ST-segment depression and crushing chest pain during an electrocardiographic (ECG) exercise test is much more likely to have coronary artery disease than a patient with 2-mm ST-segment depression and no pain, even though both tests are “positive.” Conversely, vitamin B₁₂ deficiency is just as likely to be present at levels of 192 ng/mL and 194 ng/mL, even though the former is “abnormal” and the latter is “normal” by laboratory nomograms. By extrapolation, one can never state that a patient does or does not have a disease, only the probability that the patient has a disease. The physician then must decide whether a threshold for action has been crossed.

PE/DVT is particularly vexing because of the attendant morbidity, the difficulty in diagnosis, and the confusing array of diagnostic tests. Many diagnostic algorithms have been proposed, but they are cumbersome and still require the dichotomous notion of cutoffs: if “negative,” go to A;

if “positive,” go to B. Diagnostic methods that permit one to acquire realistic estimates of disease and to decide whether an action threshold has been crossed would be more useful. Such methods would circumvent cumbersome algorithms and enable clinicians to think of a continuum of risk. It is likely that concrete assessments of risk are understood more universally by clinicians than vaguer terms, such as *low probability* and *high risk*. For example, the perioperative risk for myocardial infarction in a high-risk population is 4% to 5%.

Glossary of Terms

Sensitivity: Rate of detection of those with disease, also true-positive rate

Specificity: Rate of detection of those without disease, also true-negative rate

False-positive rate: (1 – specificity)

False-negative rate: (1 – sensitivity)

Probability (or chance): Occurrence of given event expressed as fraction of all possible events. For

example, when tossing a coin twice, the probability of getting heads is $2/(2+2) = 2/4 = 50\%$

Odds: Number of occurrences of one event expressed as a ratio to the number of occurrences of a second event. For example, for two heads and two tails, the odds are 2/2 or 1/1 for heads. Thus, an odds ratio of 1/1 = probability of 1/2 (50%). (Note that odds may not be multiplied together.)

Positive likelihood ratio (+LLR): True-positive rate divided by false-positive rate

Negative likelihood ratio (-LLR): False-negative rate divided by true-negative rate

Pretest probability of disease: The probability that a patient has a given disease before testing. The pretest probability of disease for a specific patient is also equal to the prevalence of the disease in a population of similar patients.

Pretest odds: As for pretest probability, but calculated as an odds

Post-test probability: With positive test, also positive predictive value. Given a positive test, the probability that a patient has the disease for which he was tested

Post-test probability: With negative test, also negative predictive value

Post-test odds with positive test: As for post-test probability, but expressed as an odds. $\text{Post-test odds} = \text{pretest odds} \times \text{LLR1} \times \text{LLR2} \times \text{LLR} \dots n = \text{post-test odds}$

Post-test odds with negative test: Similar to above

The Case for Likelihood Ratios

Traditionally, tests with high sensitivities have been advocated to “rule out” disease and tests with high specificities are considered to “rule in” disease. Consider, however, the following two tests. If negative, which test best excludes disease in a patient with a 50% chance (pretest odds, 1/1) of having the disease?

	Sensitivity	Specificity	+LLR	-LLR
Test A	90%	10%	1.0	1.0
Test B	80%	30%	1.1	0.7

Test A pretest odds $(1/1) \times -\text{LLR} (1.0) = \text{post-test odds} (1/1) = \text{post-test probability of } 50\% \text{ (no change).}$

Test B pretest odds $(1/1) \times -\text{LLR} (0.7) = \text{post-test odds} (0.7/1) = \text{post-test probability of } 0.7/1.7 = 41\%.$ Therefore, test B is a better test. Thus, an LLR can fully express the value of a test in a single number. As a guide, +LLRs near 10 and -LLRs near 1/10 are quite good and will affect decisions substantially.

Remember, according to Bayes’ theorem, testing at very high pretest probabilities of disease or at very low pretest probabilities may not greatly affect a clinical decision. For example, what is the probability of breast cancer in a 40-year-old woman whose screening mammogram is read as

suspicious? Pretest probability of breast cancer (prevalence) in 40-year-old = $1/4000 = \text{pretest odds of } 1/3999.$ +LLR for screening mammogram in 40-year-old = 80. $\text{Post-test odds} = 1/3999 \times 80 = 80/3999.$ Probability is $80/4079,$ or 1.9%. Thus, 98% of women such as this do not have breast cancer even if they have a suspicious mammogram.

As a corollary, expressing test performance as an “accuracy” (a positive or negative predictive value) is of little use because these terms are composites of pretest probability (highly dependent on the clinical scenario) and LLR (the only invariant measure of test performance).

Estimates of Pretest Probability of Thromboembolism (DVT/PE)

Calculating the post-test probability of disease depends, therefore, on knowledge of the LLR for a test and a reasonably accurate assessment of pretest probability (prevalence).

Pulmonary Embolism

The two best known scoring tools for pretest assessment of risk for PE are the Geneva score (outpatients) and the Wells score (inpatients and outpatients). Concordance between the two is excellent, but the latter is simpler, more widely used, and possibly more accurate:

Previous PE/DVT	1.5 points
Heart rate >100 beats/minute	1.5
Recent surgery or immobilization	1.5
Clinical signs of DVT	3.0
Other diagnoses less likely	3.0
Malignancy	1.0
Hemoptysis	1.0

Values ≤ 1 (<5% probability); 2 to 6 (20% to 30%); ≥ 7 (50% to 70%). Others have suggested dichotomizing the results into low (0 to 4) and high (≥ 5) probabilities, but this modification lessens its discriminant power.

Deep Venous Thrombosis

Similarly, the simplified Wells prediction score for DVT has proved useful as a clinical tool for evaluation of outpatients, although its validity in primary care may require further study.

Cancer in past 6 months, treated or not	1 point
Paralysis, casting, or splinting of lower leg	1
Bedridden 3 days, major surgery past 3 months	1
Tenderness along the deep venous system	1
Entire leg swelling	1
Pitting edema confined to the affected leg	1
Calf swelling >3 cm larger than contralateral leg	1

Table 3-1 Testing for Pulmonary Embolism

Test	+LLR	-LLR
Arterial blood gas, A-a gradient, etc.	~1	~1
V/Q scan		
High probability	17	
Intermediate	1.1	
Low	0.7	
Normal or near normal	0.1	
Multidetector chest CT	7.8	0.24
Chest magnetic resonance imaging	Unknown	
Pulmonary angiography	50	0.02
D-Dimer		
Low sensitivity	1.7-5.0	0.15-0.35
High sensitivity	1.5-2.4	0.06-0.10

A-a, alveolar-arterial; CT, computed tomography; V/Q, ventilation-perfusion.

Table 3-2 Testing for Deep Venous Thrombosis

Test (Symptomatic Patients)	+LLR	-LLR
Duplex and color-flow ultrasonography	24	0.04
Impedance plethysmography	10	0.06
D-Dimer (as above)		

Superficial collateral veins (not varicosities)	1
Previous documented DVT	1
Other diagnosis equally as likely as DVT	-2

Values ≤ 0 (2% to 5% probability); 1 to 2 (30%); ≥ 3 (50% to 60%).

Laboratory Testing for DVT/PE

See Tables 3-1 and 3-2.

The LLRs for chest computed tomography (CT) presented in the table are less optimistic than those proposed by the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II investigators because the investigators omitted any indeterminate scan from their calculations, a method that falsely inflates the sensitivities and specificities of a test. Thus, despite its wide use, the performance characteristics of chest CT are inferior to those of the ventilation-perfusion (V/Q) scan. In the presence of chronic lung disease, however, the LLRs for V/Q scans are degraded, perhaps by half, because of the presence of more indeterminate scans, rendering CT scans and V/Q scans of equal value in this setting.

Confidence in the D-dimer test is justified by the growing precision of estimates of its sensitivity and specificity, but it should be emphasized that this test is not applicable in sick inpatients, in whom the LLRs are less favorable because of low-grade clotting in venous access sites. Use of the D-dimer to estimate the risk for recurrence has been proposed but not extensively verified.

Strategies for Testing

Strategies for the diagnosis of PE rely heavily on an understanding of the disease. First, immediate evidence of a proximal venous thrombosis is often lacking in those presenting with PE, presumably because the clot is now in the lung. Second, in the stable patient with a recent PE, the goal of therapy is not to treat the current PE but to prevent a recurrence. Third, if the deep venous system (defined as the veins from the popliteal fossa proximally) remains empty of clot, the risk for recurrent PE is very low. These findings, coupled with the realization that calf vein thrombi rarely embolize unless they propagate proximally, have focused diagnostic strategies on proximal DVT in patients who cannot easily be shown to have a PE. Fourth, because these strategies for diagnosis have been validated only in the outpatient setting, caution should be exercised in applying them to sick inpatients. Finally, there is no firm evidence that each of these tests and prediction rules is statistically independent.

In the patient whose presentation suggests PE, the initial strategy is to perform a V/Q or CT scan because the pretest probability of finding clot in the chest is higher than finding it in the leg. For similar reasons, when DVT is suspected, investigation begins with studies of the leg (Boxes 3-1 and 3-2).

For both PE and DVT, the calculated action threshold is about 5% (the probability of disease at which the net benefits of therapy begin to exceed the net harm of no therapy). Therefore, because the goals of therapy are identical, the purpose of testing is to reduce the probability of venous thromboembolism to below 5%. If this threshold cannot be reached by any combination of tests, then one is forced to treat.

Further Testing

For the diagnosis of PE, when the V/Q scan (or CT scan) fails to lower the post-test probability of thromboembolism to below the action threshold of 5% to 10%, further

Box 3-1 Pulmonary Embolism

High-risk patient (75% probability) and the initial test is:

- Positive V/Q scan: pretest odds $(3/1) \times +LLR (17) =$ post-test odds $(51/1)$ or post-test probability of 98%. Action: treat
- Positive CT scan: $(3/1) \times (7.8) =$ post-test odds $(23/1) =$ post-test probability of 96%. Action: treat
- Normal V/Q scan: $(3/1) \times (0.1) =$ post-test odds $(0.3/1)$ or post-test probability of 23%, well above action threshold. Action: test further for DVT (see below)
- Negative CT scan: post-test probability of 38%. Action: test further

Moderate-risk patient (33% probability) and the initial test is:

- Positive V/Q scan: pretest odds $(1/2) \times +LLR (17) =$ post-test odds $(17/2)$ or post-test probability of 89%. Action: treat
- Normal scan: $(1/2) \times (0.1) =$ post-test odds $(0.1/2) =$ post-test probability of 5%. Action: no treatment

- Negative CT: Post-test probability of 9%. Action: test further
- Negative D-dimer: post-test probability (using conservative LLR) of 5%

Low-risk patient (5%) and the initial test is:

- Positive V/Q scan: pretest odds $(5/95) \times +LLR (17) =$ post-test odds $(85/95)$ or post-test probability of 47%. Action: test further for DVT because negative study can reduce probability below action threshold. (see DVT, below)
- Negative V/Q scan: $(5/95) \times (0.1) =$ post-test odds $(0.5/95)$ or probability of 0.5%. Action: no treatment
- Negative CT scan: $(5/95) \times (.24) =$ post-test odds $(1.2/95)$ or probability of 1%. Action: no treatment
- Negative D-dimer: $(5/95) \times (0.1) =$ post-test odds $(0.5/95)$ or probability of 0.5%. Action: no treatment

Low- or intermediate-probability V/Q scans have no impact on decision because the LLRs are near unity.

CT, computed tomography; DVT, deep venous thrombosis; LLR, likelihood ratio; V/Q, ventilation-perfusion.

Box 3-2 Deep Venous Thrombosis

High-risk patient (85%) and the initial test is:

- Positive US: pretest odds $(85/15) \times (24) =$ post-test odds $(2040/15)$ or post-test probability of 99%. Action: treat
- Negative US: $(85/15) \times (0.04) =$ post-test odds $(3.4/15)$ or post-test probability of 18%. Action: no further testing required

Moderate-risk patient (33%) and the initial test is:

- Positive US: pretest odds $(1/2) \times (24) =$ post-test odds $(24/2)$ or probability of 92%. Action: treat
- Negative US: $(1/2) \times (0.04) =$ post-test odds $(0.04/2)$ or post-test probability of 2.0%. Action: no treatment
- Negative D-dimer: $(1/2) \times (0.1) =$ post-test odds $= 0.1/2$ or post-test probability of 5%. Action: no treatment

Low-risk patient and the initial test is:

- Positive US: pretest odds $(5/95) \times (24) =$ post-test odds $(120/95)$ or probability of 56%. Action: treat. (Only venography can lower probability below action threshold.)
- Negative US: $(5/95) \times (0.04) =$ post-test odds $(0.2/95)$ or probability of 0.2%
- Negative D-dimer: $(5/95) \times (0.1) =$ post-test probability of 0.5%. If the initial test is the D-dimer, and it is positive (post-test probability of disease about 10%), then further testing with US is needed

US, ultrasound.

testing with ultrasound can better estimate the probability of thromboembolism (Box 3-3).

The authors discuss methods for the use of LLRs and pretest probability estimates for many medical problems.

Box 3-3 Further Testing for Equivocal Results

High-risk patient (75%) for PE, with negative V/Q scan (see Box 3-1) post-test probability of 23%:

- If US now positive: odds $(0.3/1) \times (24) =$ post-test odds $(7.2/1)$ or probability of 88%. Action: now treat
- If US now negative: odds $(0.3/1) \times (0.04) =$ post-test odds $(0.012/1)$ or probability of 1.2%. Action: no treatment

For the diagnosis of DVT, further testing with the D-dimer assay can alter the estimate of disease.

High-risk patient (85%) for DVT, with negative US (see Box 3-2) post-test probability of 18%

- If D-dimer now negative: odds $(3.4/15) \times (0.1) =$ post-test odds $(0.34/15)$ or probability of 2.2%. Action: no treatment

Obesity

Introduction

Obesity is a complex multifactorial disorder that results in the accumulation of excess adipose tissue, increases the risk for morbidity and mortality, and lessens life expectancy markedly (Figs. 4-1 and 4-2). Definitions of the terms *overweight*, *obesity*, and *severe or morbid obesity* vary among authoritative sources and depend on gender and ethnic background. Generally, overweight and obesity are defined based on body mass index (BMI), the weight in kilograms divided by the height in meters squared. Overweight in whites is defined as a BMI of 25 to 29.9 kg/m² and obesity as a BMI greater than 30 kg/m². Severe or morbid obesity refers to those patients with a BMI of greater than 40 kg/m². Some studies have demonstrated that the waist-to-hip ratio, which defines the degree of visceral obesity, correlates better with cardiovascular and other morbidity; however, the BMI-based definition is the common standard used in most clinical guidelines (see Fig. 4-1).

The developed world currently faces an epidemic of obesity. Based on National Health and Nutrition Examination Survey (NHANES) data comparing 1999 to 2000, 2001 to 2002, and 2003 to 2004 data for the United States, the prevalence of obesity among men increased significantly from 1999 to 2000 (27.4%) to 2003 to 2004 (31.1%). Data from 2003 to 2004 documented that 32.1% of adults in the United States were obese. The prevalence of morbid obesity among American men in 2003-2004 was 2.8% and among American women, 6.9%. Perhaps even more worrisome is the increasing prevalence of overweight children and adolescents: 17.1% in 2003 to 2004. The percentages are even higher in Hispanic Americans and African Americans. The current epidemic in obesity and obesity-related illnesses likely represents the fastest-growing health risk for men, women, and children in the United States. Although obesity is most prevalent in the United States, its rapidly increasing incidence is becoming a worldwide problem, with similar trends in most European countries.

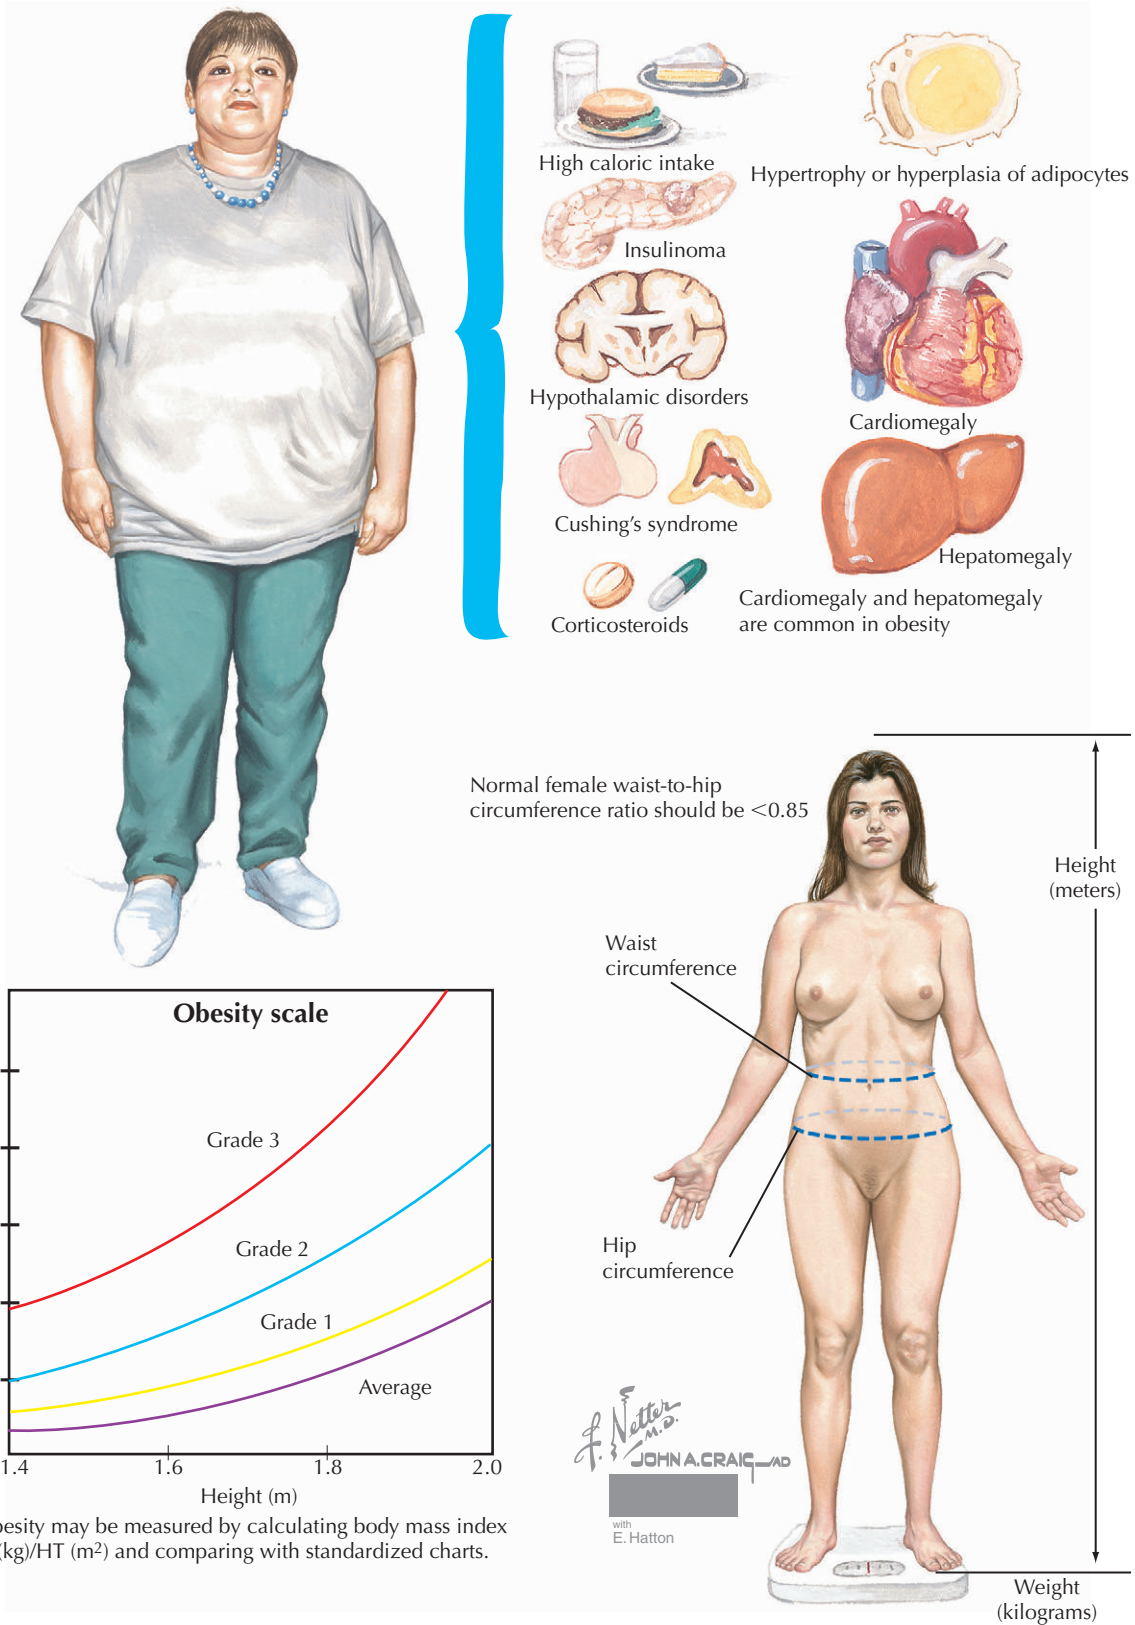

Etiology and Pathogenesis

Obesity results from the complicated interaction of environmental and genetic factors and an imbalance between caloric intake and expenditure. Both increased caloric intake and decreased exercise are hallmarks of obesity (Fig. 4-3). The factors that affect adult obesity probably begin in utero with maternal caloric intake influencing later body size and composition. Maternal smoking and diabetes mellitus increase the risk for obesity in later life. Breastfeeding decreases the risk for childhood obesity and obesity later in life. Having an obese parent more than doubles the risk for obesity as an adult.

Although genetic factors are undoubtedly important, most experts believe that the marked increase in obesity in the United States during the past 40 years is caused by a convergence of two primary factors:

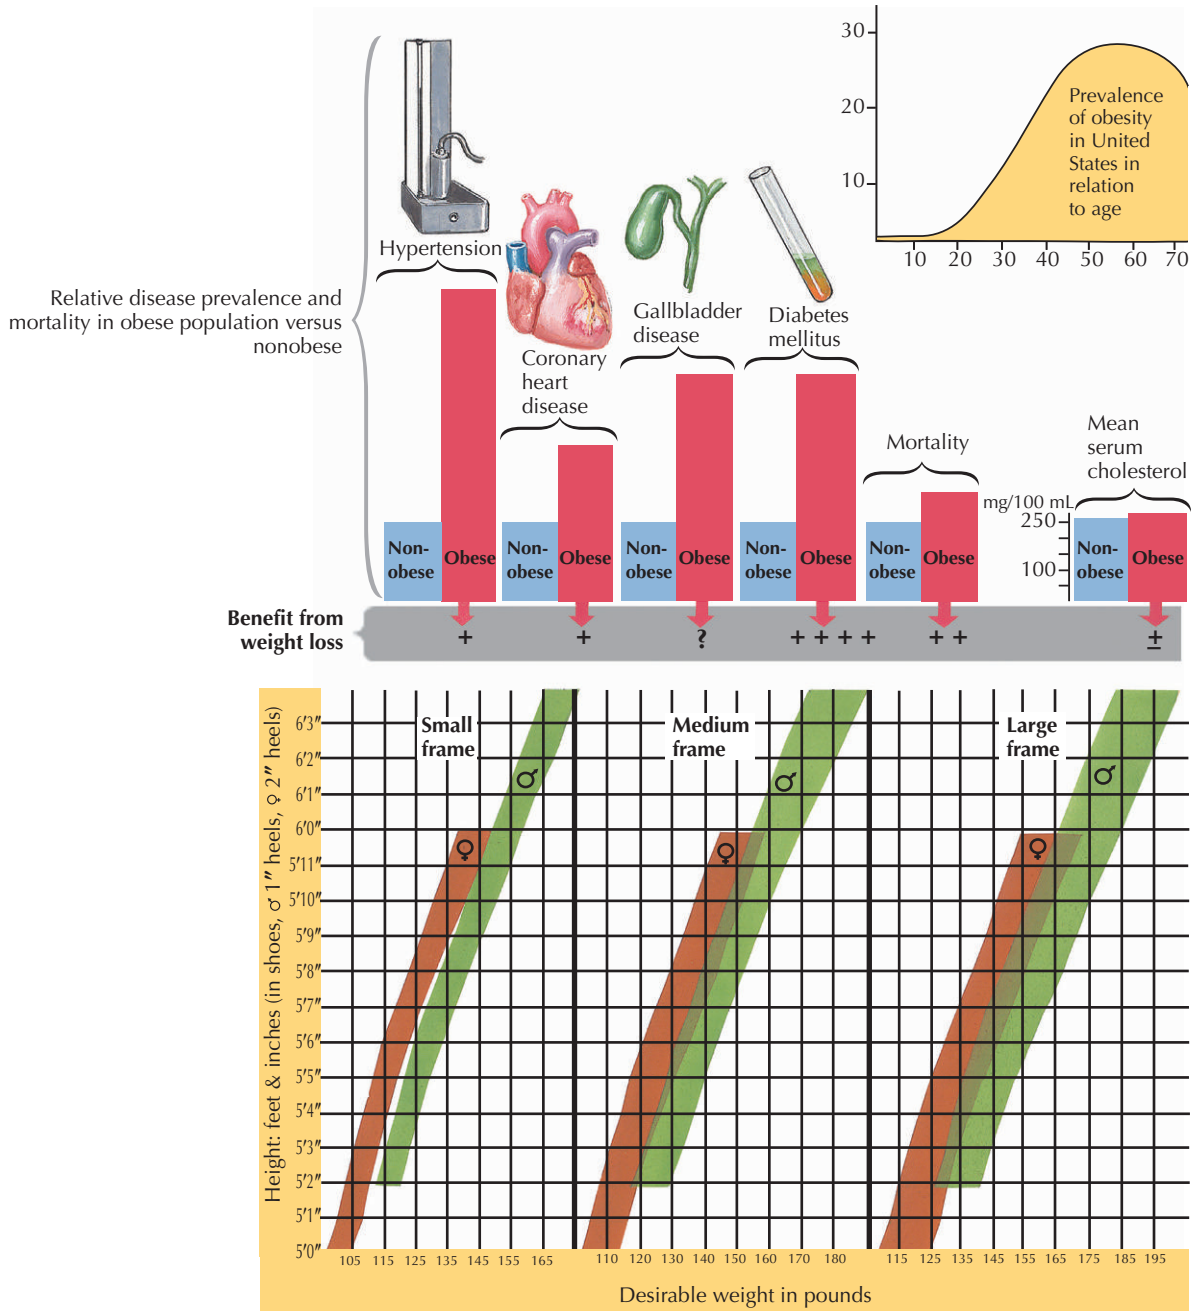

1. Only 20% of the population exercises enough to be considered physically fit. The percentage of adult Americans who engage in physical activity decreases with age, and the associated decrease in energy expenditure predicts weight gain. Multiple influences have resulted in a generation of Americans who do not regularly exercise. These include the movement from a rural and agricultural to a metropolitan society, the reduced emphasis on exercise in the formative years (particularly primary and secondary school), and the ever-increasing “pace of life” cited by many Americans. Another important relationship is that the daily length of time spent watching television predicts obesity and the risk for diabetes mellitus: every 2-hour increment is associated with a 14% increased risk for diabetes mellitus and a 23% increased risk for obesity.

Figure 4-1 Obesity I.

Degree of obesity may be measured by calculating body mass index (BMI) = WT (kg)/HT (m²) and comparing with standardized charts.

Figure 4-2 Obesity II.

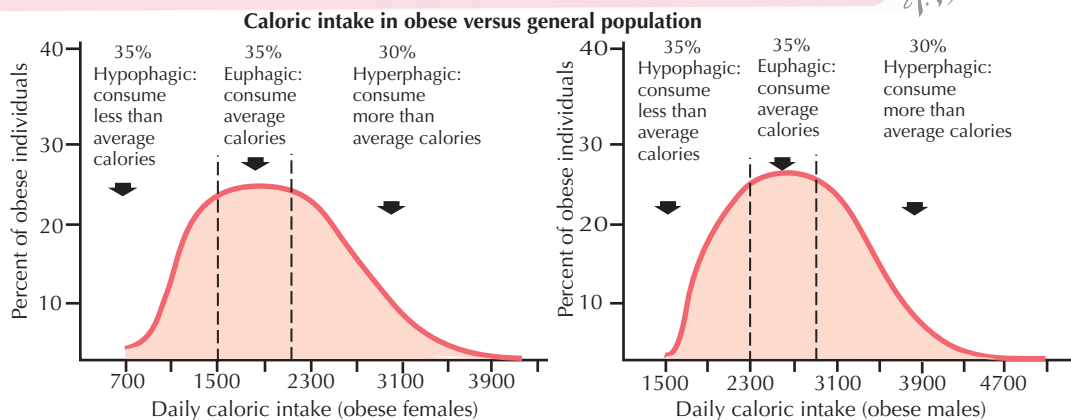

F. Netter M.D.

2. Dietary changes are equally important. The overwhelming influence of readily available high-fat foods through fast-food restaurants and vending machines (even in public schools), plus the emphasis on increased consumption of simple carbohydrates as exemplified by the traditional Food Pyramid of the American Dietetic Association, has contributed to the imbalance between caloric intake and expenditure. Population studies have clearly documented the direct relationship between the percentage of dietary

fat and body weight. The ability to restrain caloric intake, a trait more commonly observed in higher socioeconomic classes, plays a role in obesity and explains, in part, the increased prevalence of obesity in lower socioeconomic classes. The habits of eating more than 50% of daily calories at night and of nocturnal binge-eating also contribute to obesity.

The increasing emphasis on the role of genetic predisposition reflects the impact of recent studies of the molec-

Figure 4-3 Obesity and Calories.

ular genetics of obesity in animals. Five single-gene defects have been identified in rodents. One of the most completely studied is the *ob* or *Lep* gene, which codes for the protein leptin produced in fat cells, gut, and placenta. Increases in adipose tissue result in leptin secretion, which signals the brain to decrease appetite, reduce energy intake, and increase energy expenditure. Leptin may act by decreasing neuropeptide Y secretion in the arcuate nucleus. Neuropeptide Y is a potent stimulator of food intake. Leptin deficiency has been reported in two consanguineous families. Treatment of affected individuals in these

families with physiologic doses of leptin resulted in decreased food intake and weight loss. Leptin receptor deficiency has also been reported in humans, a condition that is manifest by resistance to leptin. Based on these observations, leptin administration in limited clinical trials has not produced significant weight loss in the general population.

The agouti gene defect causes obesity in mice based on its signaling protein competing with the binding of melanocyte-stimulating hormone (MSH) to the melanocortin-4 receptor in the hypothalamus. This receptor decreases

food intake, and its absence produces hyperphagia. The role of the agouti signaling protein in human obesity remains unclear, as does that of two other genes studied in mice: the fat mouse gene and the tub mouse gene.

In the general population, although specific gene defects have yet to be identified, family studies, including studies of twins and adoptees, clearly suggest the role of genetic factors in human obesity. The β_3 -adrenergic receptor gene, the peroxisome proliferator-activated receptor- $\gamma 2$, and the melanocortin-4 receptor are among candidate genes being studied.

Obesity may also develop because of abnormalities of an intricate feedback control system involving signals from fat stores and the gastrointestinal tract. The role of leptin in signaling from adipose tissue has been discussed. Studies have implicated several gut hormones, including ghrelin, which stimulates growth hormone secretion and food intake. Levels of ghrelin decrease after a meal. Weight loss after gastric bypass surgery may in part be secondary to below-normal postoperative levels of ghrelin.

Whether the underlying primary pathogenesis is environmental, genetic, or a combination, obese patients have great difficulty maintaining weight loss because of metabolic changes that accompany changes in weight. In effect, weight loss in a person predisposed to obesity triggers feedback mechanisms that increase appetite and lower energy expenditure as the body attempts to return weight to baseline. Studies have documented that total energy expenditure drops 15% more than the percentage decrease in body weight. One theory is that in earlier times, a physiologic system may have protected humans when food accessibility was limited, leading to a survival advantage. Today, with high-fat food readily available, this physiology is clearly maladaptive, and it may explain the many frustrations faced by obese patients who fail repeatedly in their attempts to sustain weight loss.

Clinical Presentation

Obesity presents in two predominant body adipose tissue distributions, each with a different health risk profile. Abdominal, central, or visceral obesity is marked by an increased deposition of fat in visceral areas. It is more common in men, manifests as an increased waist-to-hip circumference ratio, and is often referred to as having an “apple shape.” Women most often have a “pear-shaped” fat distribution, with a preponderance of adipose tissue in the gluteofemoral areas and an associated decrease in waist-to-hip circumference (see Fig. 4-1). The well-known metabolic consequences and risks of increased visceral fat (abdominal obesity) include hyperinsulinemia, insulin resistance, glucose intolerance, adult-onset diabetes mellitus, and lipid abnormalities—an increase in very-low-density lipoproteins (VLDLs) and low-density lipoproteins (LDLs) and a decrease in high-density lipoproteins

(HDLs). The relationship of abdominal obesity to hypertension is well documented, as is the increased prevalence of gallstones and cholecystitis. Visceral obesity in some women is associated with hyperandrogenemia, anovulation, and increased cortisol secretion (the polycystic ovary syndrome). The hyperinsulinemia associated with visceral obesity enhances the availability of androgens and manifests with hirsutism and other features of increased androgen levels. In both men and women, the risk of visceral (abdominal) obesity is additive to that associated with an increased BMI and correlates with a waist greater than 35 inches in women and 40 inches in men.

In contrast, gluteofemoral obesity is associated with a lower prevalence of hyperinsulinemia, hypertension, and cardiovascular disease. Visceral fat is mobilized faster than peripheral fat and therefore has a greater negative impact on metabolism.

Diagnostic Approach

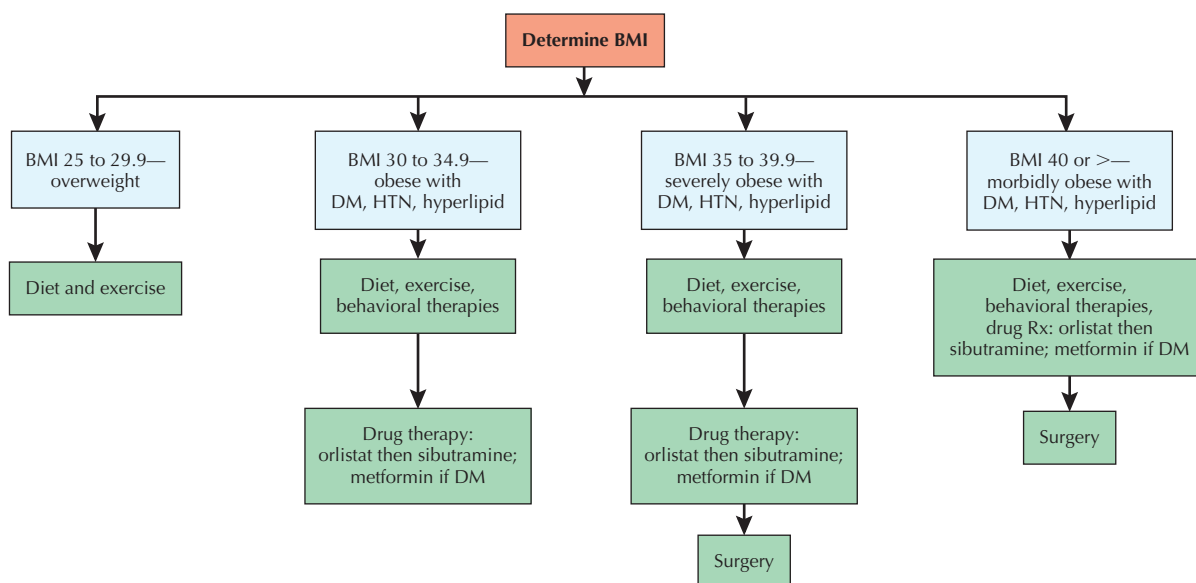

The diagnosis of overweight, obesity, and morbid obesity is based on the previously discussed definitions of BMI and waist-to-hip circumference. Determining the weight at age 18 to 20 years and the weight gain since is helpful. Other key historical information includes whether there is a regular exercise program and whether the patient takes any medications associated with weight gain, including antidepressants, antipsychotics, or anticonvulsants. Given the association of obesity with hypertension, an accurate blood pressure reading is critical. Evaluation should include the following laboratory tests: fasting blood glucose, hemoglobin A1C, thyroid-stimulating hormone, total cholesterol, HDL cholesterol, LDL cholesterol, and triglycerides.

Differential Diagnosis

The differential diagnosis of obesity is limited, and most obese individuals do *not* have an endocrinologic or other identifiable underlying cause (see Fig. 4-1). However, endocrine diseases, including hypothyroidism and hypercortisolism, warrant consideration. These causes are usually readily excluded on physical examination and routine laboratory testing. The gluteofemoral distribution of adipose tissue in hypercortisolism and the associated buffalo hump, abdominal striae, and proximal muscle weakness provide helpful clues to cortisol excess. Obesity is often associated with a positive history in multiple family members. Moreover, obese persons often trace their problem to early childhood or puberty. Damage to the ventromedial hypothalamus secondary to trauma, inflammation, surgery in the posterior fossa, or increased intracranial pressure may result in the rare syndrome of hyperphagic obesity. The polycystic ovary syndrome is associated with obesity in more than half of women with this diagnosis.

Management and Therapy

The treatment of obesity is one of the most frustrating problems for patients and health care providers alike, reflecting the less than 10% rate of a sustained response to therapy and the unrealistic expectation of some patients who feel that they should lose 20% to 30% of their total body weight. A goal of a 5% to 15% reduction is probably more rational and likely to be achieved and sustained. This amount of weight loss will decrease the health risk profile of most patients, including the risk for diabetes mellitus, hyperlipidemia, and hypertension. Figure 4-4 provides an overview of therapeutic options.

Diet and Exercise Therapy

Caloric restriction is an absolute requirement of any successful weight-reduction program and may be achieved by following general guidelines for healthful eating or by adopting a more restrictive food or liquid diet. Successful weight reduction requires that the total calories consumed remain below the total calories expended. Because of their increased lean body mass, men expend more calories and lose more weight than women of similar BMI. Older obese patients expend less energy and lose weight more slowly.

The optimal balance among carbohydrate, fat, and protein content remains controversial. Most guidelines recommend that the daily dietary fat content remain at 30% or below of the total caloric intake. Recent research has emphasized that low-fat foods often contain elevated levels of unhealthy carbohydrates that produce hyperinsulinemia, increasing the risk for cardiovascular compli-

cations. Furthermore, the subtle swings in plasma glucose concentrations (in nondiabetic patients) that result from diets high in junk food and simple carbohydrates accentuate difficulties in appetite control in obese individuals. Diets high in healthy carbohydrates, including fruit, vegetables, and grains, do not produce appetite control problems. These observations have led to an emphasis on low-calorie, high-fiber (healthy carbohydrate), low-fat, and high-protein diets that do not stimulate high levels of insulin secretion. Low-carbohydrate, high-fat diets initially raised concerns about the potential to produce a high-risk serum lipid profile; however, several randomized trials have demonstrated that such diets are safe and are more effective than low-fat diets in achieving short-term weight loss. If a higher-fat content diet is chosen, it is important to make sure that monounsaturated and polyunsaturated fats are selected. Long-term adherence to low-carbohydrate diets is difficult for many patients. In the final analysis, the critical issue is not the diet but whether the patient adheres to any prescribed diet, no matter what the specific food class balance is.

Obese patients with a BMI of more than 30 may require a more aggressive approach to dietary caloric restriction—800 calories or less per day. There is no evidence that diets of less than 800 calories per day are any more effective in the long-term; however, they do achieve more rapid weight loss initially. When very-low-calorie diets are discontinued, rapid weight gain often occurs—an obvious disadvantage. The key to this degree of restriction is to ensure a high biologic value protein intake of at least 1.5 grams per kilogram of ideal body weight and adequate amounts of vitamins, minerals, electrolytes, and essential fatty acids.

These diets are contraindicated during pregnancy and lactation, in patients with bulimia, and in patients with anorexia nervosa. They are also relatively contraindicated in patients with chronic medical diseases, including type I diabetes mellitus, chronic liver disease, chronic renal disease, and coronary heart disease manifested by arrhythmias or unstable angina, and in patients on chronic corticosteroid therapy. Complications include constitutional complaints of fatigue, weakness, and constipation or diarrhea. Gallstones and gout may also occur in the setting of rapid weight reduction, secondary to rapid cholesterol mobilization from fat stores and protein breakdown, respectively. One advantage of the more restrictive diets is that rapid weight loss produces more immediate positive feedback.

Many patients prefer to enroll in commercial and self-help programs such as Weight Watchers, OPTIFAST, and Take Off Pounds Sensibly. With the exception of a single randomized, controlled trial of Weight Watchers that reported a loss of 3.2% of initial weight at 2 years, the evidence to support the use of these programs is suboptimal.

Caloric restriction is more likely to be successful when combined with behavioral therapy and exercise. Group-focused weight reduction programs have the advantage of peer support, especially if the group remains intact over time and is led by a professional who has experience dealing with the nuances of eating behaviors. Participation in a group program provides reinforcement when behavioral change is successful and support when it is unsuccessful. The group leaders must teach self-monitoring, including maintaining a diary of what is eaten under what circumstances and under which outside stressors. This allows more effective stimulus control, for example, avoiding eating while watching television or other activities if doing both activities together predictably results in higher caloric intake. For many obese people, stress is a major stimulus for overeating, a problem that necessitates the teaching of more productive approaches to stress control, such as exercise and meditation.

Exercise is key, but its impact is limited by the previously described tendency for the body to do everything possible to maintain weight in the setting of weight reduction. The energy expended for a given level of physical activity is less after weight loss occurs. Patients frequently become discouraged when they find that any weight decrease requires a disproportionately large amount of exercise. Aerobic exercise has remained a key component of successful programs and is often supplemented by anaerobic strength training to build lean body mass. At least 30 minutes of exercise 3 days a week is recommended, with a maximum of 1 hour daily 6 days a week. Incorporating more exercise into daily activities, such as taking stairs rather than elevators, is also helpful.

Although exercise alone rarely results in sustained weight loss, the importance of exercise should not be

underemphasized. Exercise may be an important surrogate for an individual's motivation to lose weight. In a recent study of 32,000 dieters by *Consumer Reports*, individuals who lost at least 10% of their starting weight and kept it off for 1 to 5 years credited exercise, not food deprivation, as the key to their sustained weight loss.

Pharmacologic Therapy

The use of drugs to treat obesity remains a hope for the future for many obese patients and is usually the next step when dietary therapy fails. Until recently, the drug therapies studied did little more than illustrate the limitations of pharmacologic approaches. In general, the literature had documented a discouraging series of initial successes followed by failure, either because of poorly sustained effectiveness or intolerable side effects. Fortunately, some recently published data offer room for guarded optimism.

Amphetamines were among the first drugs tried to suppress appetite. Although associated with short-term weight reduction, amphetamines were found to have an intolerable side-effect profile and a very high addictive potential. Subsequently, trials of amphetamine-like appetite suppressants (phentermine and others) failed to show sustained benefits.

The short-lived enthusiasm for the combination of phentermine and fenfluramine (the "Phen-fen" diet) was based on reports of a 16.5% reduction in body weight compared with 4.3% in the placebo group over 34 weeks of therapy. Weight reduction leveled off after 6 months, and continuous therapy was necessary to prevent regaining what had been lost. No worrisome side effects were noted initially; in fact, proponents emphasized that the known side effects of one agent seemed to cancel those of the other. Initial questions about this therapy were raised by a 1997 report from the Mayo Clinic that described 24 cases of an unusual valvular disorder resembling the valvular disease associated with carcinoid syndrome. Despite early conflicting reports in the literature, valvular thickening, left-sided valvular regurgitation, and pulmonary hypertension are now believed to be related to this therapy. These observations led to the U.S. Food and Drug Administration (FDA) recall of both fenfluramine and dexfenfluramine, another agent like fenfluramine that increases serotonin release and decreases reuptake. Dexfenfluramine had become one of the most commonly used agents outside of the United States and had enjoyed an anecdotal record of success in weight loss.

Sympathomimetic agents that have been studied include phentermine, benzphetamine, phendimetrazine, diethylpropion, sibutramine, and phenylpropranolamine. Except for sibutramine, they have short plasma half-lives. Phenylpropranolamine and diethylpropion have been shown to be effective in short-term studies; however, a positive long-term benefit on health outcomes has not been demon-

strated. Moreover, the association of phenylpropranolamine with a small but significant risk for hemorrhagic stroke in women has resulted in its removal from the market. Diethylpropion is a Schedule IV drug that is now approved only for short-term use—up to 12 weeks.

Sibutramine, a centrally acting neurotransmitter reuptake inhibitor that effectively inhibits norepinephrine, serotonin, and to a lesser extent, dopamine reuptake, has shown encouraging results for the treatment of obesity. In a multicenter trial with doses ranging from 5 to 30 mg/day, there was a clear dose response, with subjects in the 30-mg group losing 9.5% of body weight while the placebo group lost 1%. Subjects in a maintenance trial after diet-induced weight loss had a further loss of 5.2 kg over 1 year. The placebo group gained weight. Another trial documented similar evidence for maintenance of weight loss in subjects treated with 10 mg of sibutramine daily for 15 months after diet-induced weight loss. Additional benefits include reductions in total and LDL cholesterol, triglycerides, and uric acid. There is also an associated increase in HDL cholesterol. Patients with diabetes mellitus have significant decreases in glucose and hemoglobin A1C. Negative effects include nausea, constipation, dry mouth, insomnia, and an increase in pulse rate in some patients. A hypertensive response does occur in some patients but is relatively mild and rarely requires withdrawal of therapy. Use of sibutramine should be avoided in patients with coronary disease, congestive heart failure, cardiac arrhythmia, and stroke.

Antidepressants like sertraline and fluoxetine in the selective serotonin reuptake inhibitor group have shown short-term benefit in some patients. Fluoxetine at a dose of 60 mg in a placebo comparison study produced a weight loss of 4.8 kg at 6 months; however, 50% of this was regained in the second 6 months.

Orlistat is an inhibitor of pancreatic lipase that results in the malabsorption of 30% of all fat consumed when used at the higher end of its dose range. The associated negative gastrointestinal effects of fat malabsorption provide an added incentive to limit fat intake. In a 4-year, double-blind, randomized, placebo-controlled trial of more than 3000 patients, the orlistat-treated group lost 11% of baseline weight, whereas the placebo group lost 6% at the end of 1 year. In another study, in addition to weight loss, positive benefits included reduced LDL cholesterol, increased HDL cholesterol, decreased fasting insulin levels, improved glycemic control, and reduced blood pressure. Remarkably, the negative gastrointestinal effects did not result in a high dropout rate. The risk for malabsorption of fat-soluble vitamins requires supplementation with a multivitamin taken separately from orlistat.

Recently, an FDA panel has recommended that orlistat be made available in a reduced dosage (60 mg versus 120 mg for the prescription strength) for over-the-counter (OTC) purchase. The panel stated that the most positive effect of orlistat on weight loss will be obtained at reduced

dose, although the best studies have shown a dose-response relationship.

The modern pharmacotherapy of diabetes mellitus has led to some success in weight reduction and in the control of associated risk factors. Metformin, a commonly used hypoglycemic agent, reduces hepatic gluconeogenesis, inhibits intestinal glucose transport, and enhances glucose uptake in muscle and adipose tissue. In contrast to exogenous insulin and insulin-stimulating oral agents, it causes weight loss, in part because it diminishes appetite. Glucose control in insulin-dependent and insulin-independent diabetic patients improves, as do lipid profiles. Lactic acidosis, a known risk, is uncommon when patients with renal and hepatic dysfunction are excluded. The thiazolidinediones, including pioglitazone, have similar positive effects secondary to increasing insulin sensitivity in peripheral tissues. Patients are often able to reduce their insulin dose and have an associated reduction in body weight. However, long-term negative effects, including edema and hypertriglyceridemia, may complicate therapy with these agents.

A new experimental drug, rimonabant, blocks the endocannabinoid system at the cannabinoid-1 receptor, which regulates appetite and body weight. Animals with a deletion of this receptor have a lean habitus and are resistant to diet-induced obesity and dyslipidemia. The initial placebo-controlled trial data documented that rimonabant at high dose (20 mg) produced 5% to 10% weight reduction substantially more often than placebo. These positive results, albeit early in the investigative process, warrant close scrutiny of this drug class in the future. Rimonabant has also shown promise in smoking cessation.

Optimum Treatment

The lack of an obvious first choice in the therapy of obesity excludes any dogmatic recommendation; nevertheless, many experts would agree that diet and exercise deserve an initial trial in patients with a BMI of 25 to 34.9 kg/m². If this approach fails, orlistat is the next line of therapy in patients with hypertension, cardiovascular disease, or dyslipidemia. Metformin therapy should be used initially in obese patients with diabetes mellitus. In obese patients who are otherwise healthy, sibutramine therapy is a rational first choice if dietary measures and exercise fail.

Surgical Therapy

Surgery should be considered in patients with a BMI of more than 40 kg/m² and in those with a BMI of more than 35 kg/m² who have failed other attempts at weight reduction and who have health complications such as sleep apnea, cardiac failure, uncontrolled diabetes mellitus, or severe venous stasis. The goal of surgery is to improve metabolic and organ function and to decrease the morbidity and mortality associated with severe obesity. Noncompliant patients must be excluded, given the need for careful

adherence to a compulsory regimen to supplement vitamins and other critical nutrients.

Two different surgical approaches have been developed: those that limit the reservoir size of the stomach (restrictive) and those that decrease the effectiveness of nutrient absorption (malabsorptive). Small intestinal bypass procedures that induce malabsorption have been largely abandoned because of an unacceptable risk for life-threatening metabolic complications and have been largely replaced by vertical banded gastroplasty, laparoscopic adjustable gastric banding, and gastric bypass procedures. Figure 4-5 presents an overview of the surgical approaches to be considered.

Gastric stapling (vertical banded gastroplasty) reduces gastric reservoir size and restricts the gastric outlet. Patients have an excess weight loss of 66% at 2 years and 55% at 9 years. The procedure fails in patients who gorge on liquid carbohydrates that can pass through the restricted gastric outlet, reversing weight loss in the process. Surgical revision has been required in a substantial number of patients (20% to 56%) for outlet band erosion, staple line disruption, stomal stenosis, gastroesophageal reflux, recurrent emesis, and gastric pouch enlargement.

Laparoscopic adjustable gastric banding involves the placement of an adjustable prosthetic band around the entrance to the stomach. This results in a restricted gastric inlet that can be further restricted by injection of saline into an accessible subcutaneous port. In general, the procedure is less prone to the complications of vertical banded gastroplasty. Study results vary, but some data document an excess weight loss of 15% to 20% at 3 months, 40% to 53% at 1 year, and 45% to 58% at 2 years. Frequent band adjustments are necessary to control the rapidity and degree of weight loss. Studies have documented improvements in diabetes mellitus, hypertension, and sleep apnea.

Gastric bypass is both a restrictive and a malabsorptive procedure involving the creation of a gastric pouch that empties into a gastrojejunostomy, the jejunal segment of which is connected to the excluded gastric segment, duodenum, and biliary-pancreatic secretions by a Roux loop. The altered bowel anatomy excludes some small bowel absorptive area. Malabsorption and the dumping syndrome result in weight reduction but with the concomitant risk for vitamin and mineral malnutrition unless a careful supplemental regimen is followed. Excess weight loss at 1 year averages 62% to 68%, and 50% to 75% at 2 years.

Mortality in the hands of an experienced bariatric surgeon is about 1%. Morbidity includes wound dehiscence or infection, anastomotic leaks, stomal stenosis, marginal ulcers, pneumonia, thrombophlebitis, and pulmonary emboli. At least some of the higher-than-expected risk relates to the risk associated with anesthesia and surgery in the morbidly obese. Refractory vomiting may occur with or without stomal stenosis. Esophageal dilation, esophageal reflux or ulceration, and pouch ulceration may

complicate gastroplasty. Folate, iron, vitamin B₁₂, and other micronutrient deficiencies are unique to gastric bypass and require careful follow-up and patient compliance. Even in the face of substantial morbidity risk, bariatric surgery offers hope for a selected group of patients, and studies continue to show advantages over diet and drug therapies.

Avoiding Treatment Errors

One of the most critical aspects in selecting a therapeutic approach that is both safe and effective is to predict the patient's level of compliance. The lack of highly effective therapies increases the likelihood that risk will exceed benefit, especially in patients who are not compliant. This is certainly true in the case of bariatric surgery, in which noncompliance after gastric bypass procedures can result in major morbidity, and even mortality. Substantial morbidity can also result in noncompliant patients who misuse pharmacologic agents that have significantly negative effects on blood pressure and cardiac function. Patients must adhere to a carefully outlined therapeutic regimen and must be committed to close medical follow-up.

Future Directions

Pharmacologic therapies will offer great promise in the coming years. Agents similar to rimonabant that block specific receptors important in the control of appetite and satiety are likely to provide a progressively more specific designer drug approach.

Although further studies are being done on existing therapeutic approaches, it must be recognized that some of these therapies may become available to the general public as OTC drugs. OTC access may, indeed, prove the safety and efficacy of these therapies, or the approaches may turn out not to be effective. Physicians and health care providers may be faced with previously unknown metabolic and electrolyte (or other) problems associated with the use of OTC drugs that principally reduce the urge to eat or reduce the absorption of food. Health care providers will need to be attentive to the use of OTC medication in obese and formerly obese patients by screening for the known side effects of these drugs.

On a brighter side, although slow in coming, there is hope that advances in genetic understanding may lead to improved pharmacologic therapy for weight loss. Leptin and its congeners are currently under study and, although limited by the need for subcutaneous or intravenous administration, may prove useful in preventing weight regain in patients who have lost weight using another therapy. The vast information now available as a result of the completion of the human genome project will likely stimulate new pharmacotherapies. The likelihood that purely genetic-based approaches will offer any significant success for obese patients is low at this time, because of

Figure 4-5 Surgical Options.

the complicated relationship of this polygenic disease and the many environmental factors that can affect weight gain or loss. Recently, the National Human Genome Project, in collaboration with the National Institute for Environmental Health Sciences, has undertaken the Genes and Environment Initiative (GEI). The GEI offers promise to better understand the specific mediators of obesity (at all levels from the cell to the organism) and the interplay between these environmentally driven factors and the human genome.

The author emphasizes the importance of an exercise program that promotes the expenditure of 300 kcal per day in maintaining weight loss induced by dietary caloric restriction.

Evaluation and Treatment of Chronic Pain

Introduction

Millions of people are affected by both acute and chronic pain conditions costing in excess of \$100 billion for treatment and lost work productivity. *Pain*, as defined by the International Association for the Study of Pain, is an unpleasant sensory or emotional experience associated with actual or potential tissue damage, or described in terms as such damage. Pain is subjective, and not all pain is equal. There is no useful clinical test that can quantify pain. A patient's pain experience is a result of interrelated physical and psychological factors, including physiologic response to actual or potential tissue damage, previous pain experience, beliefs about pain, coping style, emotions, and family and social influences. Chronic pain is a persistent pain that is refractory to treatments based on specific remedies, or to the routine methods of pain control such as non-narcotic analgesics. In the chronic setting, pain becomes a disease rather than merely a symptom. The best strategy for the management of the patient with chronic pain employs a multidisciplinary approach with pharmacologic, interventional, physical, and psychological therapies. Each patient is an individual whose response to therapy may be unpredictable, and sequential trials of alternative therapies are often required to arrive at an optimal treatment plan. Some types of intractable pain are resistant to virtually every available therapy.

Etiology and Pathogenesis

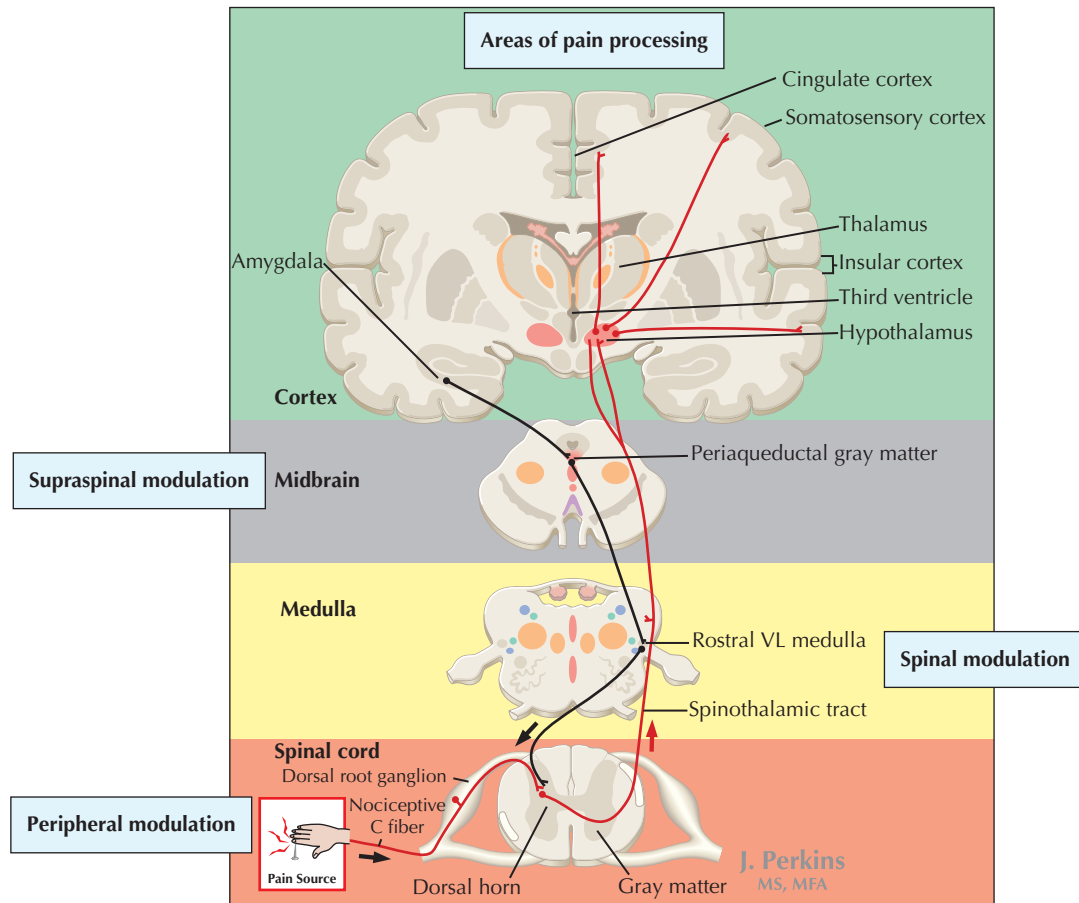

Pain transduction involves free nerve endings in the integument, viscera, and periosteum. Nociceptor responses are triggered directly by exogenous tissue trauma, but are also influenced by many endogenous factors whose precise mechanisms are unknown. Three classes of endogenous mediators are involved: (1) those that activate nociceptive afferents and produce pain by local application (e.g., bradykinin, acetylcholine, potassium); (2) those that facilitate pain by sensitizing nociceptors but are ineffective in evoking pain themselves (e.g., prostaglandins); and (3) those that produce local extravasation (e.g., substance P). These mediators contribute to primary hyperalgesia, in which pain thresholds in traumatized tissue are lowered.

Nociceptive transmission involves primarily unmyelinated C and thinly myelinated A delta nerve fibers. The cell bodies are located in the dorsal root ganglia, with first-order synapse within the marginal layers of the spinal cord dorsal horn. Substance P, glutamate, calcitonin gene-related peptide, cholecystokinin, and vasoactive intestinal

polypeptide have all been implicated in synaptic pain transmission. Spinothalamic, spinoreticular, and spinomesencephalic pathways are the primary routes of transmission to the brain, where pain is ultimately perceived. The hypothalamus, medial thalamus, and limbic systems are involved in the motivational and affective features of pain (Fig. 5-1).

The periaqueductal gray and descending inhibitory pathways selectively inhibit pain transmission at the level of the spinal cord. Norepinephrine, serotonin, enkephalin, and endorphins are the predominant inhibitory neurotransmitters.

Chronic pain may involve ongoing peripheral nociception, as in osteoarthritis or pain associated with intervertebral disk degeneration. In many other cases, persistent neuropathic pain may result from pathologic alteration in the pain signaling processes themselves, for example, in diabetic or postherpetic neuralgia. In either case, pain may become self-perpetuating to some extent as a consequence of *N*-methyl-D-aspartate-mediated plasticity in the central nervous system, leading to central sensitization.

Figure 5-1 Pain Transmission.

Pain Classification

Pain severity may be classified using various scales, such as verbal (mild, moderate, severe), numeric (0 to 10, where 0 = no pain and 10 = worst imaginable), visual analogue, faces (most appropriate for pediatric assessment), or more elaborate questionnaires (e.g., McGill Pain Questionnaire). Ultimately, all clinically useful scales are subjective and rely upon the report of the patient.

Current schemes for classification of pain according to the underlying pathophysiology remain relatively unsophisticated. Nociceptive pain arises from ongoing stimulation of peripheral nociceptors, as in the case of chronic or recurrent trauma or degenerative disease; the source may be somatic or visceral. Neuropathic pain is associated with some of the most severe pain disorders (Box 5-1). Typical descriptors include burning, tingling, shooting, numbing, and constricting. Cutaneous sensory abnormalities may range from anesthesia to hyperalgesia or allodynia (painful response to a nonpainful stimulus). Some varieties of neuropathic pain depend on tonic activity of the sympathetic

nervous system (sympathetically maintained pain), so that pain and other symptoms may be abolished by sympathetic blockade with local anesthetics. Complex regional pain syndrome (reflex sympathetic dystrophy and causalgia) is characterized by persistent spontaneous pain after an injury, accompanied by sudomotor abnormalities, edema, and alterations in skin color and texture; it is often sympathetically maintained.

Anesthesia dolorosa is the clinical finding that defines a deafferentation pain syndrome—spontaneous pain in an area otherwise devoid of sensation. Phantom limb pain may be understood as an extreme example of deafferentation. The presence of pain in the absence of intact nerve conduction pathways implicates a problem with sensory integration at the level of the central nervous system. Other central pain disorders may follow direct tissue injury to the central nervous system (e.g., post-spinal cord injury pain, post-thalamic stroke syndrome) or may be functional (psychogenic).

Cancer-related pain is sometimes considered a separate category, although this is somewhat artificial because it is

defined by the context rather than the pathophysiology. In fact, cancer pain can be caused by any one or more of the previously described categories of pain.

Clinical Presentation

Patients may present with one or more types of pain, and the precise pain diagnosis may remain obscure. Some clinical features distinguish common neuropathic pain syndromes (Table 5-1).

Box 5-1 Etiology of Painful Neuropathies: Major Categories
Toxic or Metabolic Endocrine (e.g., diabetic) Chemotherapy (e.g., isoniazid) Chemical exposure associated Nutritional (e.g., beriberi)
Post-traumatic Complex regional pain syndrome types I and II
Compressive Nerve entrapment syndromes (e.g., carpal tunnel syndrome)
Autoimmune Vasculitic Demyelinating Paraneoplastic Parainfectious
Infectious Viral (e.g., HIV, herpes zoster) Spirochetal (e.g., Lyme disease) Guillain-Barré disease
Hereditary Fabry's disease Amyloid

Diagnostic Approach

Different algorithms can be used to develop the best treatment options for chronic pain patients. A 10-step process can be used for long-term opioid therapy in chronic pain (Box 5-2).

Management and Therapies

Chronic pain syndromes often involve significant emotional and behavioral issues, often lead to significant functional impairments, and are accompanied by significant sleep disturbance. These aspects of the patient's disease must not be neglected, and it is often necessary to enlist the assistance of specialists in psychology, psychiatry, physiatry, physical or occupational therapy, and others.

Medical treatment of the pain often begins with pharmacologic therapy. There are only two classes of general-purpose primary analgesics in use: nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids. The utility of these classes of drugs is limited by toxicity, side effects, inefficacy for many varieties of chronic pain or pain with activity, tolerance, physical dependence, and risk for addiction or withdrawal.

Adjuvants such as antidepressants or anticonvulsants enhance the effectiveness of a primary analgesic, limit the side effects, treat concurrent symptoms that can increase pain, and provide analgesia for certain types of pain. They may be used alone or in combination with primary analgesics. Some adjuvants also have sedating or anxiolytic side effects that can be useful in treating insomnia or anxiety. Adjuvants should be started in low doses and titrated slowly to minimize side effects and maximize benefit. It is important to provide medication trials of adequate duration. Sometimes maximal analgesic effects are not seen for 4 to 6 weeks after therapeutic levels are reached. Educate the patient about the potential delay in action of these drugs. Patients should also be informed that serial drug trials may be required before an adequate combination is found.

Table 5-1 Clinical Features of Common Neuropathic Pain Syndromes

Diagnosis	Typical Clinical Features
Painful diabetic neuropathy	Symmetrical sensory loss and burning pain in lower legs
Lumbosacral radiculopathy	Lancinating pain radiating into the anterior thigh (L2, L3) or lower leg (L4-S1) with motor weakness or sensory loss
Postherpetic neuralgia	Unilateral pain, sensory loss, or allodynia in the dermatome where herpes zoster had previously erupted
HIV-related neuropathy	Symmetrical painful paresthesias, most prominent in the toes and soles of the feet
Complex regional pain syndromes	Regional (e.g., limb) pain with edema, cutaneous blood flow, and sweating abnormalities
Postsurgical neuropathic pain	Peri-incisional sensory loss, pain, and allodynia for more than 3 months after surgery, phantom limb pain after amputation or mastectomy

Box 5-2 Ten-Step Process for Long-Term Opioid Therapy in Chronic Pain
Step I: Perform comprehensive initial evaluation
Step II: Establish diagnosis X-rays, magnetic resonance imaging, computed tomography scan
Step III: Establish medical necessity Physical diagnosis Therapeutic interventional pain management Physical modalities Behavior therapy
Step IV: Assess risk-to-benefit ratio Treatment is beneficial
Step V: Establish treatment goals
Step VI: Obtain informed medical consent and agreement
Step VII: Institute initial dose adjustment (up to 8-12 weeks) Start low dose Utilize opioids, nonsteroidal anti-inflammatory drugs, and adjuvants Discontinue because of side effects Lack of analgesia Side effects Lack of functional improvement
Step VIII: Assess stable phase Assess for the four A's Analgesia Activity Aberrant behavior Adverse effect
Step IX: Monitor adherence Prescription monitoring program Random drug screen Pill counts
Step X: Assess outcomes Successful: continue Stable doses Analgesia, activity No abuse, side effects Failed: discontinue if No analgesia Noncompliance Abuse Side effects Complications

Adapted from Trescot AM, Boswell MV, Atluri SL, et al: *Opioid guidelines in the management of chronic non-cancer pain. Pain Physician* 9:1-39, 2006.

Nonsteroidal Anti-inflammatory Drugs (Acetaminophen)

NSAIDs are most effective for mild to moderate inflammatory pain, postsurgical pain, and pain associated with trauma, arthritis, and cancer (Table 5-2). The analgesic effect is potentiated when used in conjunction with opiates

or other adjuvants. NSAIDs differ from opiate analgesics in the following ways: (1) there is a ceiling effect to analgesia; (2) they do not produce tolerance, physical dependence, or psychological dependence; (3) they have the potential for significant end-organ toxicity; and (4) the primary mechanism of action is inhibition of cyclooxygenase (COX), preventing the formation of prostaglandins that sensitize peripheral nerves and central sensory neurons to painful stimuli. COX-2-specific inhibitors have been developed that decrease the risk for gastrointestinal bleeding and do not inhibit platelet aggregation. However, evidence suggests an increased risk for myocardial infarction and stroke with the COX-2 inhibitors. Thus, the NSAIDs as a class are being reevaluated for safety. In the United States, there is a black box warning on all NSAIDs, and their use is contraindicated in patients undergoing coronary artery bypass grafting.

Opiates

Opiate therapy is indicated when chronic cancer or non-malignant pain does not respond to nonopiate therapy alone (Table 5-3). Opiates have a central and peripheral site of action, particularly in the presence of inflammation. Many opiates available are in combination with nonopioids; this latter component is the limiting factor. For example, the upper dose limits for acetaminophen preparations is 4000 mg/day in adults and 90 mg/kg/day in children weighing less than 45 kg. For daily pain, long-acting drug formulations are preferred.

The undertreatment of pain is often caused by the misconception that opiate therapy will lead to unmanageable tolerance and physical and psychological dependence. Tolerance can occur, but it is not the most likely cause of increased narcotic requirement. Disease progression or new pain syndrome should be excluded. Physical dependence and withdrawal symptoms can be prevented by careful monitoring and slow withdrawal and tapering of narcotics. Psychological dependence is rare if narcotics are prescribed correctly. Pseudoaddiction is a pattern of drug-seeking behavior in an attempt to gain pain relief and may be perceived as addiction. It is often the result of uncontrolled pain due to inadequate treatment. This behavior stops once pain relief is adequately relieved. The long-term use of opioid analgesics is often appropriate for the control of otherwise intractable pain, but it requires close monitoring and an ongoing patient-physician relationship.

Antidepressants

Tricyclic antidepressants have been used as first-line therapy for a variety of neuropathic pain disorders and may be helpful in managing sleep disturbance associated with chronic pain. Atypical antidepressants, serotonin reuptake inhibitors, and monoamine oxidase inhibitors may also have a role, although the results of clinical trials of their efficacy as analgesics have been equivocal (Table 5-4).

Table 5-2 Commonly Used Nonsteroidal Anti-inflammatory Drugs and Doses

Drug	Average Dose (mg)	Dosing Interval (hr)	Maximum Daily (mg)	Comments
Ibuprofen	200-400	4-6	3200	
Naproxen	500 initial, 250 subsequent	8-12	1250	
Indomethacin	25	8-12	100	
Choline magnesium trisalicylate	1000-1500	8-12	1500	Does not increase bleeding time
Nabumetone	1000-1500	12-24	2000	Absorption increased with food
Diclofenac sodium	50-100	6-8	200	
Celecoxib	200	12	400	Cyclooxygenase-2 selective
Acetaminophen	500-1000	4-6	4000	Hepatotoxicity can occur if maximum dose exceeded

Table 5-3 Commonly Used Long-Acting Opiates and Doses

Drug	Equianalgesic Dose (Oral)	Start PO	Comments
Morphine (MS Contin, Oramorph, Kadian)	30 mg	15-30 mg/d	For all opioids, use caution in patients with impaired ventilation, asthma, increased intracranial pressure, or liver failure.
Oxycodone (OxyContin)	20 mg	20-40 mg/d	Long plasma half-life (>12 hr); accumulates over several days; do not escalate dose rapidly.
Methadone	Use extreme caution when converting because of variability of patient response.	10-20 mg/d	
Fentanyl (Duragesic transdermal patch)	Transdermal fentanyl patch 25 µg/hr roughly equals 45 mg/day of sustained release morphine.	25-µg/hr patch	12-hr delay in onset and offset of patch

Table 5-4 Commonly Used Antidepressants and Doses

Drug	Dose	Side Effects
Tricyclic		Anticholinergic and α -adrenergic blocking effects, cardiotoxicity, orthostatic hypotension, narrow angle glaucoma, lower seizure threshold
Amitriptyline	10-100 mg	
Nortriptyline	25-60 mg	
Desipramine	25-100 mg	
Doxepin	25-100 mg	
Atypical		Priapism Little anticholinergic effect
Trazodone	25-300 mg	
SSRIs		Insomnia, restlessness, gastrointestinal distress, tremor, primary ejaculatory delay, nausea
Fluoxetine	20-60 mg	
Paroxetine	10-40 mg	
Sertraline	50-200 mg	
SNRIs		Sedation, ataxia, nausea, dry mouth, hyperhidrosis
Duloxetine	60 mg/d (max, 120 mg/d)	
Venlafaxine	150-225 mg/d (max, 375 mg/d)	Hypertension, ataxia, sedation, insomnia, nausea, anxiety, anorexia

SNRI, serotonin-norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

Table 5-5 Commonly Used Anticonvulsants and Doses

Drug	Daily Dose	Side Effects
Gabapentin	Start 300 mg every hour as needed; titrate to 900-1200 mg three times a day	Sedation, ataxia, edema, tremor, psychomotor slowing, difficulty concentrating
Pregabalin	Start 50 mg/d in divided doses every 8 hr; titrate to 300-600 mg/d (max, 600 mg/d)	Sedation, ataxia, edema, weight gain, diplopia, dry mouth
Topiramate	Start 50 mg every hour as needed; titrate to max dose 200 mg twice a day	Sedation, fatigue, psychomotor slowing, difficulty concentrating, paresthesias, kidney stones
Lamotrigine	Start 25 mg every hour as needed; titrate to 300-500 mg twice a day	Rash, drug interaction with other anticonvulsants
Carbamazepine	Start 200 mg every hour as needed; titrate to 400-2400 mg/day	Sedation, ataxia, hepatitis, aplastic anemia, slow intracardiac conduction
Valproate	5-10 mg/kg/d; titrate to 15-60 mg/kg/d	Sedation, transient elevation AST/ALT, thrombocytopenia, platelet dysfunction at higher doses

ALT, alanine transaminase; AST, aspartate aminotransferase.

Duloxetine has been approved for diabetic peripheral neuropathy.

Anticonvulsants

Anticonvulsants may relieve lancinating pain arising from peripheral nerve syndromes such as trigeminal neuralgia, postherpetic neuralgia, diabetic neuropathy, cancer pain, and post-traumatic neuralgia. These drugs are also effective as mood-stabilizing drugs and in migraine prophylaxis (Table 5-5).

Other Adjuvants

Antispasmodics are beneficial for pain of musculature origin. Their use for long-term therapy is limited by somnolence and the potential for abuse and dependency. Baclofen is most useful in treatment of spasticity of spinal cord origin. Patients with spinal cord injury and multiple sclerosis typically respond best. Tizanidine is a centrally acting α_2 -adrenergic agonist. It is effective in the treatment of both spasticity and painful muscle spasm.

Tramadol binds with modest activity to μ opiate receptors and has weaker affinity for σ and κ receptors. It also inhibits the reuptake of norepinephrine and serotonin. Side effects include dizziness, nausea, constipation, dry mouth, and headache. It should be used with caution in patients with increased intracranial pressure and renal disease.

Mexiletine, an oral local anesthetic, has been used safely in neuropathic pain disorders such as myotonia, chronic painful diabetic neuropathy, and spasticity. Contraindications to use include preexisting second- or third-degree heart block, chronic hypotension, congestive heart failure, and hepatic injury.

Capsaicin is the most commonly used topical medication for neuropathic pain, particularly diabetic neuropathy, postherpetic neuralgia, and postmastectomy pain. Many

patients report good pain relief, but many are unable to tolerate the burning at the application site.

Physical Interventions

Exercise, massage, applications of heat and cold, transcutaneous electrical stimulation, and acupuncture are physical interventions that are used in addition to medication therapy. These are particularly helpful in myofascial or localized pain disorders.

Various types of injections and nerve blocks can be employed as important diagnostic and therapeutic tools. Trigger-point injections are effective in myofascial pain disorders to help facilitate exercise and restoration of normal muscle function. Epidural steroid injection and selective nerve root blocks are effective for radicular neuropathic pain problems and spinal stenosis. Facet joint injections and medial branch nerve blocks are useful in mechanical back and neck pain.

Sympathetic nerve blocks (stellate ganglion, celiac plexus, lumbar sympathetic) can be diagnostic and therapeutic for sympathetically maintained pain and can facilitate rehabilitation-oriented therapy. A patient who experiences profound but temporary benefit from nerve blocks may be considered for chemical or surgical neurolysis. Such procedures are generally not permanent and are not without risk; they are best considered only as a last resort, especially for patients with limited life expectancy.

More aggressive interventional pain therapies include radiofrequency denervation, spinal cord stimulation, or intrathecal pumps.

Avoiding Treatment Errors

An individualized program is important in chronic pain management. The best available treatment options are based on an understanding of the pain mechanism, medical

history, and available medications. The side effects of some drugs, particularly sedative medications, can be advantageous. Chronic pain management also requires ongoing patient evaluation, patient education, and diagnostic evaluation of any treatable underlying conditions. Analgesia, tolerability, and other benefits such as improved sleep or quality of life should be monitored. Patient education should include a discussion about the natural history of the condition and realistic treatment expectations. Functional goals such as improvement in sleep, activity, and quality of life should be emphasized. Reassessment and titration of medications should be tailored to improve functionality and quality of life. If one treatment regimen is not beneficial, the pain problem should be reevaluated, use other adjuvants or a different opiate should be considered, or the patient should be evaluated for possible interventional or injection therapies.

Future Directions

Until such time as we have the means to effectively eliminate chronic pain, newer cost-effective models of multidisciplinary assessment and care of patients are needed. Our understanding of neuropathic pain mechanisms and pathophysiology is still in its infancy but is advancing rapidly; more novel analgesic drugs are under investigation than ever before in history. Custom-designed analgesics seek to affect pain processes on a cellular level: to block nociception, counteract the processes of neuropathic pain, and

prevent central sensitization. New interventional techniques will continue to be developed and explored as means to treat the sources of intractable pain. Chronic pain prevention is an area ripe for research and clinical development.

Additional Resources

This is an excellent resource for concise information about drug selection, dosing, the treatment of breakthrough pain, and minimization of side effects.

EVIDENCE

1. Gilron I, Watson CP, Cahill CM, Moulin DE: Neuropathic pain: A practical guide for the clinician. *CMAJ* 175(3):265-275, 2006.

This article gives an excellent description of the pathophysiology, clinical features, and pharmacology indicated for the treatment of neuropathic pain. A primary care algorithm is also provided to assist with neuropathic pain management.

2. Trescot AM, Boswell MV, Atluri SL, et al: Opioid guidelines in the management of chronic non-cancer pain. *Pain Physician* 9:1-39, 2006.

These guidelines were established after systematic review and analysis of the available literature on opioid use in the management of chronic non-cancer pain. These evidence-based guidelines should help provide consistency in opioid philosophy and treatment among diverse chronic pain groups.

Chronic Fatigue Syndrome

Introduction

The chronic fatigue syndrome (CFS) was first operationally defined in 1988 to describe patients who present, usually after a viral illness, with incapacitating fatigue of such severity that continuation of regular activities is impossible. Associated symptoms include generalized muscle pain and weakness, poor concentration, irritability, and postexertional fatigue lasting longer than 24 hours. The onset is most often abrupt, occurring over a few hours to a few days, and disruptive of an otherwise productive life, often of a previously highly motivated and energetic individual. Medical experts have not provided an acceptable explanation based on an underlying organic or nonorganic disease process such as anxiety or depression. The lack of a definitive explanation has led to the frustration of patients and physicians alike, and CFS has become one of several so-called medically unexplained diseases.

Historical Overview and General Perspective

Medical authors have described patients with chronic fatigue at least since the late 1800s when the term *neurasthenia* defined a similar condition of uncertain cause characterized by severe physical and mental fatigue, protracted postexertional fatigue, nervous dyspepsia, and mood abnormalities. The syndrome seemed to present more commonly in women and hard-working professionals. It was often ascribed to the impact of life stresses on the nervous system. Over time, the term neurasthenia has given way to a variety of others, each defining a similar clinical syndrome often developing in localized cluster outbreaks or epidemics: *Iceland disease*, *Royal-Free disease*, *epidemic neuro-myasthenia*, *myalgic encephalomyelitis*, *postviral fatigue syndrome*, *chronic brucellosis*, *chronic Epstein-Barr virus infection*, and *Lake Tahoe disease*, among others. The presentation of clusters of cases led to an infectious disease hypothesis and the designation of the syndrome as postinfectious or postviral. Much of the research on CFS over the past 50 to 60 years has focused on a possible viral etiology.

CFS has become one of several highly prevalent conditions that defy a clear-cut etiologic and pathogenetic explanation and challenge the dualistic model of medical illness. This model assumes that the mind and body are separate

and categorizes every illness as mental or physical. The often-heated debate of recent years stems from moralistic prejudices that associate those illnesses characterized as “mental” with personal weakness and inferiority. In contrast, “physical” illnesses do not imply personal fault.

The dualistic model of illness has produced two approaches, each representing an attempt to explain the somatic and psychological symptoms that characterize CFS. The medical approach defines such syndromes as chronic fatigue, irritable bowel, and fibromyalgia as organic diseases with functional, rather than structural, abnormalities. The psychiatric approach regards these diseases as psychological disorders with somatic manifestations. Under this model, the somatic symptoms of CFS represent underlying depression and anxiety being manifest in an atypical somatoform manner. The focus on psychological factors was supported by a 1970 reanalysis of previously reported outbreaks of benign myalgic encephalomyelitis that concluded that the epidemics were secondary to a mass hysterical reaction. The debate continues as patients and their physicians search for answers.

Epidemiology

Not surprisingly, the lack of consensus on the definition of CFS and the lack of a diagnostic test have produced

great variability in prevalence estimates, ranging from 2.3 to 600 cases per 100,000 population. Using the Centers for Disease Control and Prevention (CDC) criteria published in 1988, the crude prevalence in four surveillance sites in persons older than 18 years was 2.3 to 7.4 cases per 100,000. These estimates are conservative because of the exclusion of patients with preexisting affective, anxiety, and somatization disorders. A more recent study of the prevalence and incidence of CFS in Wichita, Kansas documented a point prevalence of 235 cases per 100,000 persons and a 1-year incidence of 180 per 100,000 persons. As previously noted, clusters are well documented; however, CFS usually occurs sporadically in adults—the mean age of presentation in five series using the CDC definition was 37.8 years. In the same five series, women comprised 76% of the patients. Based on limited demographic information, most of those affected are white, middle class, and well educated—hence the label, yuppie flu. As in the case of irritable bowel syndrome and other similar entities, more aggressive case finding could lead to a higher estimate of prevalence.

Etiology and Pathogenesis

A specific etiology has evaded investigators. Since CFS usually develops acutely after a respiratory or gastrointestinal infection, researchers have focused many of their efforts on the search for an infectious pathogen. Other pathogenic mechanisms have also been considered.

Viruses

Studies have implicated a number of viruses, including enteroviruses, particularly Coxsackie B. Other viruses considered include human herpes virus 6, herpes simplex types 1 and 2, human T-cell lymphotropic virus-2, retroviruses, and the Epstein-Barr virus (EBV). The proposed theory is that initial infection with a viral pathogen can induce long-term immune dysfunction in susceptible hosts. Chronic EBV infection has received the most attention. Several epidemics of CFS have seemed to follow the pattern of an extended illness after acute infectious mononucleosis. This association has depended on the serologic markers of EBV infection. Recent studies have documented that there is no greater incidence of EBV seropositivity in CFS patients than in the general population. It now seems unlikely that EBV or another virus will be the highly sought-after underlying pathogen.

Chronic Lyme Disease and Other Infections

Initial excitement about the Lyme disease spirochete as a causative agent has also waned. As in the case of viral agents, investigators have had great difficulty confirming a definite pathogenic association. The same holds for studies

of other pathogens, including *Brucella abortus*, *Campylobacter jejuni*, *Mycoplasma pneumoniae*, and *Toxoplasma gondii*, among others.

Immune System Dysfunction

The literature has documented a number of immune system abnormalities, including peripheral blood lymphopenia, decreased lymphocyte proliferation in response to mitogens, abnormal numbers of helper and suppressor T cells, impaired killer cell activity, impairment of delayed skin test sensitivity, immunoglobulin G subclass deficiencies, and excessive production of interferon- α by mononuclear cells. Studies have not yielded consistent and reproducible results, and more data are needed to define more specific associations.

Psychological Causes

The proportion of CFS patients who have a previous history of psychiatric disorders or symptoms compatible with depression, anxiety, and somatoform disorders varies between 42% and 82% in some studies. The association with nonpsychotic depression is especially notable and has led to debate about what is primary and what is secondary; that is, is depression a reaction to the syndrome, or is it the primary cause? Another basic question is whether psychiatric disorders can produce the observed dysregulation and impairment of immunity.

Clinical Presentation

The most recent case definition, based on an international consensus of investigators, represents an attempt to provide a useful working definition pending the development of a better understanding of the etiology and pathogenesis of CFS. Box 6-1 lists the diagnostic criteria.

The overlap of the symptoms listed and those of depression and anxiety is obvious (Fig. 6-1). Clinical diagnosis is complicated further by the fact that a large proportion of CFS patients have a previous history of major depression. In those patients who meet the criteria of both CFS and major depression, the onset of the two disorders commonly coincides. Despite this strong association, as many as half of the patients diagnosed with CFS cannot be categorized operationally under the diagnosis of a major depressive disorder. The consideration of anxiety as an underlying disorder in addition to depression still does not fully explain the full complement of symptoms experienced by many patients with CFS.

Most patients do not have definitively abnormal physical findings, at least ones that are specific. Some experience low-grade fever (37.6° C to 38.6° C). Others have a non-exudative pharyngitis with palpable or tender cervical lymph nodes. Axillary adenopathy has also been observed.

Box 6-1 Case Definition of Chronic Fatigue Syndrome**Inclusion Criteria**

Clinically evaluated, medically unexplained fatigue of at least 6 months' duration that is:

- Of new onset (not lifelong)
- Not a result of ongoing exertion
- Not substantially alleviated by rest
- Causing a substantial reduction in previous level of activity

The occurrence of four or more of the following symptoms:

- Subjective memory impairment
- Sore throat
- Tender lymph nodes
- Muscle pain
- Joint pain
- Headache
- Unrefreshing sleep
- Postexertional malaise lasting more than 24 hours

Exclusion Criteria

- Active, unresolved, or suspected disease
- Psychotic, melancholic, or bipolar depression (but not uncomplicated major depression)
- Psychotic disorders
- Dementia
- Anorexia and bulimia nervosa
- Alcohol or other substance misuse
- Severe obesity

From Fakuda K, Straus SE, Hickie I, et al: *The chronic fatigue syndrome: A comprehensive approach to its definition and study.* *Ann Intern Med* 121:953, 1994.

Differential Diagnosis

Diseases that can present as fatigue include anemia, hypothyroidism, Addison's disease, chronic liver disease, hypercalcemia, low cardiac output states, neuromuscular diseases, sleep disorders, and depression.

Diagnostic Approach

The diagnosis depends on a careful review of the patient's history. In general, laboratory testing is not helpful given the lack of a sensitive and specific test and the associated poor likelihood ratios. The utility of laboratory testing lies in the need to exclude other diagnoses that can present as fatigue. Depression is an especially difficult diagnosis to exclude. Recommended testing includes the following: complete blood count, erythrocyte sedimentation rate, electrolyte profile, calcium, phosphorus, serum creatinine, urinalysis, glucose, liver function tests, thyroid-stimulating hormone, and creatine kinase. Testing for antinuclear antibodies and rheumatoid factor is rational in patients with especially severe arthralgias and myalgias. Excluding adrenal insufficiency with morning and evening cortisol levels should be considered. Evaluation for an underlying sleep disorder is also rational, especially if there is evidence of daytime somnolence. Testing for antibodies to EBV and

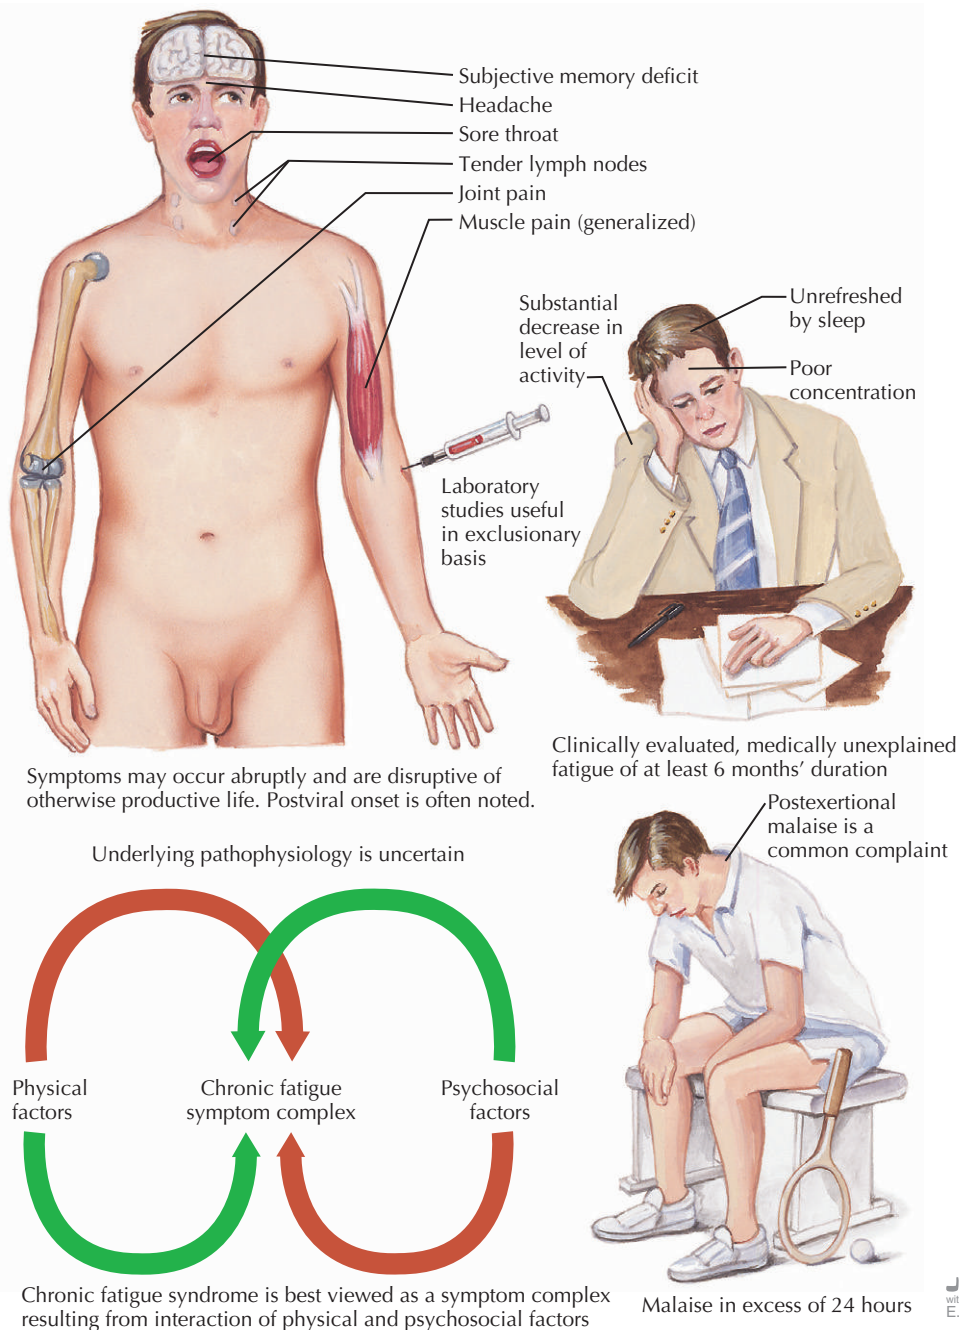

enteroviruses is not recommended. Similarly, immune function testing is of no diagnostic value given the variability of the results. The basic approach is to exclude other causes of fatigue first. This avoids labeling a patient with CFS prematurely.

Management and Therapy

In general, the goals of therapy are to provide emotional support, to relieve the patient's symptoms and overall distress, and to protect the patient from the harm of an increasing array of poorly evaluated and documented therapies. Given the lack of a definitive etiology, the focus must be on symptomatic therapy. Accepting the patient's symptoms and disability as "real" is an essential first step. CFS patients, after interacting with the medical system on several occasions, understand that medical science places them in an "unexplained" category, one that often questions whether they are really sick. Discussion of possible underlying anxiety or depression regularly evokes overt hostility because such diagnoses equate with personal weakness and inferiority and, in effect, with the lack of "real" illness. It is helpful to emphasize that, in the face of insufficient knowledge about etiology, the patient and the physician must deal with a variety of possible underlying etiologies, but both must focus on treating the symptoms no matter what the cause. This requires them to abandon the dualistic model and to accept the inseparability of the mind and body in every disease process. Patients are much more willing to accept depression and anxiety as components of their disease process after being reassured that "it is not all in your head." They are also more willing to acknowledge that there is no quick fix given the complex interrelationships involved.

Optimum Treatment

As is often the case for diseases without definitive etiologies, therapy must be individualized. It is essential to provide the patient and the family with educational materials about the nature of the syndrome, while avoiding unproductive arguments about what is and is not a likely etiology in the patient's case. Identifiable depression and anxiety must be treated with antidepressant drugs. Serotonin reuptake inhibitors with anxiolytic characteristics are often helpful. These agents may also help with insomnia that can only worsen fatigue. The physician should gently encourage the patient to return to normal functioning and to remain physically active. Exercise programs should be graded in intensity and allow for patient input about what is and is not tolerated. Forcing poorly tolerated exercise can decrease rapport and patient self-confidence in the ability to recover function. Some studies have documented that cognitive behavioral therapy over extended intervals and with skilled therapists can help the patient develop coping skills in the face of a chronic illness. Supportive

Figure 6-1 Chronic Fatigue Syndrome: Signs and Symptoms.

psychotherapy can help restore patient confidence and self-esteem.

Avoiding Treatment Errors

There is no convincing evidence that the use of intravenous or oral antibiotics, antivirals, or intramuscular or intravenous γ -globulin therapy is effective. The abiding concern is that such therapies can lead to iatrogenic complications, including renal dysfunction, intravenous-line infections, and allergic reactions.

Often, therapy is impaired by differences between the patient's and the physician's views on underlying disease mechanisms and therapy. Patients and their family members may have strong opinions based on the lay literature, Internet information, and information from self-help groups. Differences arise when the provider has to complete an official report about disability and is torn between helping the patient and avoiding a self-fulfilling prophecy that CFS is a hopeless disease process. The physician should not immediately reject the patient's ideas in any of these areas. Special time must often be set aside to allow

extended discussion with the patient and the patient's family. The need for such "special time" is one of many aspects that make the management of CFS patients challenging and leads to avoidance of this patient group by health care providers.

Prognosis

The current literature does not provide reliable information about prognosis; however, there is clearly substantial variation among patients. The disease seems to be highly variable with day-to-day fluctuations and periods of incapacitating relapses occurring after periods of improvement. The duration of the disease is also variable, ranging from 1 to 5 years or more. Twenty-six to 57% of patients improve or recover after varying periods of follow-up. The risk for morbidity is high, especially in patients who have the disease indefinitely. In contrast, mortality is rare. Iatrogenic illness is a major risk brought on by frustrated attempts of both patients and their physicians to try any therapy, no matter how poorly documented. Patients fare worse when they insist that only an organic explanation is viable and fail to accept the biopsychosocial model of disease that espouses an intricate mind-body connection. This situation is greatly exacerbated by a health care system that insists on separating medical and psychiatric services, in effect catalyzing the dualistic approach. The exclusion of psychotherapeutic options by patients greatly limits what can be done to palliate their disease process. Unfortunately, the hesitancy of busy physicians, even those with the necessary training and experience, to take on so-called problem patients also perpetuates the dualistic model.

Future Directions

The need to move from the highly descriptive term, chronic fatigue syndrome, which defines a very heterogeneous group of patients, to one or several that define a more homogeneous group or groups, remains a central issue. Like other syndromes that are medically unexplained, CFS reminds us that our current classification model of disease perpetuates the dualistic mind-body separation and leads to the suboptimal care of this large group of patients. The publicity surrounding CFS has made the need to move toward the biopsychosocial model more apparent to patients, their physicians, and hopefully, those who fund research. There is no other alternative until a more specific etiology of CFS is defined. The need for more research that addresses underlying disease mechanisms and more useful ways to classify diseases that cross the mind-body divide is clear.

This paper presents the results of a study of the prevalence and incidence of CFS in the general population of Wichita, Kansas in an attempt to provide more accurate population-based epidemiologic data.

Poisoning and Drug Overdose

Introduction

Intentional overdose in suicidal adults is the most common cause of poisoning that leads to hospitalization or death. Ingestion of substances in the home by children younger than 6 years accounts for most reported poisonings; however, the morbidity is much lower. The incidence has more than doubled in the past decade, particularly in the teenage and elderly populations. Other poisoning scenarios include parenteral drug abuse, chemical exposure, medication interactions, and envenomations. Diagnosis can require the recognition of toxic syndromes and appropriate utilization of laboratory studies. Specific treatments using decontamination methods and antidotes may be required for some poisonings, although most are treated with supportive measures.

Etiology and Pathogenesis

Pharmaceuticals, particularly analgesics and over-the-counter preparations, are involved most frequently, followed by cleaning products, cosmetics, and plants. Ingestion is the most common route of exposure, but poisonings can occur through dermal, inhalational, mucosal, and parenteral exposures or through envenomation.

The mechanism of toxicity varies with the substance. Effects may be limited to the site of exposure and represent nonspecific chemical reactions. Systemic effects are the result of interactions between the toxin and specific target sites, such as receptors or organs. Most deaths occur before arrival at the hospital, often as a result of central nervous system and respiratory depression. Other life-threatening mechanisms include dysrhythmias, hypotension, and organ necrosis.

Clinical Presentation

Presentations are extremely variable, not only between different substances but also for a specific toxin. Signs and symptoms depend on the time from ingestion, the amount taken, and the interaction of coingestants. This variability in clinical presentation demands a thorough history and physical examination, and the consideration of a possible

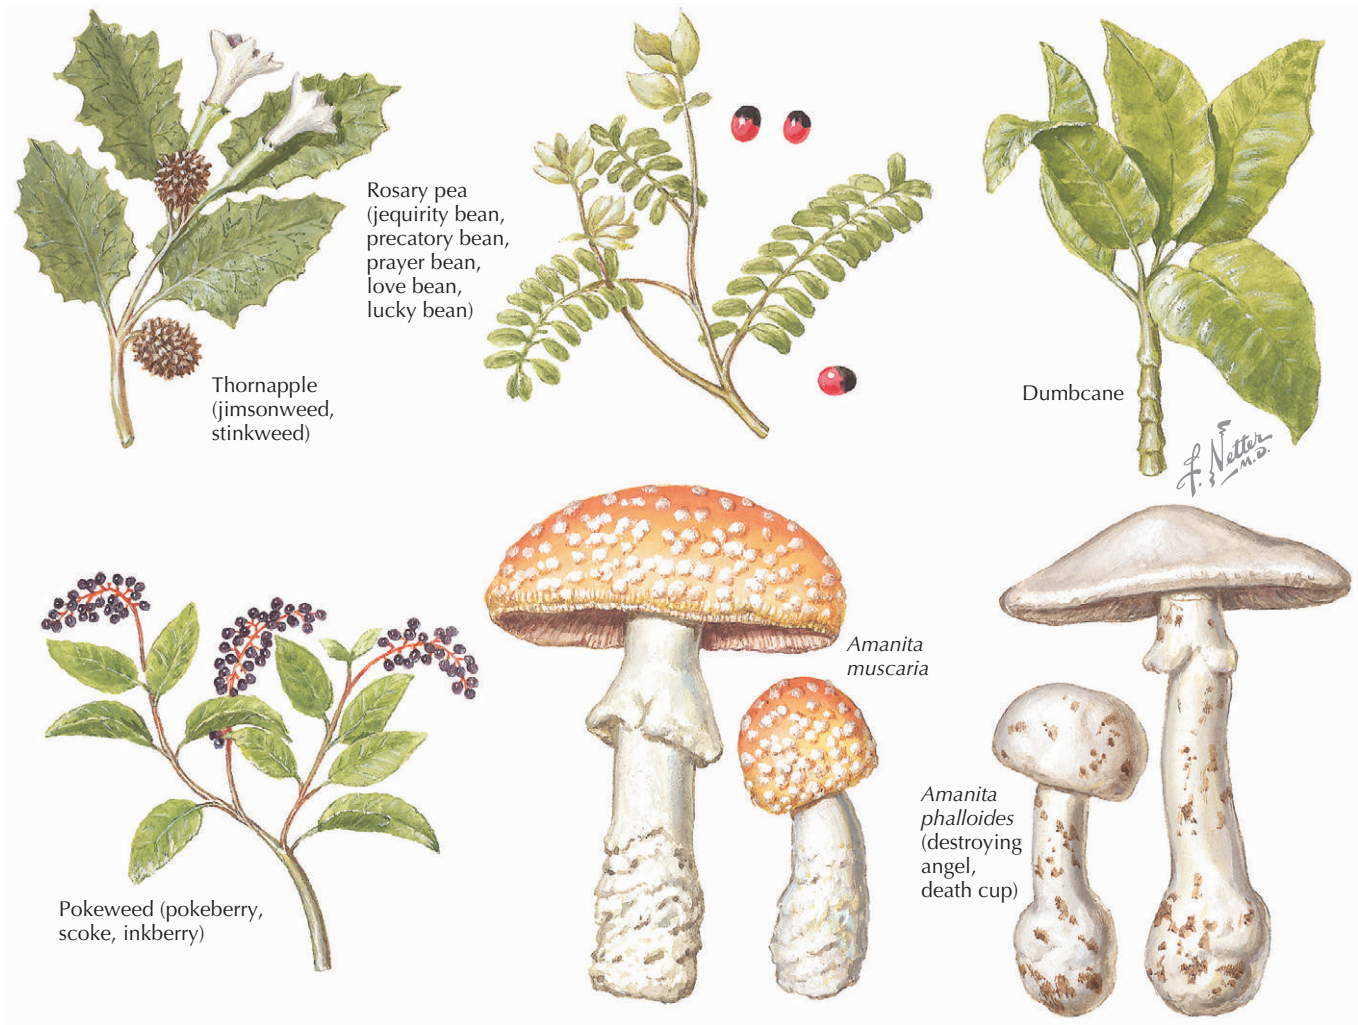

toxic ingestion in the differential diagnosis of all patients with an unexplained sudden change in their physiologic status. Poisoned patients can deteriorate quickly, and as a result, frequent reassessments and close monitoring are essential.

Identification of potential toxins and the time of ingestion are critical for diagnosis and management (Fig. 7-1). Most patients will admit to the substances ingested; however, the accuracy of the amount taken is notoriously unreliable. In addition, patients may be unable to give a history because of altered consciousness. Always assume a worst-case scenario regarding the amount taken (assume the bottle was full) and the probable presence of other coingestants. Collateral history from family members, friends, and prehospital personnel is often helpful. Intentional overdoses are associated with a much higher potential mortality than accidental overdose.

A complete physical examination of all systems, followed by frequently repeated vital signs and examinations, serves several purposes: (1) the identification of toxic syndromes (or *toxidromes*) and complications associated with the toxin; (2) the detection of underlying disease states or coexisting trauma; and (3) careful monitoring of the response to therapy (Table 7-1; Fig. 7-2).

Both sympathomimetic and anticholinergic drugs can cause central nervous system excitation, mydriasis, and an

Figure 7-1 Some Common Poisonous Plants.

Syndrome	Clinical Manifestations	Associated Toxins
Sympathomimetic	CNS excitation, seizures, tachycardia, hypertension, mydriasis, diaphoresis	Cocaine, caffeine, theophylline, amphetamines
Anticholinergic	Delirium, hallucinations, dry mucosa, mydriasis, decreased bowel sounds, dry skin, tachycardia, seizures	Atropine, tricyclic antidepressants, antihistamines, phenothiazines
Cholinergic	CNS excitation or depression, bradycardia or tachycardia, miosis or mydriasis, diarrhea, salivation, diaphoresis, lacrimation, paralysis	Organophosphates, pilocarpine, acetylcholine
Opiate	CNS depression, miosis, hypoventilation, hypotension, response to naloxone	Heroin, codeine, propoxyphene, pentazocine, oxycodone
Serotonin	Altered mental status, increased muscle tone, hyperreflexia, hyperthermia, tremors	MAOI + SSRI, MAOI + meperidine, SSRI + tricyclic, SSRI overdose

CNS, central nervous system; MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor.

elevation of blood pressure, pulse rate, respiratory rate, and temperature. Anticholinergic agents may be distinguished by the findings of dry skin and mucous membranes, diminished bowel sounds, urinary retention, skin flushing, and decreased visual acuity. Poisoning with a cholinergic agent produces a mixture of muscarinic and nicotinic effects. The muscarinic effects produce a hypersecretory state of salivation, lacrimation, urination, defecation, gastrointestinal hyperactivity, and emesis—thus the acronym, *slUDGE*. Nicotinic effects include mydriasis, hypertension, tachycardia, muscle fasciculations, and weakness. Patients may present atypically when multiple toxins are involved.

Differential Diagnosis

The differential is extensive and varies with the presentation. Poisonings need to be considered in patients with unexplained, acute alterations of mental status, seizures, or dysrhythmias.

Diagnostic Approach

Laboratory

Drug screens have limited utility in acute management. It is preferable to request specific drug assays in probable ingestions and when identification affects patient management. Specific quantitative toxicologic tests that may assist in management include acetaminophen, carboxyhemoglo-

bin, digoxin, ethanol, ethylene glycol, methanol, iron, lithium, methemoglobin, salicylates, and theophylline.

Routine screening for acetaminophen is indicated in all intentional overdoses because of the frequency of acetaminophen overdose, its asymptomatic presentation, and the associated preventable hepatic toxicity. A similar consideration may be given to screening for acetylsalicylic acid and ethanol; however, the evidence is not as compelling. An increased anion gap or an elevated osmolal gap suggests the presence of specific toxins (Box 7-1).

Liver function tests can be useful in acetaminophen toxicity. Calcium oxalate crystals in the urine are associated with ethylene glycol ingestion.

Electrocardiography and Radiography

An electrocardiogram is rarely diagnostic but can identify complications, particularly for toxins associated with sodium channel blockade. Widening of the QRS in tricyclic antidepressant overdoses is associated with seizures and dysrhythmias. Abdominal radiographs can occasionally demonstrate, but not rule out, some radiopaque ingestions (iron, phenothiazines, cocaine condoms, enteric coated tablets, heavy metals).

Management and Therapy

Most ingestions are successfully treated through supportive care as opposed to specific antidotal therapy. Support

of the airway, breathing, and circulation should take first priority. Ventilatory failure may occur secondary to respiratory depression, pulmonary edema, bronchoconstriction, or paralysis. Endotracheal intubation is often necessary to maintain the airway and to facilitate oxygenation and ventilation. Hypotension usually reflects venous pooling as opposed to myocardial depression; therefore, initial therapy consists of intravenous fluid boluses and Trendelenburg positioning. Norepinephrine is a good choice for inotropic support because α blockade is a common cause of hypotension in poisonings.

Altered Mental Status and Coma

Altered mental status is a frequent complication of poisoning. Attributing the symptoms to alcohol alone is a potential pitfall because many ingestions involve multiple toxins. Computed tomography scanning is indicated in patients with focal neurologic deficits or a history of head trauma. All patients who present with coma or altered sensorium should have an immediate bedside glucose check. Intravenous dextrose 50% is the most effective acute therapy for hypoglycemia. All malnourished and ethanol-abusing patients should receive thiamine, 100 mg intravenously. Intravenous naloxone, 2 mg, is recommended in all patients with coma of unknown etiology. Titrated doses of 0.4 mg should be considered in patients who are at high risk for withdrawal. If an opioid overdose is strongly suspected (see toxidromes discussed earlier), up to 10 mg may be required to reverse some opioids (propoxyphene, pentazocine, codeine). Flumazenil is a competitive antagonist of benzodiazepines. Intractable seizures and ventricular dysrhythmias may complicate its administration in patients with a history of ethanol or benzodiazepine abuse, or a history of seizures. Its indiscriminate use in comatose patients is not recommended.

Surface Decontamination

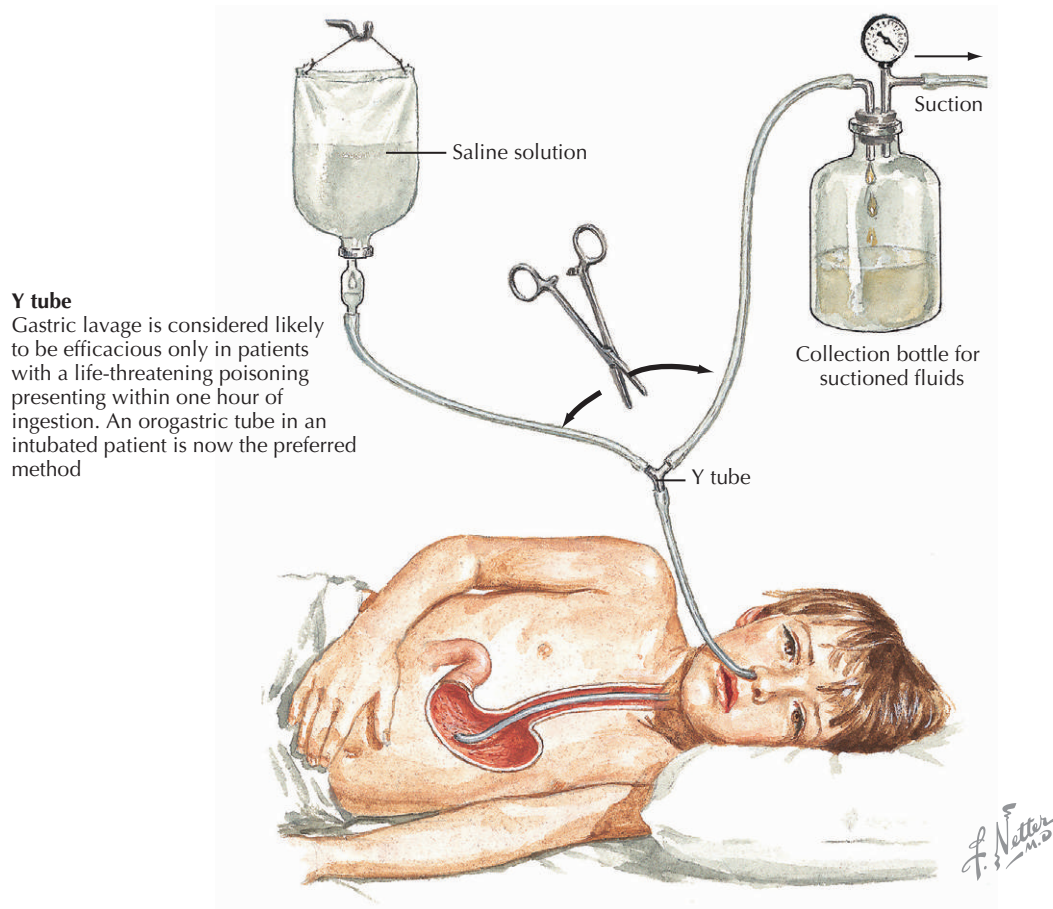

Surface decontamination requires removal of clothing and flushing the patient's skin with copious amounts of water. There is no indication for using an acid or base neutralizing solution. Precautions must be taken to protect caregivers from secondary contamination.

Gastrointestinal Decontamination

Gastrointestinal decontamination refers to interventions that empty the gastrointestinal tract, remove the toxin from the gastrointestinal tract, or bind to the toxin to prevent its absorption. Syrup of ipecac is an emetic agent that no longer has an indication in the hospital setting, and it has been removed from the market because of abuse by bulimics. Orogastric or nasogastric lavage is now rarely used because of its questionable efficacy in most ingestions and the potential for complications (Fig. 7-3). It may be beneficial in some patients who present within 1 hour of ingestion of a life-threatening toxin. Lavage is contraindicated in alkali ingestions and in nonintubated patients who are unable to protect their airway. It is performed through a large-bore, (36- to 40-French) tube. Patients should be placed in a left lateral decubitus, Trendelenburg position. Aspiration of the stomach is performed after confirmation of tube placement, and gastric lavage is repeated in 300-mL aliquots until return is clear. Whole-bowel irrigation uses large amounts of surgical bowel cleansing solution, administered through a nasogastric tube, to speed gastrointestinal transit time and reduce absorption of the toxin. It is indicated for toxins poorly bound to charcoal (iron, lithium), sealed containers (body-packers), and sustained-release products. Contraindications include bowel ileus, obstruction, or perforation. Activated charcoal has a remarkable ability to bind toxins because of its large surface area. In the past, it was recommended in most poisonings; however, its use is now being restricted to cases most likely to be beneficial (see later). Activated charcoal can obscure endoscopy in caustic ingestions and does not bind well to lithium, iron, alcohols, and strong acids and bases. The recommended dose of 1 g/kg given orally or nasogastrically may be combined with the cathartic sorbitol to reduce constipation and make the ingestion more palatable. Multiple dosing and the addition of cathartics are probably not useful.

Enhanced Elimination

Forced diuresis is no longer recommended because of unproven efficacy and the potential for volume overload. Alkalinization of the urine (urine pH 7 to 8) may enhance the elimination of some toxins (salicylates, phenobarbital). Urinary acidification is not recommended for any poisoning because of the potential to exacerbate renal failure in the presence of rhabdomyolysis. Dialysis is useful only for

Figure 7-3 Gastric Lavage: Specialized Equipment.

a limited number of toxins, ideally those that are water soluble and have a low volume of distribution and low protein binding (amphetamines, chloral hydrate, ethylene glycol, lithium, methanol, phenobarbital, salicylates, theophylline). The decision to dialyze is based on serum levels, deterioration despite supportive care, the presence of renal failure, and comorbidities.

Antidotes

Specific antidotal therapy is available for very few poisonings; however, there are a few toxins for which antidotal therapy can be life saving (Table 7-2). The therapeutic half-life of the antidote may be shorter than the toxin, requiring repeat dosing or infusions (e.g., naloxone for a methadone overdose).

Management Resources

Regional poison center consultation is usually available 24 hours a day. Experienced nurses are commonly first-line consultants; however, a toxicologist is often on call and available for assistance with complex cases. POISINDEX

Table 7-2 Toxins with a Specific Antidotal Therapy

Toxin	Antidote
Acetaminophen	N-acetylcysteine
β-Blockers	IV glucagons
Calcium channel blockers	IV calcium, glucagons
Cholinesterase inhibitors	Atropine, pralidoxime
Cyanide	Cyanide kit
Cyclic antidepressants	Sodium bicarbonate
Carbon monoxide	Oxygen
Digitalis	Digibind
Ethylene glycol	Ethanol, 4-methylpyrazole
Fluoride	IV calcium, magnesium
Hypoglycemics	IV glucose
Isoniazid	IV pyridoxine
Iron	Deferoxamine
Methanol	Ethanol, 4-methylpyrazole
Methemoglobin producers	IV methylene blue
Narcotics	Naloxone, Naltrexone
Salicylates	Sodium bicarbonate

is a computer database available in most emergency departments and online. Nomograms are available for toxins such as acetaminophen; however, specific criteria, such as accurate timing, a single ingestion, and the absence of a slow-release formulation must be met for them to be clinically useful. Early administration of *N*-acetylcysteine may be life saving in acetaminophen overdose.

Optimum Treatment

The toxicology literature remains primarily case based. However, some recent clinical studies have changed the treatment of poisoned patients, particularly with regard to the questionable efficacy of gastric decontamination. Gastric lavage is now rarely, if ever, indicated. Activated charcoal can no longer be recommended as routine in poisoned patients. Its use should be restricted to those cases with potential for clinical benefit, such as patients presenting early after ingestion or for drugs with delayed emptying (anticholinergic, opioids, or sustained-release drugs). Whole-bowel irrigation may be useful in severe lithium or metal poisonings and to assist with evacuation of drug packets from body-packers.

In some circumstances, specific therapy such as antidotes and dialysis may be life saving. However, most poisonings are managed with supportive care, attention to airway maintenance, and cardiovascular support.

Avoiding Treatment Errors

A toxicology screen rarely guides patient management and disposition. Many commonly ingested substances are not screened for, and most screening tests are fraught with significant false-positive and false-negative result rates. Routine drug screening cannot be recommended in all cases of poisoning. Rather, discrete drug levels should be requested based on clinical suspicion. Acetaminophen is one of the rare drugs that should be routinely screened for in most intentional adult ingestions because of its frequency, delayed clinical manifestations, and potential to change clinical outcome. A 6-hour observation period for minimally symptomatic patients is usually adequate; however, extended-release preparations may require longer monitoring and admission.

Future Directions

Fab fragment antidotes are drug-specific antibody fragments that bind drug or protein antigen to prevent toxicity. The antibody-toxin is then excreted in the urine. Fab fragment therapy exists for digoxin and crotalid envenomations and is being developed for a number of other toxins. An alcohol dehydrogenase inhibitor, 4-methylpyrazole

(4-MP), is available as an antidote to methanol and ethylene glycol poisoning. It does not cause the sedation that is associated with traditional ethanol therapy. Hallucinogenic designer drugs, such as Ecstasy and γ -hydroxybutyrate, present new challenges in identification and management. Traditional herbal therapies can also be associated with significant toxicities, and databases are available to assist in their identification and management. There is a need for heightened disaster preparedness for mass toxin exposures associated with chemical warfare and terrorism.

Pharyngitis

Introduction

Pharyngitis accounts for 1% to 2% of visits to outpatient clinics, physicians' offices, and emergency rooms. Between 10% and 20% of these cases are caused by infection with group A β -hemolytic streptococcus (GABHS). Identifying and treating this subset is the principal goal in routine clinical practice.

Etiology and Pathogenesis

Respiratory viruses such as adenovirus and rhinovirus cause most cases of pharyngitis. Pharyngitis is also seen as part of the acute infectious mononucleosis syndrome, primarily in adolescents and young adults. Other viral etiologies include primary HIV infection, herpes simplex virus, and Coxsackie A virus.

The most important common bacterial pathogen, GABHS or *Streptococcus pyogenes* (strep), is generally more common in urgent care and emergency department settings, especially during the winter. The organisms are spread by droplets from patients with pharyngitis or from asymptomatic nasopharyngeal carriers. They elaborate a variety of enzymes, including streptolysin, streptokinase, deoxyribonuclease, and hyaluronidase, that promote direct invasion of tissue. GABHS can also produce exotoxins, which are central in the pathogenesis of scarlet fever and the streptococcal toxic shock syndrome. Other streptococci from groups C and G can cause pharyngitis, although without the complications that can follow GABHS infection.

Clinical Presentation

Although no single clinical finding reliably distinguishes between viral sore throats and those caused by GABHS, combinations of clinical findings and laboratory test results can be used to make rational treatment decisions. The following four clinical features tend to be associated with pharyngitis caused by GABHS:

- History of fever
- Tonsillar exudates
- Anterior cervical adenopathy
- Absence of cough

A clinical algorithm for estimating the likelihood of GABHS infection in patients with sore throat that uses these four clinical findings has been developed and validated. (See "Diagnostic Approach").

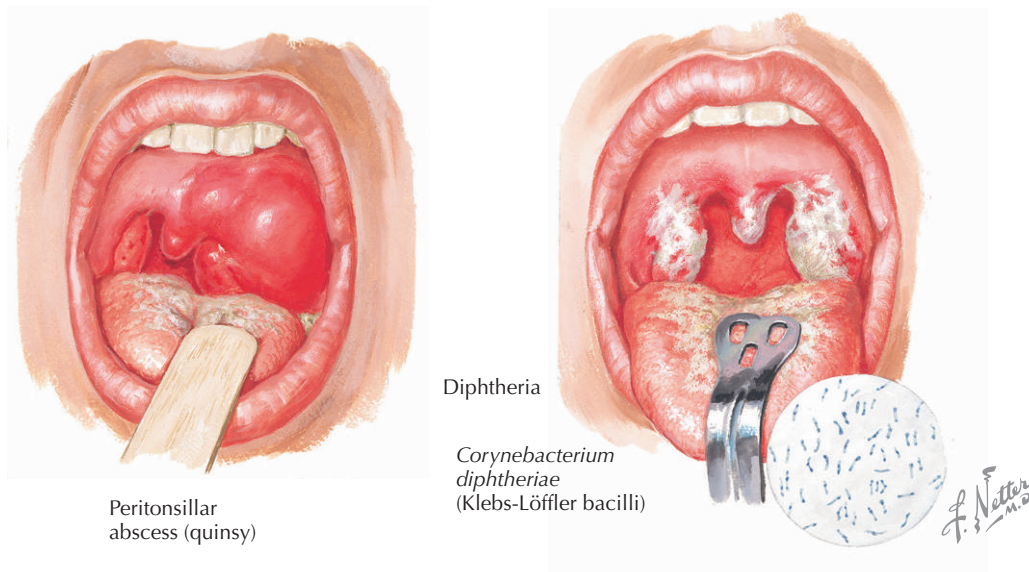

Complications of Streptococcal Pharyngitis

Complications of streptococcal pharyngitis are classified as either *suppurative* or *nonsuppurative*.

Suppurative Complications

Suppurative complications such as *peritonsillar* or *retropharyngeal abscess* occur in just 1% to 2% of cases but require prompt recognition and treatment to avoid major morbidity and even mortality. Symptoms are severe and typically include fever and systemic toxicity. The pain is such that patients are often unable to take liquids, resulting in dehydration. In peritonsillar abscess, the voice becomes altered and muffled, and there is swelling of the anterior tonsillar pillar and medial displacement of the tonsil (Fig. 8-1). Streptococcal *bacteremia* with shock is a rare but serious complication of pharyngeal GABHS infection. Early treatment of GABHS-associated pharyngitis with antibiotics appears to reduce the incidence of these complications.

The term *Ludwig's angina* (see Chapter 16, Fig. 16-1) refers to other parapharyngeal space infections, including the submandibular, sublingual, and submaxillary spaces. These are sometimes polymicrobial and associated with foreign bodies or poor dental hygiene. Epiglottitis, caused by GABHS or *Haemophilus influenzae*, is rare in adults but can progress rapidly and lead to airway obstruction.

Figure 8-1 Infections of the Pharynx.

Suspicion for any of these conditions is an indication for urgent referral to an otolaryngologist.

Scarlet fever occurs primarily in children and is associated with certain toxin-elaborating strains of GABHS. It presents with a fine, erythematous, papular rash that starts on the trunk. Facial flushing with perioral pallor, petechiae, and palmar desquamation may be seen. It is generally self-limited.

Nonsuppurative Complications

Acute rheumatic fever is the most serious of the nonsuppurative complications of streptococcal pharyngitis. Antibiotics reduce the risk by more than two thirds. However, given the very low absolute risk for this complication in the developed world, antibiotic prescribing solely to prevent rheumatic fever is controversial. *Poststreptococcal glomerulonephritis*, the other main nonsuppurative complication, occurs with varying severity, although it is usually self-limited. It is not known whether antibiotic treatment of GABHS reduces the risk for this complication.

Differential Diagnosis

Pharyngitis may be caused by oropharyngeal candidiasis (*thrush*) in immunocompromised hosts and in those receiving broad-spectrum antibiotics or corticosteroids (both systemic and inhaled). Gonococci occasionally cause pharyngitis in patients engaging in orogenital sex. Although rarely diagnosed, other organisms associated with pharyngitis include *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *Treponema pallidum* (primary or secondary syphilis), *Yersinia enterocolitica*, and fusobacteria. Certain spirochetes and anaerobes can cause a membranous pharyngitis associated with a foul odor known as Vincent's angina. Diphthe-

ria, caused by *Corynebacterium diphtheriae*, presents with a grayish membrane on the tonsils, pharynx, uvula, and nares and requires prompt recognition and therapy (see Fig. 8-1). Outbreaks can occur in unimmunized populations. Pharyngitis is also part of the acute retroviral syndrome, along with fever, arthralgias, and lymphadenopathy, associated with primary HIV infection.

Diagnostic Approach

Table 8-1 offers an evidence-based approach to diagnosis and treatment of patients presenting with pharyngitis. The prevalence (i.e., pretest probability) of GABHS in a typical office practice is about 10%. In emergency departments, the prevalence is about 20%. The Centor score is used for refining this pretest estimate of the probability of streptococcal disease and is obtained by assigning one point for the presence of each clinical finding: history of fever, tonsillar exudates, anterior cervical lymphadenopathy, and absence of cough.

Use of Laboratory Tests

Office-based antigen tests have sensitivities of about 85% and specificities of about 95%. They offer rapid results that improve the diagnostic accuracy over clinical assessment alone. Throat cultures, when performed by reference laboratories, have sensitivities of 90% and specificities approaching 99%. Some controversy surrounds whether or not negative antigen tests should be confirmed by culture. The Infectious Diseases Society of America recommends laboratory confirmation, whereas the American College of Physicians endorses several options, including empiric treatment of patients with Centor scores of 3 and 4. One reasonable compromise is to consider performing a confirmatory throat culture when the clinical suspicion

Table 8-1 Suggested Office-Based Approach to the Patient with Pharyngitis

Centor Score*	Post-test Probability of Streptococcal Infection (%)	Action
0	1	Supportive care
1	4	Supportive care
2	9	Antigen testing, antibiotics if positive
3	21	Empiric antibiotics <i>or</i> antigen testing, antibiotics if positive
4	43	Empiric antibiotics

* The Centor score is obtained by assigning 1 point for each of the following clinical findings: history of fever, tonsillar exudates, anterior cervical lymphadenopathy, absence of cough. Note that post-test probabilities will be higher (approximately double) in emergency department settings.

for strep is moderately high (i.e., a strep score of 3) and the initial antigen test is negative.

Management and Therapy

Although guidelines vary somewhat, empiric antibiotic therapy is generally recommended for patients with acute pharyngitis and a Centor score of 4 as well as for those with intermediate scores (2 or 3) and a positive rapid antigen test (see Table 8-1). Lower thresholds for antibiotic therapy should be considered for patients having a household contact with current documented strep infection as well as for those with a history of rheumatic fever.

Optimum Antibiotic Treatment

Penicillin is still the antibiotic treatment of choice for adults, although use of cephalosporins is associated with fewer treatment failures in children. Penicillin V at a dose of 500 mg taken 3 times daily for 10 days shortens the course of the illness. When adherence is a problem, benzathine penicillin given intramuscularly is highly effective, although the risk for anaphylaxis is higher. In penicillin-allergic patients, erythromycin, azithromycin, clarithromycin, clindamycin, or an oral cephalosporin is a reasonable alternative.

Symptomatic Treatment

Regardless of etiology, patients with pharyngitis require symptom relief. Acetaminophen, aspirin, and nonsteroidal anti-inflammatory drugs are probably similarly effective in relieving symptoms. There is limited evidence on the effectiveness of other treatments such as corticosteroids. At least one small study has shown a reduction in duration of symptoms in children with moderate to severe pharyngitis treated with oral dexamethasone. However, no evidence supports routine use of these agents to treat pharyngitis in adults.

Avoiding Treatment Errors

Using the treatment algorithm in Table 8-1 should reduce both overtreatment of viral infections and undertreatment of GABHS infections. Maintaining an index of suspicion

for complications, including peritonsillar or retropharyngeal abscess, is important.

Future Directions

Given that the overall benefit of antibiotic treatment for GABHS-associated pharyngitis is low, studies distinguishing populations at higher or lower risk for complications would help refine estimates of benefit in certain settings. Specifically, studies of prognosis in developing countries as well as in more crowded or socioeconomically depressed areas in developed countries would help define risks for complications of streptococcal pharyngitis in these populations. Studies using rigorously defined, patient-centered outcome measures, including those that measure *severity* as well as the duration of symptoms, may help assess the true degree of benefit from antibiotic treatment in streptococcal pharyngitis.

Rhinosinusitis

Introduction

Rhinosinusitis, characterized by inflammation of the maxillary and ethmoid sinuses, accounts for about 25 million office visits annually in the United States. It is the fifth most common reason physicians prescribe antibiotics. For practical purposes, *sinusitis* and *rhinosinusitis* are interchangeable terms, although many experts now prefer the latter because the nasal structures that are contiguous with the paranasal sinuses are also invariably inflamed along with the sinuses.

Etiology and Pathogenesis

The normal sterility of the sinuses is maintained by continuous mucociliary clearance. A variety of physiologic and anatomic abnormalities can lead to loss of patency of the sinus ostia and the ostiomeatal complex, the region of common sinus drainage in the anterior middle meatus. This mechanism is thought to be common to the pathogenesis of most cases of bacterial sinusitis (Fig. 9-1), both acute and chronic. Although viral upper respiratory infection (URI) is the most common antecedent, allergic and vasomotor rhinitis can also predispose to bacterial sinusitis. Anatomic factors that may play a role include deviated nasal septum and enlarged, pneumatized nasal turbinates (concha bullosae). Nasal polyps arising in the presence of chronic inflammation in the sinuses may also lead to more infection. Foreign bodies such as nasotracheal and nasogastric tubes are significant in the hospitalized patient.

Cigarette smoking and certain intranasal drugs can impair ciliary action, predisposing to sinusitis. Any of these conditions may increase edema at the sinus ostia or impair clearance from the sinuses. A relatively distinct pathogenetic mechanism is the occasional extension of a dental abscess into the maxillary sinuses that may spread into adjacent sinuses.

Cultures obtained by maxillary sinus puncture, as well as endoscopically directed cultures obtained from the middle meatus, show that the most common bacterial pathogens, if present, are *Streptococcus pneumoniae* and *Haemophilus influenzae*; however, other streptococci and *Moraxella catarrhalis* are sometimes isolated.

In patients with uncontrolled diabetes, neutropenia, or other immune-compromised states, pathogens such as

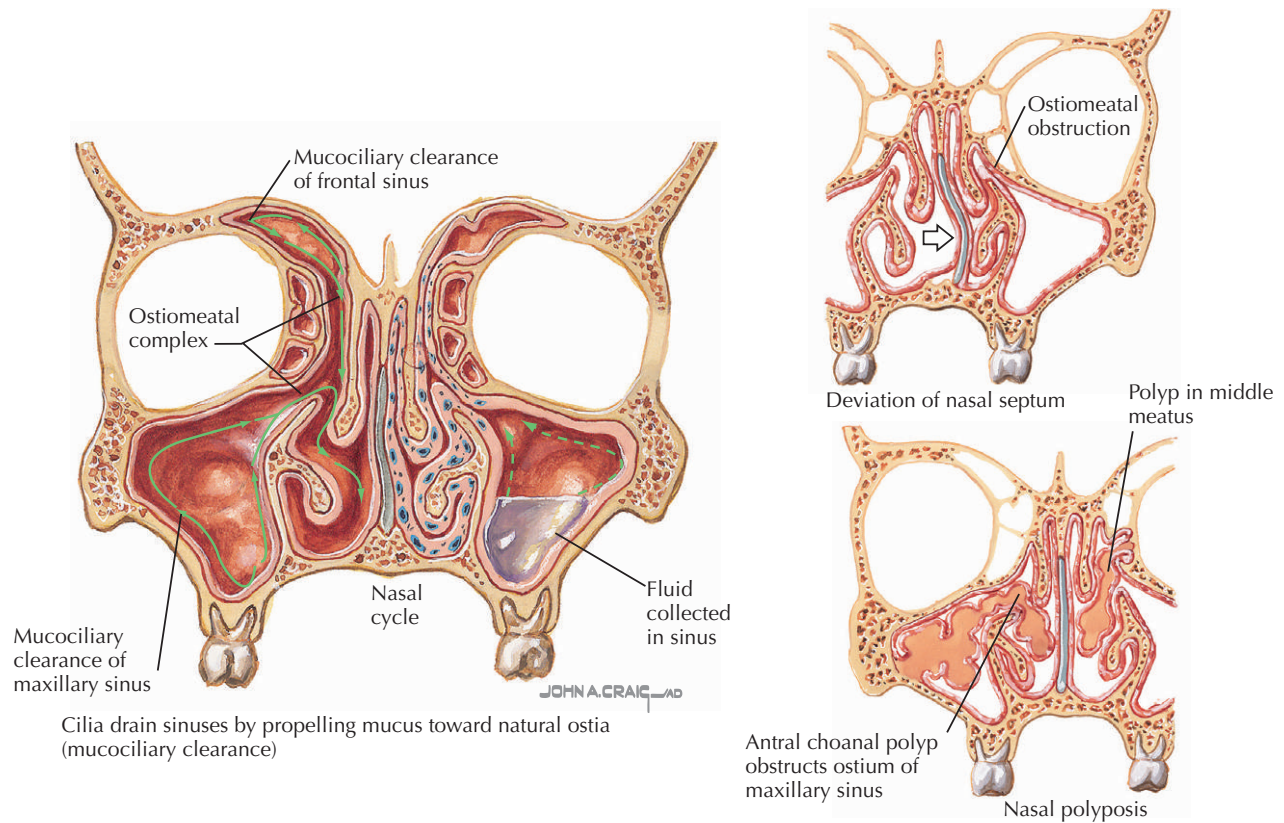

Aspergillus, *Rhizopus* (*Mucor*), *Candida*, *Alternaria*, *Pseudomonas*, *Nocardia*, *Legionella*, atypical mycobacteria, and certain parasites are unusual but important etiologic considerations. Nosocomial sinusitis associated with nasotracheal or nasogastric tubes is frequently polymicrobial. In this setting, *Staphylococcus aureus*, enteric gram-negative bacteria, and anaerobes, particularly anaerobic streptococci and *Bacteroides*, may be present.

Culture studies of chronic rhinosinusitis reveal a different bacteriology. Anaerobes have been associated with some cases of chronic rhinosinusitis, although their pathologic role is unclear. Similarly unclear is the high rate of coagulase-negative staphylococcus as well as *S. aureus* frequently isolated in the presence of frank purulence. In the setting of previous surgery, cultures reveal a greater prominence of gram-negative bacteria, including *Pseudomonas aeruginosa*, in up to 30% of cases.

Recent studies have suggested several different associated mechanisms that may contribute to the development of chronic rhinosinusitis, distinguishing it from acute disease and suggesting novel treatment modalities. Theories suggested include staphylococcal superantigen, chronic osteitis, biofilms, and an abnormal response to the presence of fungus in the nose.

Clinical Presentation

Patients with a “common cold” (viral rhinosinusitis or URI) usually have some combination of the following symptoms: sneezing, rhinorrhea, congestion, facial pressure, postnasal drip, hyposmia or anosmia, sore throat, cough, ear fullness, fever, and myalgia. Color of the mucus discharge is not an accurate indicator of bacterial infection.

Figure 9-1 Histology and Physiology of Nasal Cavity and Sinuses.

There is considerable overlap in the presentation between viral and bacterial rhinosinusitis. A prolonged (>10 days) “cold” with congestion and facial pain, with or without purulent drainage, raises the probability of bacterial involvement. Some patients report a biphasic illness. Fever may be present, but is not typical. Some patients may have subacute (lasting 4 to 12 weeks) or chronic (lasting more than 12 weeks) symptoms.

The clinical exam may reveal facial tenderness, whereas anterior rhinoscopy may identify edema of the inferior turbinates and possibly the presence of polyps or mucopurulence (Fig. 9-2). The value of transillumination in routine clinical decision making is probably limited at best.

Serious life-threatening complications of sinusitis are uncommon but can occur and require rapid intervention. The bony orbits are surrounded by the paranasal sinuses; consequently, orbital infection can result from sinusitis, particularly ethmoid sinusitis with extension through the lamina papyracea in children. A swollen upper lid may be the initial sign, followed by ptosis, chemosis, proptosis, and ophthalmoplegia. Anterior spread of infection from the frontal sinus can lead to osteomyelitis of the frontal bone, which presents with headache, fever, and a palpable doughy edema of the frontal bone called *Pott’s puffy tumor*.

Retrograde migration of septic thrombi along venous channels from infection in the posterior sinuses, including the sphenoid sinus, can lead to thrombophlebitis of the cav-

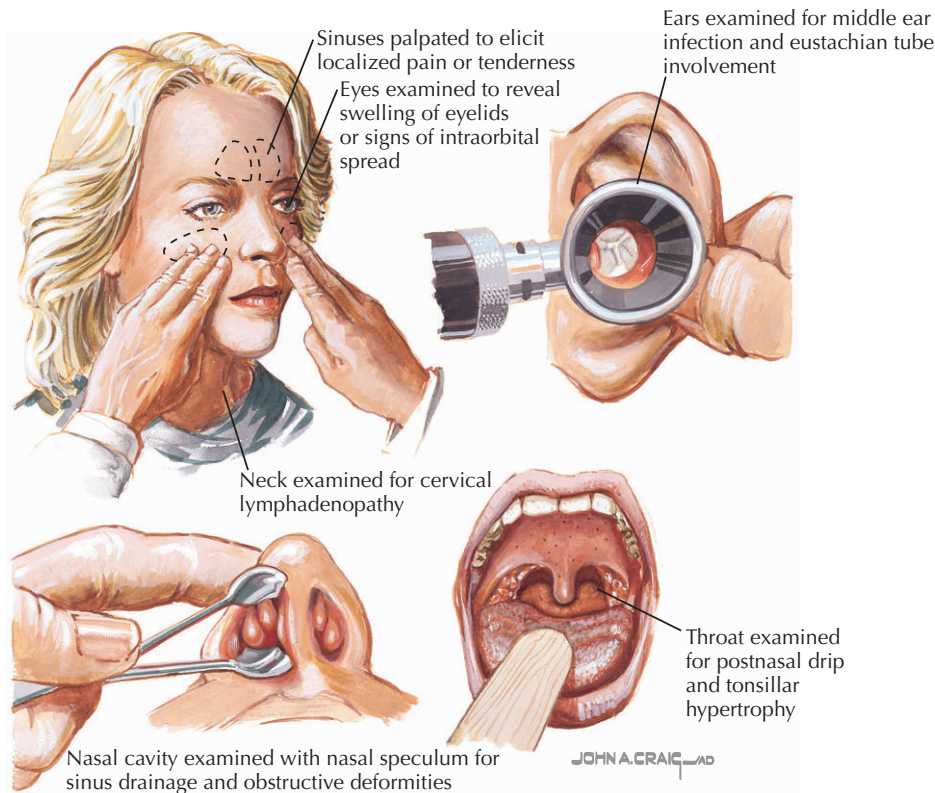

ernous sinus. Presenting findings include fever, toxicity, chemosis, proptosis, and cranial nerve palsies involving nerves III (oculomotor), IV (trochlear), and VI (abducens). Cavernous sinus thrombosis may quickly become bilateral because of spread through the intercavernous communications. Extension to the meninges or brain parenchyma can occur directly or through venous channels and can lead to epidural or subdural abscess, frontal lobe abscess, or meningitis.

Immune-compromised individuals, including diabetic patients, are at risk for invasive fungal infection of the sinuses primarily with species of *Aspergillus* and *Mucor*.

Differential Diagnosis

Viral URI, allergic rhinitis, vasomotor (nonallergic) rhinitis, chronic use of topical nasal decongestants (rhinitis medicamentosa), and deviated nasal septum are the most common diagnostic considerations in patients with sinus complaints.

Less common causes of sinusitis include vasculitis or granulomatous disorders (Wegener’s granulomatosis, Churg-Strauss, sarcoidosis), tumor, cerebrospinal fluid leak, drug-induced vasomotor rhinitis (from cocaine, prazosin, and angiotensin-converting enzyme inhibitors), foreign body, and certain hormonal conditions (hypothyroidism, pregnancy). Some patients with “sinus” may also be manifesting symptoms of migraine (with or without aura).

Figure 9-2 Physical Examination.

Diagnostic Approach

The clinical diagnosis of acute bacterial rhinosinusitis should generally be reserved for patients presenting with sinus symptoms lasting more than 7 days, unilateral maxillary sinus pain or tenderness, and purulent nasal secretions. Many of these patients will still have a viral etiology, and although antibiotics are often prescribed, many experts believe watchful waiting is a reasonable option.

Imaging tests such as plain radiography or computed tomography (CT) are generally of limited utility in the initial evaluation of a patient with clinical rhinosinusitis. Plain radiography is only moderately sensitive and specific for bacteriologically proven sinusitis. Sinus CT is a highly sensitive test, but has poor specificity, and does not distinguish between viral and bacterial inflammation. Maxillary sinus radiographs of young adults with typical viral URI show mucosal abnormalities in about 40% of cases on the seventh day of illness, and CT scans are abnormal in about 85% of similar cases.

The use of imaging in the initial evaluation of suspected sinusitis is more expensive and not much more effective than other strategies, such as empiric antibiotic treatment of patients with reasonably high clinical likelihood of bacterial rhinosinusitis and symptomatic therapy for others. For these reasons, radiography is recommended only when initial therapy is ineffective, or for cases of recurrent or chronic rhinosinusitis. Furthermore, many ear, nose, and

throat specialists find nasal endoscopy to be more useful than imaging in refractory, recurrent, or otherwise complicated cases because of the ability to see and culture purulent secretions.

Management and Therapy

Selection of Patients for Antibiotic Therapy

Most so-called cases of acute sinusitis diagnosed in general ambulatory practice are uncomplicated viral URIs. Even when there is inflammation of the sinuses, bacterial and viral etiologies are difficult to distinguish on clinical grounds. Although antibiotics are clearly overprescribed for this indication, their use can be justified in a subset of patients with sinus complaints. Recent systematic reviews have examined the issue of antibiotic therapy for acute rhinosinusitis. When considered in aggregate, placebo-controlled studies of clinical response show an absolute benefit of about 15%, which means that about seven patients need to be treated for each patient who benefits. The degree of benefit is small, and most placebo-treated patients improve without antibiotic therapy. No serious complications have been reported in sinusitis trials among patients who received placebo.

Given the increasing problem of antibiotic resistance, most experts advocate reserving antibiotics for patients

who have symptoms lasting longer than 7 days, maxillary pain or tenderness in the face or teeth, and purulent nasal secretions, as well as for those who fail to respond to decongestants or who have severe symptoms. These recommendations apply to most routine cases in immunocompetent patients. Early antibiotic therapy along with aggressive diagnostic evaluation and referral is indicated for any patient with signs of toxicity or evidence of complications. Referral to an otolaryngologist is also indicated when sinusitis is either recurrent or refractory to empiric treatment.

Optimum Therapy

Antibiotic Treatment for Acute Bacterial Rhinosinusitis

Three recent meta-analyses have concluded that newer, broad-spectrum antibiotics are no more effective than narrow-spectrum agents. When an antibiotic is prescribed, it should be the agent with the narrowest spectrum that is active against the most common bacterial pathogens, *S. pneumoniae* and *H. influenzae*. Newer consensus guidelines from the American Academy of Otolaryngology and the Centers for Disease Control and Prevention suggest that amoxicillin with or without clavulanate and the cephalosporins cefpodoxime and cefuroxime appear to be as effective as newer, more expensive agents when used as first-line therapies in patients who have not received an antibiotic in the preceding 4 to 6 weeks. Trimethoprim-sulfamethoxazole (TMP-SMX), doxycycline, and macrolides are alternatives for penicillin-allergic patients. In those who have received recent antibiotic therapy, newer quinolones may be appropriate. The optimal duration of therapy is unknown, but 7- to 14-day regimens are typically used. In one study, 3 days of TMP-SMX was as effective as 10 days of therapy. Given the rapid increase of antibiotic resistance among *S. pneumoniae* and *H. influenzae*, the clinician may also want to consider current recommendations for therapy against these organisms when making treatment decisions, particularly if the prevalence of resistant organisms or the risk for complications is high.

Nonantibiotic Therapy

Because complications are rare and rhinosinusitis usually resolves without antibiotic treatment, ambulatory patients with acute, uncomplicated rhinosinusitis can often be treated with analgesics, decongestants, and topical heat for discomfort. Topical decongestants are thought to decrease edema at the sinus ostia and ostiomeatal complex. The problem of short-term rebound is minimized when these medications are used for fewer than 4 days. Antihistamines are said to promote thickening of the secretions and therefore are discouraged, at least initially, although evidence for this is limited. Inhalation of warm, humid vapor may be helpful, as may nasal saline irrigation.

Avoiding Treatment Errors

Physicians tend to prescribe antibiotics in about 90% of cases of sinusitis, even though most cases resolve spontaneously. Clearly, overprescribing of antibiotics to treat what is most often a viral infection is the most common treatment error. This is not entirely avoidable given the difficulty in distinguishing between viral and bacterial etiologies. However, reminding patients of both the increasing problem of antibiotic resistance and the relatively modest benefits of antibiotics for acute rhinosinusitis may help reduce overprescribing in routine clinical practice.

Future Directions

Because no simple, accurate office-based test is currently available to diagnose sinusitis, studies aimed at improving our ability to use clinical findings to make appropriate decisions would be helpful. Particular attention needs to be paid to assessing clinical outcomes at different time points, as well as incorporating symptom severity and patient-assigned utilities to help apply this increasing body of evidence to clinical practice. More studies are needed to assess the prevalence of drug-resistant organisms and the implications for therapy.

This is one of several examples of well-designed, randomized clinical trials demonstrating the modest utility of empiric antibiotics and the absent utility of radiography in managing primary care patients with rhinosinusitis.

Rhinitis: Allergic and Idiopathic

Introduction

Rhinitis presents clinically as nasal congestion. Other symptoms include discharge, itching, sneezing, and sinus pressure attributed to upper airway mucosal inflammatory hyperreactivity. The inflammatory process often progresses to involve the paranasal sinus cavities and the eustachian tubes, producing frontal headaches and a popping sensation in the ears. The associated postnasal mucus discharge can also cause cough and often aggravates lower airway symptoms such as wheezing in asthmatics. Most people experience rhinitis symptoms during their lives.

Several syndromes are associated with chronic rhinitis, including allergic, idiopathic, and secondary rhinitis. Allergic rhinitis is triggered by exposure to allergen, but symptoms can be perennial when exposure is chronic. Classically, there are also associated ocular symptoms, including excess tearing and itching. Idiopathic rhinitis, previously called vasomotor rhinitis or nonallergic noninfectious perennial rhinitis, shares many features with allergic rhinitis, including nasal mucosal hyperreactivity, but lacks the associated skin test sensitivity. Acute and self-limited infectious rhinitis, “the common cold,” is not reviewed here.

Allergic rhinitis is the fifth most prevalent chronic condition in the United States, affecting more than 24 million people. The prevalence of allergic rhinitis has increased 25% in the past two decades. Related diagnoses such as nasal polyps, deviated nasal septum, and chronic disease of the tonsils and adenoids affect an additional 5.3 million Americans. The direct costs of allergic rhinitis in the United States are estimated to be \$1.23 billion annually. These figures do not include over-the-counter pharmacotherapy costs, nor do they allow for the costs associated with the introduction of new generations of antihistamines, diagnostic testing, or immunotherapy. In patients with asthma and allergic rhinitis as opposed to asthma alone, the cost of care increases by 46%.

Etiology and Pathogenesis

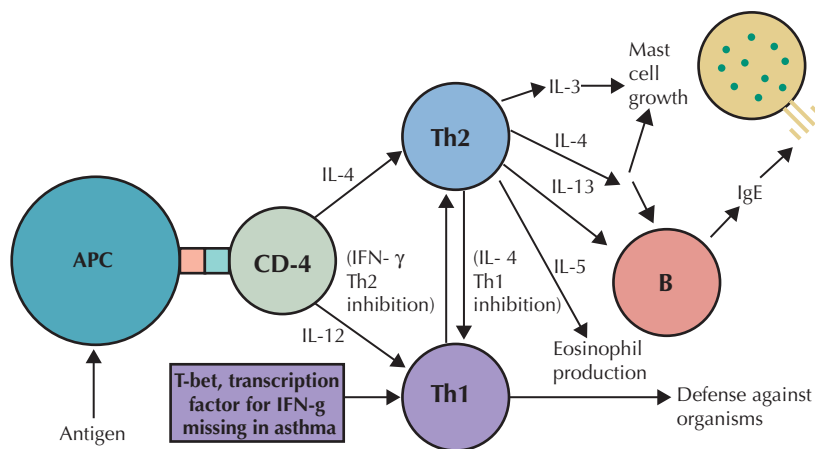

Nonallergic and allergic rhinitis is associated with the release of histamine, prostaglandins, leukotrienes, and cytokines from mast cells, basophils, and eosinophils. In allergic disease, the release of mediators is associated with the cross-linking of immunoglobulin E (IgE) on the mast cell by allergen (Figs. 10-1 and 10-2). A similar cellular reaction occurs in nonallergic rhinitis by an undefined mechanism.

The clinical expression of allergic rhinitis has been linked to whether the immune response is driven by Th1 or Th2 lymphocytes as determined by the interactions between the T cells and antigen-presenting cells (see Fig. 10-2). If the antigen-presenting cell (e.g., the dendritic

cell) triggers the expression of Th2 cells, a number of factors, including interleukin-4 (IL-4), IL-5, IL-9, and IL-13, histamine-releasing factor, and neuropeptides, are released. These factors interact with other mediators, including interferon- γ , IL-11, IL-12, and leukotrienes. The response leads to IgE production, the accumulation of eosinophils and basophils in the lung and upper airway, mast cell proliferation, airway hyper-responsiveness, mucus overproduction, and the exudation of bloodstream-derived proteins into the airways. A specific association of a new subclass of natural killer T (NKT) cells, CD1d-restricted NKT cells, with asthma may prove relevant to developing a better understanding of rhinitis, because the conditions are closely linked.

Figure 10-1 Extrinsic Asthma: Mechanism of Type 1 (Immediate) Hypersensitivity.

APC, antigen-presenting cell.

**Figure 10-2 Allergic Inflammation.**APC, antigen-presenting cell; IFN- γ , interferon- γ ; IgE, immunoglobulin E; IL, interleukin.

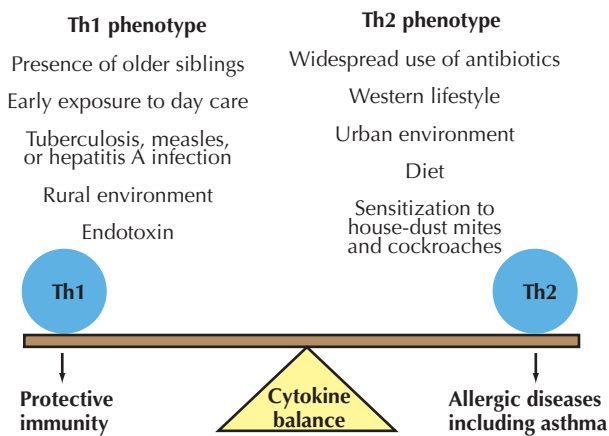

Both genetic and environmental factors appear to play a role in selecting for a Th2 inflammatory response. In nonatopic individuals, there is a switch to a Th1 response to allergen shortly after birth. There is an association between an allele of HLA-DR and a polymorphism for IgE and atopy. Atopic disease also appears to be associated with (1) the Western lifestyle, even when lived in a third-world environment; (2) excessive hygiene; (3) antibiotics in the first 2 years of life; and (4) vaccination (Fig. 10-3).

There is some evidence to support the notion that microorganisms can influence T-cell responses. For example, products of *Aspergillus fumigatus* evoke Th2-mediated IgE production. In contrast, interferon- γ from Th1 cells and IL-18 from macrophages potentially inhibit the production of IgE. Immunotherapy and bacterial cytosine guanosine (C-p-G) DNA repeats, especially when used as adjuvants, may switch the Th2 to the Th1 phenotype.

The increased prevalence in allergic rhinitis has also been linked to higher concentrations of pollen that in turn have been attributed to increased atmospheric CO₂. It has also been associated with the development of energy-efficient buildings that slow the exchange of outside air and promote the concentration of indoor allergens.

Clinical Presentation

The various forms of rhinitis are diagnosed by recognizing the patient's symptom patterns and associations and to a lesser extent by physical examination and laboratory testing. Symptoms include sneezing, watery eyes, pruritic eyes and ears, popping in the ears, sinus pain, and rhinorrhea. It is important to establish the duration, chronicity, and temporal patterns of the symptoms. Triggers such as exposures to flowering plants, mold-rich environments, and animal dander, exacerbations during the spring and

Figure 10-3 Factors Favoring the Th1 and Th2 Phenotypes.

fall, and a positive family history suggest allergic rhinitis. But there are many other considerations when evaluating nasal congestion. Symptoms secondary to illicit drug use include upper airway irritation.

The frequent use of nasal decongestants may provide the clue to the diagnosis of rhinitis medicamentosa. Possible reactions to β blockers and nonsteroidal anti-inflammatory drugs (NSAIDs) in asthmatic individuals should be investigated. An occupational and hobby history may reveal exposure to nasal irritants and potentially carcinogenic wood dusts. Food allergies rarely cause adult rhinitis, but do so more commonly in children. Allergic rhinitis can cause the upper airway resistance syndrome (UARS), which leads to hypersomnolence. These patients may not have frank obstructive sleep apnea.

A physical examination revealing an “allergic crease” from frequent nose rubbing, reddened and inflamed upper airway mucosa, periorbital edema, and a bluish periorbital discoloration secondary to venous stasis (“allergic shiners”) supports the diagnosis of chronic rhinorrhea. Polyps, foreign bodies, septal deviations or perforation, tumors, conjunctivitis, serous otitis, vasculitic rash, urticaria, and wheezing suggest specific etiologies and require careful consideration. Sinus pain, purulent drainage, and fever indicate complicating infection. The diagnosis of idiopathic rhinitis is one of exclusion.

Laboratory testing and physical examination are needed to diagnose local and systemic disorders that can mimic allergic rhinitis. Rhinitis has been linked to cystic fibrosis, tumors, foreign bodies, atrophic rhinitis, hypothyroidism, HIV infection, conditions associated with hormonal fluctuations such as pregnancy, Wegener’s granulomatosis, sarcoidosis, and allergic granulomatosis of Churg-Strauss syndrome.

The diagnosis of allergic rhinitis is established by demonstrating specific IgE either by in vivo scratch skin test or by in vitro radioallergosorbent test (RAST). Such testing

is important when designing avoidance strategies and immunotherapy. A blood count differential demonstrating hypereosinophilia, an elevated IgE, and pulmonary function testing revealing reversible airflow obstruction, bronchial hyperreactivity, and an elevated diffusing capacity for carbon monoxide (DLCO) can be useful to confirm the diagnosis of allergic rhinitis associated with asthma.

Management and Therapy

Optimum Treatment

Conservative interventions include topical or systemic decongestants, topical corticosteroids, anticholinergics, antihistamines, allergen and irritant avoidance strategies, immunotherapy, and mechanical devices such as continuous positive airway pressure (CPAP) when UARS is diagnosed. Surgery warrants consideration if these measures fail and there is anatomic pathology such as nasal polyps that account for the patient’s persistent symptoms. Optimizing therapy for allergic rhinitis is patient specific. However, the first goal in all patients is to control symptoms employing one or more of these therapies. Controlling symptoms is especially important when allergic rhinitis is a trigger for a patient’s asthma. When symptom control is achieved, a systematic tapering of therapies should begin to reduce or eliminate systemic therapies first with the long-term goal of minimizing unwanted medicine side effects. Generally, however, it is difficult to completely stop systemic antihistamines, especially when immunotherapy is not a part of the intervention.

Decongestants

Topical decongestants are therapeutic but cause rhinitis medicamentosa when overused. Rhinitis medicamentosa is treated by slowly tapering the medication and using topical nasal steroids. When employed as therapy, topical decongestants should be used sparingly and for no longer than 7 days. Systemic decongestants work well as nasal decongestants but are associated with tremor, oral dryness, palpitations, and insomnia. They also can aggravate cardiac disease, hypertension, diabetes, glaucoma, thyrotoxicosis, and bladder obstruction. Neither topical nor systemic decongestants significantly influence pruritus, sneezing, or rhinorrhea. The combination of decongestants and antihistamines is more effective than either agent alone (Boxes 10-1 and 10-2).

Corticosteroids

Corticosteroids reduce inflammation, promote vascular constriction, and diminish hyperactivity and vascular permeability. Topical application is the preferred route of administration because it avoids many of the unwanted systemic effects associated with oral and parenteral corticosteroids. The vasoconstrictive property of topical nasal steroids also provides a rapid therapeutic decongestant

effect. However, mucosal drying can produce nasal irritation, bleeding, septal perforations, and candidiasis. Patients should titrate topical steroids to control symptoms and should avoid excessive mucosal drying; one alternative is to use products available in aqueous formulation. Topical steroids are superior to antihistamines in controlling nasal symptoms (Box 10-3).

Antihistamines

Oral H₁ blockers are employed in the therapy for allergic rhinitis (see Box 10-1). H₁ blockers are in fact one of the most successful and widely used therapies. Sedation is a major limiting factor. The latest generation of antihistamines (acrivastine, cetirizine, fexofenadine, loratadine, and desloratadine) is less sedating and does not cause delayed cardiac repolarization (QT prolongation on electrocardiogram), thus avoiding the potential complication of sudden cardiac death caused by torsades de pointes associated with astemizole and terfenadine. The newer antihistamines (azelastine, levocabastine, and olopatadine) are available in topical formulations. Azelastine inhibits histamine release, as well as other inflammatory mediator production,

although use is associated with drowsiness. Levocabastine and olopatadine are available as topical ocular agents with a rapid onset of action and no sedating effects (see Box 10-1).

Antileukotriene Agents

The arachidonic acid metabolites, leukotrienes, are important mediators thought to play a role in many inflammatory diseases. The leukotriene D₄ receptor blocker, montelukast, has been shown to be effective in controlling allergic rhinitis. It is more widely prescribed than zileuton, a 5-lipoxygenase inhibitor that inhibits the formation of all leukotrienes, because it is dosed once a day, as opposed to more frequent dosing with zileuton, and because it lacks the liver toxicity associated with zileuton (see Chapter 20).

Mast Cell Stabilizers

Cromolyn and its more potent derivative, nedocromil, increase intracellular cyclic adenosine monophosphate, thereby raising the threshold for mast cell degranulation and release of histamine. They ameliorate allergic symptoms, although to a less extent than topical steroids. Cromolyn is available over the counter; nedocromil is available as an ophthalmic preparation but is not yet available in a topical nasal application. A drawback to the use of mast cell stabilizers is the need to use them multiple times each day.

Anticholinergics

Ipratropium bromide inhibits secretions from vagally innervated serous and seromucous glands by antagonizing acetylcholine at the cholinergic receptor. The drug is poorly absorbed, not associated with rebound rhinorrhea, and well tolerated. Ipratropium is effective in reducing rhinorrhea but has less effect on nasal congestion and sneezing.

Immunotherapy

Immunotherapy is reserved for patients with severe symptoms of allergic rhinitis who suffer much of the year or who cannot be managed with medications and avoidance strategies. The exact therapeutic mechanism is unknown. It is now thought that there is a switch in T-helper (Th) cell antigen processing away from pathways associated with IgE production. In general, this therapy is continued

for about 6 years and then stopped. After discontinuing, there is often a honeymoon period, of variable duration, during which no therapy of any type may be required. Patients with severe asthma are considered at greatest risk for significant adverse reactions to immunotherapy, including anaphylaxis and death.

Avoiding Treatment Errors

There are two issues regarding the treatment of allergic rhinitis. The first focuses on the absolute requirement that the diagnosis is correct because other treatable serious conditions, such as cystic fibrosis, sarcoidosis, and vasculitis, as mentioned earlier, are associated with chronic rhinitis. The second is the need to avoid aggravating other medical conditions patients may have with therapy, as mentioned associated with systemic decongestants.

Future Directions

Discriminating between allergic and idiopathic rhinitis is difficult. Fas, a cell surface molecule that induces apoptosis, has been linked to rhinitis. The serum soluble Fas (Sfas) level is normal in idiopathic rhinitis, a condition attributed to an imbalance in the autonomic nervous system. It is reduced in allergic rhinitis. Allergic rhinitis, to date, is the only disease associated with reduced levels.

The anti-IgE antibody, omalizumab, has clinical efficacy in allergic rhinitis and asthma, but its use for allergic rhinitis is unlikely until the cost of the drug, average \$12,000 per annum, has been reduced. Agents that block interleukins are also of therapeutic interest. A soluble IL-4 receptor, for example, has demonstrated effectiveness in asthma and may prove useful in treating allergic rhinitis. Anti IL-5 lowered circulating eosinophils in asthmatics but had no clinical effect.

Future therapies may employ CpG bacterial DNA repeats as adjuvants with vaccines and in immunotherapy with the goal of altering allergen processing to avoid or cure an atopic condition. They are also likely to increasingly focus on the functions of the immunoregulatory CD1d-restricted NKT cell.

Common Oral Lesions

Introduction

The oral cavity, along with the nasal cavity, represents the initial point of contact for pathogens and irritants entering the respiratory and digestive systems. The borders for this region extend from the vermilion border of the lips to the junction of the hard and soft palate and the circumvallate papillae of the tongue. The oral cavity includes the lips, buccal and gingival mucosa, teeth, hard palate, floor of the mouth, retromolar trigone, and the anterior two thirds of the tongue. Complete examination of the oral cavity should include visualization of all mucosal surfaces and palpation of the buccal surfaces, tongue, palate, and floor of the mouth. A wide variety of disease processes can present in the mouth as similar lesions, creating a diagnostic challenge in the evaluation of the oral cavity.

Recurrent Aphthous Ulcers

Recurrent aphthous ulcers (RAUs) are the most common oral mucosal ulcers in North America, affecting 5% to 66% of the adult population (Fig. 11-1). RAUs are more common in higher socioeconomic classes and typically present in the second decade of life. Their etiology remains uncertain. Nutritional deficiencies, hormonal changes, bacterial and viral infections, food hypersensitivities, stress, and genetic predisposition have all been postulated as causative factors.

Depending on the presentation, RAUs are classified as *major*, *minor*, or *herpetiform*. All types are generally found on the nonkeratinized, mobile mucosa of the buccal region, lips, and floor of the mouth. RAUs are not associated with fever or other systemic reactions. Recurrence is most frequent in younger patients, and 30% of patients may have constant disease for months to years.

Major RAUs, the most severe form, affects 7% to 20% of patients. Lesions of this type are greater than 10 mm in diameter and may last from weeks to months. They may coalesce into large, irregular ulcers that produce scars when healed. These ulcers are found on soft, movable mucosa but may also be located posteriorly, on the soft palate, tonsils, and pharynx.

Minor RAUs are most common, accounting for 70% to 87% of all aphthous ulcers. They measure less than 10 mm in diameter and present as discrete, shallow, painful ulcers with central fibrous exudate surrounded by an erythema-

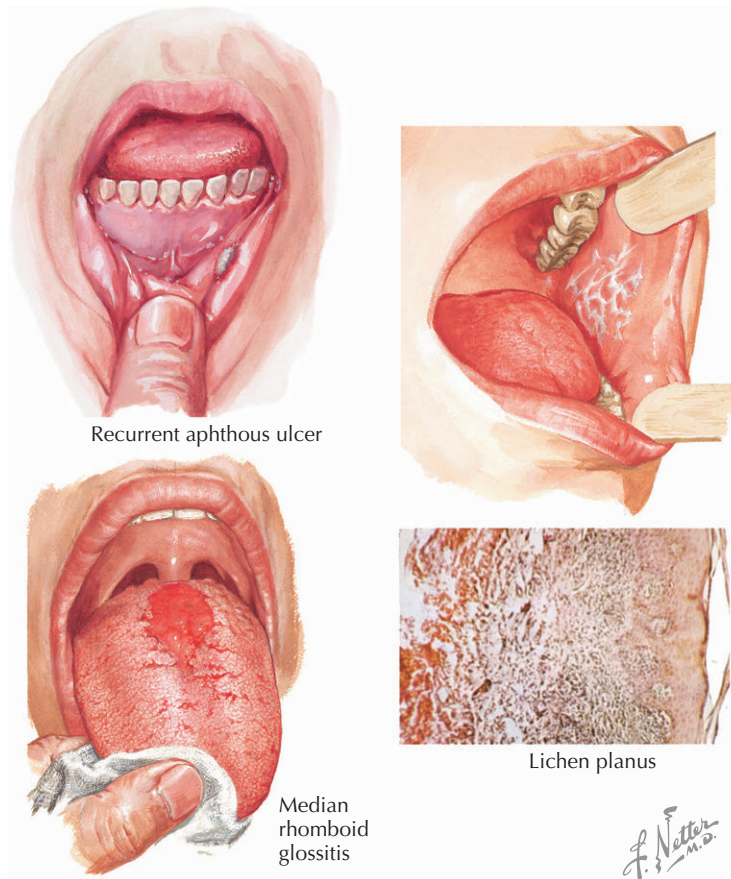

tous border. They are usually located on the buccal mucosa. The duration of the ulcer is 1 to 2 weeks and is followed by spontaneous healing without scarring.

Herpetiform RAUs make up 7% to 10% of all RAU lesions. These ulcers measure less than 5 mm and occur in groups of 10 to 100. They can also coalesce into larger ulcers and are found throughout the oral cavity. The ulcers are usually located on the dorsal tongue and palate and heal spontaneously over 1 to 4 weeks.

Differential diagnosis includes infectious (herpes viruses, HIV), rheumatic disease (Behçet's syndrome, Reiter's syndrome), cutaneous disease (erythema multiforme), gastrointestinal disease (gluten-sensitive enteropathy), and drugs (nonsteroidal anti-inflammatory drugs, β blockers, nicorandil, alendronate). Diagnosis is based primarily on a thorough history and physical exam. Patients with lesions that do not resolve after 3 weeks of therapy should be referred to a specialist for biopsy and further management.

Optimum Treatment

There are many available treatments, and their use should be guided by severity of disease, frequency of ulceration, and potential adverse effects of the medication used to treat the ulcers. New U.S. Food and Drug Administration–approved therapies include 0.1% triamcinolone dental paste, which works to decrease inflammation, and 5% amlexanox paste, which also mediates the inflamma-

Figure 11-1 Common Oral Lesions.

tory cascade specifically acting against interleukin-3. These are applied to the ulcer two to four times daily until healing occurs. Topical corticosteroids are also used in treatment. When applied directly to the dried ulcer or area of prodromal pain and paresthesia, they reduce the duration of the lesion, but they do not affect the frequency of recurrence. Intralesional steroid injections and systemic corticosteroids are reserved for more persistent cases of major RAUs. Thalidomide has been shown to decrease lesion duration and disease-free time in refractory RAUs. However, this treatment has severe side effects—teratogenicity and peripheral neuropathy—which have limited its use.

Infectious Lesions

Viral Stomatitis

Herpes Simplex

Herpes simplex is the most common organism causing viral stomatitis. Initial exposure to herpes simplex virus (HSV) usually occurs during childhood. After resolution of the initial infection, the virus remains latent in the trigeminal ganglion. Primary infection is often asymptomatic. When

symptoms occur, they typically include the sudden onset of 1- to 2-mm vesicles bordered by an inflammatory, erythematous base associated with fever. These lesions rupture to form ulcers. Primary oral HSV lesions tend to involve the buccal mucosa. Recurrent disease is usually confined to keratinized areas, like the lips or perioral areas. The ulcers undergo spontaneous healing in 10 to 14 days. Recurrent oral herpes is not associated with fever and may be incited by exposure to sunlight, trauma, and emotional stress. Most patients develop pain, burning, and tingling about 24 hours before the appearance of recurrent lesions. The differential diagnosis of these lesions is similar to that of aphthous ulcers. The diagnosis is generally clinical but may be confirmed by identifying multinucleated giant cells on a Tzanck smear. Viral culture from lesions is the gold standard for diagnosis.

OPTIMUM TREATMENT. Most immunocompetent individuals with recurrent herpes labialis do not require treatment other than the occasional use of local analgesics. Steroid treatment is contraindicated. Systemic acyclovir may shorten episodes and increase disease-free intervals but works when the virus is most active, which is usually

before the characteristic lesions appear. Other antiviral agents like valacyclovir are similarly effective.

Primary Varicella-Zoster

Primary varicella-zoster virus (VZV) infection occurs during childhood when the human herpesvirus 3 causes chickenpox. Infection with VZV can appear as grouped vesicles or erosions on the hard palate, buccal mucosa, tongue, and gingiva. The virus then remains dormant in sensory ganglia and is sometimes reactivated, causing shingles. Shingles presents as an eruption of multiple 1- to 2-mm painful vesicles that soon burst resulting in ulcerative lesions. These lesions present in a classic unilateral dermatomal pattern. In the head and neck, there are varied presentations of zoster ranging from facial nerve paralysis in Ramsay Hunt syndrome to uveitis, keratoconjunctivitis, and optic neuritis in zoster ophthalmicus. Eruptions generally indicate an immunosuppressed state, which may require further investigation.

OPTIMUM TREATMENT OF PRIMARY VZV. Varicella treatment is generally supportive in immunocompetent hosts, and acyclovir is the drug of choice for varicella infection in adults and immunosuppressed patients. Valacyclovir and famciclovir are also effective. Corticosteroids are contraindicated in initial VZV infection. Vaccination is recommended in all children between 12 months and 13 years of age. Vaccination is also recommended in adults with ongoing risk for exposure (e.g., day care employees), those who are household contacts of immunosuppressed hosts, and women of childbearing age. Vaccination is not recommended for immunocompromised hosts because the vaccine is made up of live attenuated VZV.

OPTIMUM TREATMENT OF RECURRENT VZV. Treatment of recurrent herpes zoster includes acyclovir, valacyclovir, or famciclovir, as well as corticosteroids. Antiviral therapy should be initiated within 72 hours of clinical presentation in patients older than 50 years to maximize the potential benefits of treatment.

Coxsackie A

Herpangina is associated with Coxsackie A virus types A1 to A6, A8, A10, and A22. It affects children aged 3 to 10 years and presents as small aphthous lesions on the soft palate and tonsillar pillars associated with fever and odynophagia. This disease is self-limited and requires only supportive therapy.

Hand, foot, and mouth disease (HFMD) is associated with Coxsackie A virus type A16. HFMD occurs most frequently in the spring and early summer in children younger than 5 years. It presents with small aphthous lesions seen on the buccal mucosa and tongue, as well as oval pale papules with a rim of erythema on the palms and soles. These lesions tend to spare the lips and gingiva, in contrast to HSV. This disease is self-limited and requires only supportive therapy.

Fungal Stomatitis

Oral Candidiasis

Candida species, the most common cause of oral fungal infections, are present in the oral cavity of 30% to 60% of healthy adults; therefore, their isolation does not necessarily indicate a pathologic process. However, the numbers of true candidal infections are rising, secondary to iatrogenic infection. Factors that predispose patients to candidal infection are age extremes, an immunocompromised state, malnourishment, concurrent infections, broad-spectrum antibiotic treatment, radiation-induced mucositis, and xerostomia. *Oral candidiasis* classically presents as pseudomembranous candidiasis, or thrush. These white, plaque-like lesions can be present on the buccal mucosa, palate, tongue, or oropharynx and scrape away easily, leaving a raw, hemorrhagic undersurface. *Hyperplastic candidiasis* presents as a white, plaque-like lesion that cannot easily be removed. *Chronic atrophic candidiasis* is the most common form of oral candidiasis and is found in up to 60% of denture-wearing patients. It presents as an erythematous, cobblestone patch on the mucosa under dentures. *Median rhomboid glossitis* (see Fig. 11-1) is confined to the dorsal tongue. It presents as an asymptomatic, erythematous, well-demarcated area of papillary atrophy found just anterior to the circumvallate papillae. *Angular cheilitis* presents as painful, bleeding, ulcerative patches at the oral commissures. Diagnosis of oral candidiasis is based on clinical presentation. The differential diagnosis includes a wide range of oral lesions from systemic infections to squamous cell carcinoma. In patients with recurrent or extensive disease, immunologic status should be evaluated with HIV testing. The diagnosis of oral candidiasis is confirmed by obtaining a potassium hydroxide (KOH) prep. Microscopic evaluation of scrapings from the white patches or erosive areas of the mucosa should reveal budding yeasts with or without pseudohyphae. Failure of these lesions to respond to adequate therapy after 1 to 2 weeks should result in referral to a specialist for possible biopsy.

OPTIMUM TREATMENT. Therapy consists of topical and systemic antifungals. Oral rinses with nystatin or clotrimazole solution 4 to 5 times per day are used for treatment of oral mucosal lesions. Denture-related lesions require treatment of the dentures with an antifungal soak or ointment as well as direct application of antifungal ointment or cream to the lesion. Angular cheilitis responds best to direct topical application of antifungal ointment to the lesion. Systemic fluconazole, ketoconazole, or itraconazole is used to treat severe or refractory lesions.

Noninfectious Oral Lesions

Lichen Planus

Oral lichen planus (OLP) (see Fig. 11-1) is a common disorder affecting about 2% of adults. Its etiology is unknown,

but it has been determined to result from a T-cell-mediated immune response directed against the basal epithelial cell. Histologic characteristics of OLP include epithelial basal cell destruction and infiltration of the adjacent tissue with lymphocytes. There are many forms of these lesions that are characterized by their appearance. The *reticular* form is the most common type of OLP and is present in most patients studied with this disease. It is seen most often as lace-like striae of Wickham on the buccal mucosa. *Erosive* OLP is the next most common form and presents as painful, ulcerative lesions affecting the gingiva, buccal mucosa, and lateral tongue. Poorly fitting dentures can be an inciting factor in OLP. Candidal superinfection can present in one third of OLP lesions, necessitating antifungal treatment. Evaluation of the patient's medications is also essential because some drugs can result in lichenoid eruptions. OLP may require biopsy for definitive diagnosis. It is important to monitor these lesions over time because there is a small risk for malignant transformation. In most reported cases, the erosive subtype most frequently underwent malignant transformation.

Symptomatic OLP is treated first with topical steroids. Refractory cases usually respond to systemic steroids. Treatment with immunomodulating medications such as cyclosporine and azathioprine may be required in severe cases.

Leukoplakia

Oral leukoplakia is a precancerous lesion that presents as white patches or plaques on the oral mucosa. These lesions are composed of hyperplastic squamous epithelium. Leukoplakia itself is a benign reactive process. However, some lesions will progress to carcinoma within 10 years. Different studies have shown varying progress to carcinoma. Lesions located in trauma-prone regions of the oral cavity, such as the cheek and dorsum of the tongue, are at less risk for malignant transformation. Any suspicious lesions should undergo biopsy to evaluate for dysplasia. If malignancy is identified, the patient should be referred to a specialist for further management, including possible resection or chemotherapy. Cyclooxygenase-2 (COX-2) inhibitors are being investigated as a treatment of leukoplakia.

Hairy Leukoplakia

Hairy leukoplakia is a benign mucosal lesion of the lateral tongue found in up to one third of HIV-positive patients. These painless lesions are caused by epithelial infection with the Epstein-Barr virus. They present as irregular, white areas of mucosal thickening on the lateral tongue. Diagnosis is based on clinical presentation, and occasionally a biopsy is needed for confirmation. No specific treat-

ment is indicated; however, patients presenting with hairy leukoplakia should undergo testing for HIV.

Oral Papilloma and Verruca Vulgaris

Oral papilloma and verruca vulgaris lesions are easily recognized in the oral cavity. Both lesions are caused by infection with strains of human papillomavirus. Papillomas present as pedunculated, cauliflower-like masses of squamous epithelium similar to papillomas seen at other sites (Fig. 11-2). Verrucae vulgaris present as hyperkeratotic, hard, round lesions similar to those seen on the skin of the hands and feet. Differential diagnosis includes condyloma acuminatum and verrucous carcinoma. Excisional biopsy is the treatment of choice.

Torus Palatinus and Torus Mandibularis

Tori are benign exostoses of the hard palate and mandible that present as smooth, hard lesions of the midline hard palate or the lingual surface of the mandible. Patients are often unaware of their presence. Diagnosis is based on physical exam. No treatment is necessary, but tori occasionally must be removed to accommodate dentures (see Fig. 11-2).

Fordyce Granules

Fordyce granules are ectopic sebaceous glands that appear as clusters of yellowish spots on the buccal mucosa, typically found just inside the oral commissure. Diagnosis is based on physical exam, and no treatment is necessary.

Amalgam Tattoo

Silver alloys used during dental procedures may become implanted in the surrounding gingiva, appearing as blue-black macules. The most common site for amalgam tattoos is the mandibular arch. Differential diagnosis for this lesion includes nevi and melanoma. Diagnosis is based on physical exam. Confirmation can be obtained with the appearance of fine, radiopaque densities on dental films. Excisional biopsy should be performed for suspicious pigmented lesions.

Mucocele

Mucocele form when saliva extrudes from a minor salivary gland into surrounding tissue. Trauma is thought to cause most mucoceles. They may present anywhere in the oral cavity but are seen most commonly on the lower lip. They present as a blue, round lesion with overlying smooth mucosa. They may burst and recur or become infected and purulent. Excision is the treatment of choice for persistent mucoceles. Marsupialization typically results in recurrence (see Fig. 11-2).

Figure 11-2 Common Oral Lesions.**Figure 11-3 Common Oral Lesions.****Fibromas**

Fibromas are soft, tan or pink lesions found at sites of repetitive trauma, typically on the buccal mucosa or lateral tongue. Recurrent trauma results in chronic inflammation and fibrous hyperplasia. Excisional biopsy is diagnostic and therapeutic (see Fig. 11-3).

Hairy Tongue

Hairy tongue is a benign condition caused by accumulation of keratin and commensal bacteria on filiform papillae of

the tongue. Hairy tongue has a characteristic appearance and is treated by reassuring the patient of the benign nature of the condition. Some improvement of appearance can be achieved by daily scraping of excess keratin and debris off the area (Fig. 11-3).

Geographic Tongue

Geographic tongue, or benign migratory glossitis, is a benign condition characterized by areas of smooth atrophy on the tongue, with loss of papillae. This leads to ulcer-like

lesions that appear as erythematous patches on the dorsal tongue with circumferential white polycyclic borders. The diagnosis is made using clinical presentation, and biopsy is not necessary. The painless lesions spontaneously regress, only to appear on other parts of the tongue. Etiology is unknown, and no treatment is necessary (see Fig. 11-3).

Avoiding Treatment Errors

A careful physical examination of the oral cavity will remain the key element in the evaluation and treatment of patients with oral lesions. These lesions need close monitoring to ensure that the initial diagnosis is correct. In some of these lesions, there is the potential for malignant transformation, mandating the need for routine follow-up after initial diagnosis. Biopsy is also a helpful tool for diagnosis and monitoring of premalignant lesions.

Future Directions

Research will continue in an attempt to define the specific etiology of aphthous ulcers, oral lichen planus, and other less well-understood lesions. The ultimate goal is to develop more specific therapies.

Acute Otitis Externa

Introduction

Acute otitis externa (AOE), commonly known as swimmer's ear, is defined as an acute inflammation of the external auditory canal. Nearly 95% of AOE is bacterial in origin but AOE can also be caused by fungal infections, allergic disorders, and dermatologic conditions.

Etiology and Pathogenesis

The pathogenesis of AOE is best understood with an appreciation of the anatomy of the external auditory canal (Fig. 12-1). The canal begins proximally at the tympanic membrane (TM) and extends distally to the external acoustic meatus. The proximal third of the canal is thinly lined with epithelium and dermis, which is immediately adjacent to the underlying periosteum; inflammation here is quite painful because of its proximity to the surrounding bone. The distal two thirds of the canal is surrounded by the cartilage supporting the external ear structures and is lined with thicker skin that contains cerumen glands, sebaceous glands, and hair follicles that collectively serve as the canal's defense system. Cerumen is hydrophobic and acidic, maintaining a dry environment that is hostile to skin flora and other bacterial pathogens. The epithelium lining the canal is continually sloughing and migrates distally to keep the ear cleansed of debris and excess cerumen. Anything that disrupts this cerumen-epithelial barrier, such as prolonged moisture, aggressive cerumen removal, indwelling hearing aids, and even eczema or psoriasis, can start the inflammatory process that allows organisms to invade. Exposure to water for long periods of time, as with swimmer's ear, for example, causes maceration of the epithelium and disrupts the protective cerumen barrier. This disruption alters the environment from a dry acidic one to a moist, nonacidic environment that allows bacteria to grow and infect. Once infection sets in, the canal becomes inflamed and fills with purulent fluid and debris that further obstruct the canal to create and maintain a warm, moist, alkaline environment for pathogens to grow. Unless fluid and debris can drain from the canal, and unless inflammation and edema can be reduced, the infection will spread

to adjacent ear structures and cranial structures and can evolve into a life-threatening infectious process.

More than 90% of cases of AOE are caused by *Staphylococcus aureus* and *Pseudomonas aeruginosa*, either as individual pathogens or together in a polymicrobial process. These pathogens thrive in a moist, alkaline environment, which is why treatment is based on removal of debris and fluid from the canal, reduction of edema, and restoration of the canal's dry, acidic environment. Much less frequently, fungi can cause external otitis, as can eczema and other skin conditions.

Clinical Presentation

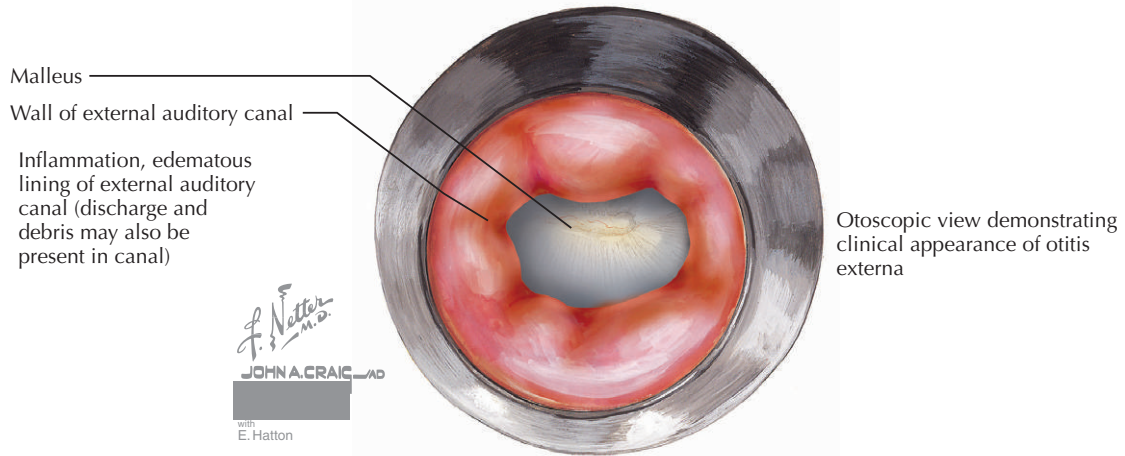

Patients with AOE present with the rapid onset of ear pain, sometimes with an antecedent history of itching or fullness. The key physical exam finding is tenderness with compression of the tragus or pain when pulling outward and upward on the auricle (pinna). In the earliest stages, otoscopy may show only erythema of the canal wall, but as the canal becomes more inflamed, the walls appear edematous and purulent with visible debris and discharge that is usually white, gray, or greenish in color. The TM should be visualized if possible by gentle removal of debris with a soft curette or by gentle irrigation if needed. The TM may appear clear but can also appear opaque, irregular, white, or gray; it should be intact and mobile on insufflation, indicating that no middle ear effusion is present and that it is not perforated.

If the patient is febrile, or if the soft tissue surrounding the auricle is red and swollen, then a periauricular cellulitis exists that will require systemic antibiotics. Periauricular cellulitis in a patient who is immunosuppressed, is febrile, or otherwise appears toxic might indicate malignant (nec-

Figure 12-1 Acute Otitis Externa.

In otitis externa, inflammation, edema, and discharge are limited to external auditory canal and its walls

rotizing) otitis externa and requires intravenous antibiotics and urgent evaluation by an otolaryngologist.

Differential Diagnosis

It is important to distinguish AOE from other causes of ear pain or drainage because the treatments are quite different and delay of diagnosis can lead to serious complications (Box 12-1). One of the more common causes of local ear pain is furunculosis, in which a tender red nodule, papule, or pustule is visible on the inner auricle or within the distal auditory canal. Pain from acute sinusitis and dental infections can be referred to the ear, as can the pain from the temporomandibular joint. Pain from cervical or cranial neuropathies is neuropathic in quality and may occur in short, stabbing volleys (trigeminal neuralgia) that

are distinct from the steady, gnawing pain of AOE. Acute otitis media with perforation causes ear drainage, but pain is a much less prominent feature once the TM ruptures and the ear starts to drain. A cholesteatoma can be associated with chronic drainage and appears on otoscopy as a cheesy mass adjacent to the wall of the canal, often near the TM. *Candida* and *Aspergillus* species cause otomycosis; this fungal infection of the external canal usually occurs after prior treatment for AOE but is also seen in diabetic and the elderly patients. Otomycosis usually presents with chronic itching and drainage rather than pain.

Noninfectious etiologies of external ear problems include dermatologic conditions such as eczema, psoriasis, and contact dermatitis. Dermatologic processes more commonly present with itching and flaking rather than pain. Carcinomas are rare causes of persistent ear drainage

Box 12-1 Differential Diagnosis of Ear Pain or Drainage**Infectious**

but should be considered if drainage is not improving with appropriate AOE treatment.

Diagnostic Approach

The diagnosis of AOE is clinical. Because most cases of AOE are caused by *P. aeruginosa* and *S. aureus*, there is no reason to culture the fluid except in unusual circumstances such as treatment failures (in which case fungal infection is possible), immunocompromised hosts, chronically draining ears, and severe cases associated with cellulitis or high fever. Blood work or radiologic studies are rarely necessary in AOE. If the patient is febrile and appears ill, however, malignant otitis externa must be considered; in such cases, a sedimentation rate may be markedly elevated, and computed tomography or magnetic resonance imaging may be indicated to make the diagnosis.

Management and Therapy

The fundamentals of treatment of AOE are (1) adequate aural toilet to allow adequate delivery of drug to the site of infection; (2) topical agents effective against the primary pathogens; (3) adequate pain relief; (4) an awareness of factors that may modify management such as a perforated TM, a history of recurrent infections, the presence of tympanostomy tubes, and immunocompromised states such as diabetes; and (5) an awareness of alternative diagnoses and potential complications.

Optimum Treatment

For treatment to work, the drug must be delivered to the site of infection, and topical therapy works best. Debris and discharge may need to be removed from the canal (aural toilet) so that the drug can reach the proximal canal.

Aural toilet is accomplished with gentle use of a soft curette, cotton swab, or a microcurette under direct visualization through the otoscope. Gentle irrigation, preferably with half-strength hydrogen peroxide, can also help remove debris, but it is best to first confirm that the TM is not perforated so as not to flush infected material into the middle ear. If the canal remains obscured by debris or edema such that the TM cannot be visualized, and there is concern as to whether topical agents can reach the proximal canal, a wick or stent should be inserted to allow adequate delivery of drug to the proximal canal.

Topical therapy is strongly recommended over systemic therapy for AOE because it allows for much higher concentrations of drug at the site of infection. Systemic reviews of topical therapy have shown that acidifying agents (e.g., acetic acid and boric acid), antiseptic agents, and antibiotics all have similar efficacy in treating AOE. The addition of topical steroids hastens resolution of pain and discharge, and some studies have shown that topical steroids can also be used alone. The choice of therapy should take into account effectiveness, cost, ease of administration (compliance), and possible side effects.

The first choice of most clinicians is an inexpensive topical antibiotic combined with a steroid such as the combination of neomycin, polymyxin B, and hydrocortisone (available as combination therapy). Topical aminoglycosides such as gentamycin and tobramycin are also effective and inexpensive but do not come combined with a steroid preparation. Acidifying agents such as acetic acid inhibit growth of *P. aeruginosa* and *S. aureus* and have been found to be just as effective as antibiotics. The primary disadvantage of these agents is patient adherence because they must be instilled 4 times a day. Additionally, neomycin-containing products are more apt to cause contact dermatitis and allergic reactions, particularly in patients with underlying eczema. There is also the rare risk for ototoxicity if aminoglycosides reach the middle ear through a perforated TM. For these reasons, topical quinolones have gained favor as drugs of choice for AOE but are significantly more expensive. Ofloxacin otic solution only has to be used once a day but is more commonly linked to subsequent otomycosis. Ciprofloxacin, with or without a steroid combination (ciprofloxacin plus dexamethasone or ciprofloxacin with hydrocortisone) is dosed twice a day. Duration of therapy for antibacterial agents is 7 days. Longer durations of 10 to 14 days may be better for acidifying agents or steroids used alone.

Adequate pain management is strongly recommended in clinical practice guidelines and will not interfere with the clinician's ability to follow the response to therapy. Mild to moderate pain can be treated with acetaminophen or nonsteroidal anti-inflammatory agents, but one should not hesitate to prescribe stronger pain medication, including narcotic agents such as codeine, because the pain of AOE can be severe. Topical analgesics are not very effective and are of too short duration of action to be of much use.

Need for Systemic Antibiotics

Systemic antibiotics may be needed in circumstances such as an immunocompromised host (HIV, diabetes), involvement of infection beyond the external canal, or inability of antibiotic to reach the proximal canal through a wick or stent. In these cases, a quinolone antibiotic with activity against *Pseudomonas* species and *S. aureus*, such as ciprofloxacin, is preferred. β -Lactams that are effective against *Staphylococcus* species (e.g., amoxicillin-clavulanate, dicloxacillin, cephalexin) can be used and are much less expensive but are not effective against *Pseudomonas* species. Cultures are advised to guide therapy when there is a high level of clinical uncertainty. If the patient does not improve within 48 hours, treatment with a quinolone is indicated. Malignant otitis must be treated urgently with intravenous antibiotics and may require surgical débridement.

Treatment of Other Etiologies

Otomycosis (fungal infection of the external auditory canal) should be considered if the patient has drainage and itching after appropriate treatment for AOE, usually after trials of two different topical therapies, or if drainage recurs soon after successful treatment. Otomycosis is not usually painful. Cultures of the fluid can help make the diagnosis. Treatment is based on adequate aural toilet and use of topical antifungals such as clotrimazole solution twice a day (available over the counter, often as a preparation sold for tinea pedis or cruris). Patients with tympanostomy tubes and a draining ear likely have otitis media but are at risk for otitis externa and tube occlusion; treatment is a topical quinolone and steroid, usually ciprofloxacin combined with dexamethasone. Eczema and psoriasis are treated with topical steroid solutions or creams.

Avoiding Treatment Errors

The most common error in treating AOE is inadequate aural toilet so that the topical agent cannot reach the proximal auditory canal. If there is significant edema or debris that cannot be removed, the patient should be referred to an otolaryngologist, who can remove debris and place a wick or stent if necessary. A patient who appears toxic with a high fever may have malignant otitis and needs immediate hospitalization for intravenous antibiotic administration. One should not hesitate to consult an otolaryngologist in cases of severe AOE or when the patient is not responding as expected to initial therapy.

Prevention

Patients need to be educated that ear wax protects the ear canal and that cleaning the ears either with Q-tips or solutions is unnecessary and can lead to infections. In patients with recurrent cerumen impactions, 2 drops of mineral oil once a week will keep the cerumen soft so that it will natu-

rally discharge from the ears. Swimmers who have a tendency to get recurrent infections can dry the area after swimming by tilting the ear down and using a towel roll to wick water from the external canal. Cotton swabs should not be inserted in the canal. After swimming, one can also use ear drops with acetic acid mixed with isopropyl alcohol (available over the counter or mixed at home using half white vinegar and half rubbing alcohol), which helps dry the canal and keep it acidic. Ear plugs are also effective in preventing recurrent infections.

Future Directions

The multiple treatments available for treating AOE all show similar efficacy in randomized trials, but this similarity may be a result of inadequately designed or powered studies; some studies have shown non-statistically significant trends in favor of certain antibiotics, especially quinolones combined with steroids. Larger, properly conducted randomized trials are still needed to determine the optimal therapy for AOE. Additionally, our aging population and the increasing prevalence of diabetes will make atypical presentations more common, particularly in the incidence of otomycosis and more severe presentations of bacterial otitis externa.

Acute Otitis Media

Introduction

Acute otitis media (AOM) is an acute inflammatory process of the middle ear. It is the single most common diagnosis of pediatric sick visits in the United States and the most common diagnosis for which antibiotics are prescribed to children. More than half of all children have AOM by their first birthday, and 80% have it at least once by age 3 years. Although most cases of AOM occur in childhood, more than 16% of cases occur after age 15 years.

Etiology and Pathogenesis

AOM is defined by the accumulation of fluid in the middle ear accompanied by signs of acute inflammation. The process by which this occurs requires an appreciation of the anatomy of the middle ear (Fig. 13-1). A properly functioning eustachian tube (pharyngotympanic tube) ventilates the middle ear, keeping the middle ear chamber in equilibrium with atmospheric pressure. If the tube becomes obstructed, most often because of swelling, secretions, and congestion from a viral upper respiratory infection (URI), the middle ear pressure becomes relatively negative and draws fluid into the chamber, creating an effusion. Bacteria then grow in this middle ear fluid and start an inflammatory, purulent process (Fig. 13-2). Dysfunction of the eustachian tube, and thus middle ear effusion and infection, is much more common in children because the tube is oriented more horizontally than that of adults, and gravity has less effect on its drainage. It is also narrower than that of adults, and the surrounding tissue is less supportive. On average, it takes about 4 days from the onset of viral symptoms for an inflammatory middle ear infection to develop.

Historically, the most common bacterial organisms isolated from middle ear fluid in AOM are *Streptococcus pneumoniae* (40%), nontypable *Haemophilus influenzae* (20%), and *Moraxella* species (10%). Group A streptococcus is much less common and usually occurs in older children. Since the introduction of the heptavalent pneumococcal conjugate vaccine (PCV7), however, studies of middle ear fluid show a decrease in the percentage of *S. pneumoniae*

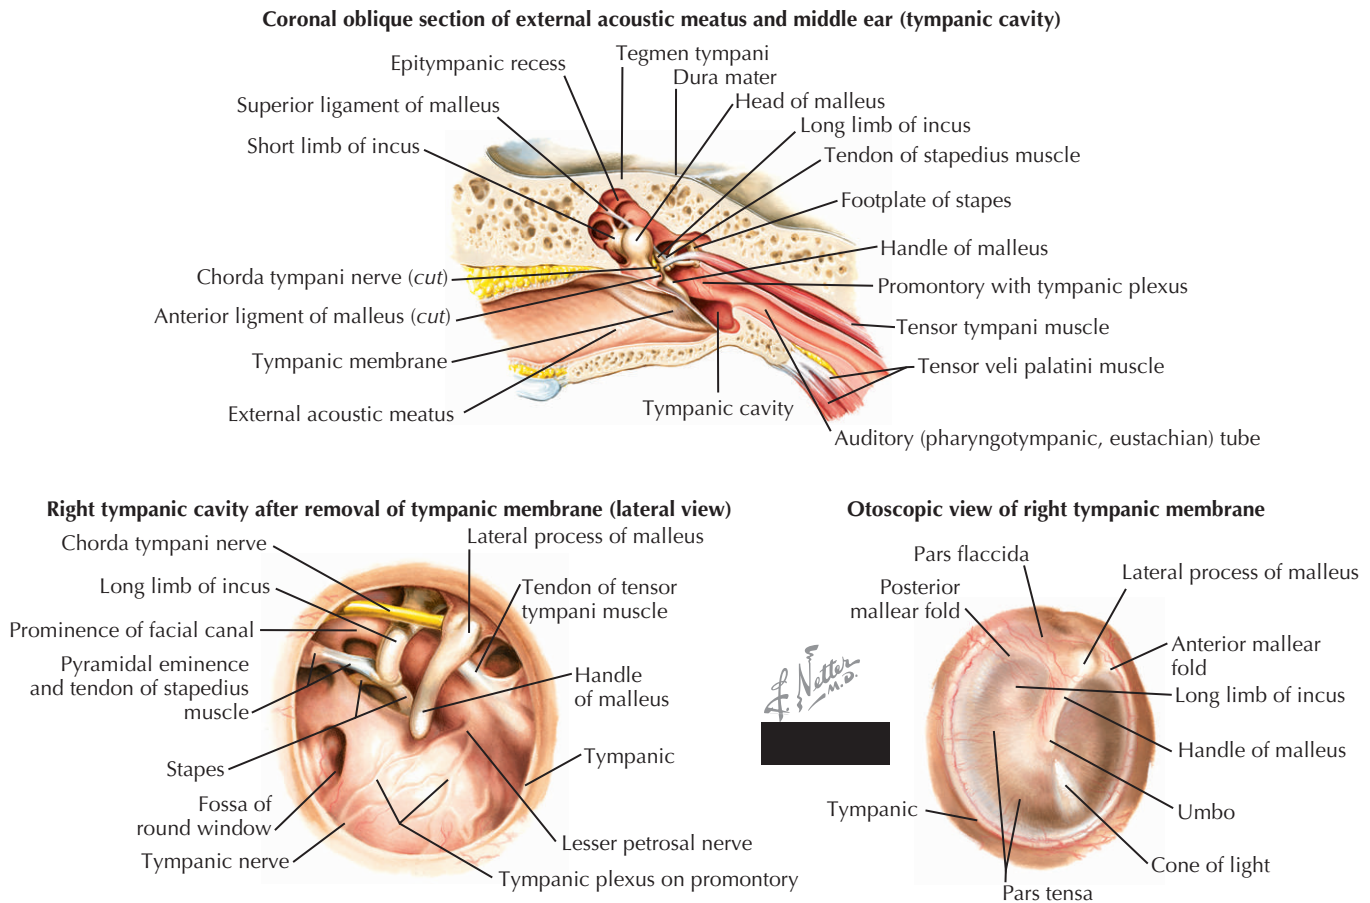

isolates to 30%, whereas the incidence of *H. influenzae* has increased to 50%. Although the percentage of penicillin-resistant pneumococci isolated from infected effusions has diminished, the incidence of AOM has not changed.

Viruses, usually rhinoviruses, can also be isolated as the sole microorganisms in about 15% of cases of AOM and may play a role in treatment failures. Respiratory syncytial virus and adenovirus cause distinct clinical syndromes, which help distinguish these infections from bacterial AOM.

Clinical Presentation

AOM is almost always preceded by several days of viral URI symptoms followed by the acute onset of ear pain or fussiness. On examination, the tympanic membrane (TM) appears red or whitish and often is bulging. The normal light reflex and landmarks are absent, and the TM is immobile or minimally mobile on pneumatic otoscopy. An air-fluid level may be noted behind the eardrum. Purulent or bloody discharge in the canal usually indicates that the TM has perforated and may correlate with a history of sudden pain relief at the time of perforation. Otorrhea may also be noted in the patient with AOM with functioning tympanostomy tubes.

The American Academy of Pediatrics and American Academy of Family Physicians have published diagnostic criteria for AOM, shown in Box 13-1. AOM is definitively diagnosed if all three diagnostic criteria are fulfilled.

Figure 13-1 External Ear and Tympanic Cavity.**Box 13-1** Diagnostic Criteria for Acute Otitis Media

1. Acute, often abrupt onset of signs of middle ear inflammation such as pain, or other signs of discomfort, fever, or hearing loss, *and*
2. The presence of a middle ear effusion based on visualization of the TM that is either bulging, has limited mobility on insufflation, is noted to contain an air-fluid level behind the TM, or reveals purulent fluid in the ear canal, *and*
3. Signs and symptoms of middle ear inflammation such as diffuse redness of the TM or significant otalgia bad enough to interfere with normal activities or sleep

Adapted from the American Academy of Pediatrics and American Academy of Family Physicians Subcommittee on Management Acute Otitis Media: Diagnosis and management of acute otitis media. *Pediatrics* 113(5):1451-1465, 2004.

Differential Diagnosis

Serous otitis, or otitis media with effusion, is a noninflammatory condition that is distinct from AOM. The TM will be immobile but will otherwise appear clear, as will the effusion. Serous otitis is common after AOM is successfully

treated and can persist for several weeks after treatment. In the setting of a URI, the effusion will usually resolve once the viral symptoms resolve. Neither situation requires the use of antibiotics. The evaluation and management of chronic otitis media with effusion is beyond the scope of this chapter but can be found in the clinical practice guideline published by the American Academy of Pediatrics (see “Evidence”).

A list of other differential diagnoses appears in Box 13-2. Some of the more common infectious causes of ear pain include acute otitis externa and acute sinusitis. Some of the most common noninfectious causes include eustachian tube dysfunction after flying (barotitis media), cerumen impaction, foreign bodies, temporomandibular joint syndrome, and referred pain from neuropathies such as occipital and trigeminal neuralgia. Bullous myringitis is an unusual cause of AOM resulting in *Mycoplasma pneumoniae* and appears as multiple bullae on the TM, often with hemorrhage; this is one of the few situations in which a macrolide antibiotic is the preferred treatment. One cause of acute hearing loss that deserves mention is “sudden sensorineural hearing loss”; recent evidence implicates varicella virus as the cause and requires rapid treatment with oral steroids and antivirals.

Figure 13-2 Acute Otitis Media.

Complications of AOM can be quite serious and include mastoiditis, meningitis, sinus vein thrombosis, cholesteatoma, chronic serous otitis media, hearing loss and speech delay, and chronic suppurative otitis media with perforation.

Diagnostic Approach

AOM is a clinical diagnosis, and visualization of the TM is required to make the diagnosis. If the view is obstructed by cerumen or debris, a reasonable attempt should be made to remove the obstruction using a soft curette or

gentle irrigation. Irrigation should be avoided if there is suspicion of a perforation (such as purulent or bloody fluid in the canal) because purulent debris could be flushed into the middle ear cavity. In practice, unfortunately, the TM cannot always be well visualized. In these cases tympanography or acoustic reflectometry can objectively assess the mobility of the TM and the presence or absence of an effusion. Cultures are rarely necessary except perhaps in the case of a chronically draining ear. Blood tests and radiologic tests are not necessary unless there is concern for mastoiditis or other extension of infection into surrounding structures.

Management and Therapy

The goal of treatment of AOM is to reduce pain and relieve symptoms, prevent complications, and minimize adverse effects of treatment. Prospective studies have shown that most children older than 2 years with AOM improve regardless of whether they receive antibiotics. As a result of this observation, there has been a trend toward observation rather than antibiotic treatment, particularly in many European countries, where most cases of AOM are not treated with antibiotics. Proponents of antibiotics recommend their use not so much to treat AOM but to prevent its complications, citing that the incidence of mastoiditis and secondary meningitis has diminished significantly in the postantibiotic era. Additionally, there is good evidence that antibiotics are superior to placebo in children younger than 2 years.

Box 13-2 Differential Diagnosis of Acute Otitis Media

Acute Ear Pain

With Upper Respiratory Symptoms

Sinusitis (allergic or viral)
Pharyngitis
Allergic rhinitis
Parotitis
Mastoiditis
Otitis externa
Bullous myringitis

Without Upper Respiratory Symptoms

Foreign body or trauma
Temporomandibular joint dysfunction
Dental caries
Referred neuropathic pain (trigeminal or occipital neuralgia)
Herpes zoster (note that pain may appear before the rash)
Furunculosis
Barotitis media

Optimum Treatment

Treatment options are age dependent. All children younger than 6 months with suspected AOM should be treated with antibiotics, with special consideration given to children younger than 2 months, who are more likely to have a systemic neonatal infection seeding the ear. Children from 6 months to 2 years of age with a clear diagnosis of AOM (one that fulfills all three criteria in Box 13-1) should be treated with antibiotics to prevent potential complications. In children 6 months to 2 years in which the diagnosis is uncertain and the child does not appear ill, one can observe closely for 48 hours and treat if they do not improve spontaneously. Children older than 2 years and adults who do not appear ill or have a high fever can be observed and provided pain relief, but follow-up must be available within 48 hours in case they worsen or do not improve. These recommendations are contained in the American Academy of Pediatrics and American Academy of Family Physicians clinical practice guidelines and are summarized in Table 13-1.

Choice of Antibiotic

Amoxicillin remains the drug of choice for AOM in all age groups beyond 2 months of age at a high dose of 80 to 90 mg/kg/day divided into two doses. This dose is higher than the traditional dose of 40 mg/kg/day and is active against most resistant strains of *S. pneumoniae*. In adults, amoxicillin is also recommended as the initial drug of choice, although high doses are not usually necessary because penicillin-resistant pneumococci are less prevalent in adults.

Amoxicillin should not be used as first-line therapy in cases in which amoxicillin resistance is likely. One such clinical scenario is AOM associated with purulent conjunctivitis, which is usually caused by nontypable *H. influenzae*. Additionally, if the patient was treated for AOM within the past 30 days with amoxicillin, or did not respond initially to amoxicillin, another antibiotic with broader coverage

Table 13-1 Criteria for Initial Antibacterial Treatment or Observation in Children with Acute Otitis Media

Age	Certain Diagnosis	Uncertain Diagnosis
<6 mo	Antibacterial therapy	Antibacterial therapy
6 mo to 2 y	Antibacterial therapy	Antibacterial therapy if severe; observation optional if not*
>2 y	Antibacterial therapy if severe; observation optional if not*	Observation optional*

* Observation for 48 to 72 hours is an appropriate option only when follow-up can be ensured, so that antibiotics can be started if symptoms persist or worsen. Nonsevere illness is defined as mild otalgia and temperature <39° C. A certain diagnosis depends on a history of acute onset, middle ear effusion, and signs of middle ear inflammation.

Modified from American Academy of Pediatrics and American Academy of Family Physicians Subcommittee on Management Acute Otitis Media: *Diagnosis and management of acute otitis media*. *Pediatrics* 113(5):1451-1465, 2004. Modified from the New York State Department of Health and the New York Region Otitis Project Committee.

should be used. The next best choices in children are amoxicillin-clavulanate, a second- or third-generation cephalosporin, or clindamycin (unless *H. influenzae* is suspected). In adults, in whom the theoretical effects of quinolones on bone and cartilage growth are not a concern, quinolones with good pneumococcal coverage such as levofloxacin or moxifloxacin (not ciprofloxacin) may also be used. Macrolides and sulfa drugs were commonly used in the past but are no longer advised for treatment of AOM because of rising bacterial resistance. One exception is the rare case of bullous myringitis caused by *Mycoplasma* species that should be treated with a macrolide. *H. influenzae* and *Moraxella* species will also respond to broad-spectrum macrolides such as azithromycin.

In children who appear toxic with a high fever (>39° C) or who have been vomiting or might otherwise not tolerate medication by mouth, intramuscular ceftriaxone, 50 mg/kg, is appropriate in a one-time dose and may be repeated in 24 to 48 hours if there is not significant improvement. In cases of persistent purulent otitis media that have not responded to two or three courses of oral antibiotics, ceftriaxone can be administered daily for 3 consecutive days. If this is ineffective, tympanostomy tubes may be indicated.

The duration of oral antibiotic therapy for AOM has traditionally been 10 days; however, recent studies have concluded that a 5-day course of treatment is as effective in older children (>2 years) and in adults without a history of recurrent AOM.

In all cases, pain control should be a priority, although the optimal regimen for such is not established. Analgesics such as acetaminophen or ibuprofen are preferred. Narcotics such as codeine may be indicated in severe cases. Topical agents such as benzocaine can provide brief relief and can be helpful in addition to oral pain relievers. Decongestants, antihistamines, and steroids have not shown much benefit in treatment of AOM and come at the cost of increased side effects.

Tube Otorrhea

Patients with a draining ear who have tympanostomy tubes in place likely have AOM with appropriate drainage through the tubes into the external canal. Topical therapy with ciprofloxacin drops with or without a steroid combination is indicated to prevent the external canal from getting infected and to maintain tube patency. Oral antibiotics are not necessary because the tubes are doing their job in allowing the middle ear chamber to drain; only if the tubes are blocked or the patient appears ill or has a high fever are systemic antibiotics indicated.

Avoiding Treatment Errors

The most common treatment error in AOM is overtreatment. Because AOM is a diagnosis based on examination

of the patient, treating it over the phone or without examining the patient is inappropriate. A red TM that is mobile indicates there is no effusion and is not AOM. Likewise, a clear TM and clear effusion is not AOM and will generally not respond to antibiotics.

Many patients with AOM can be observed without antibiotics; however, a patient with AOM who appears ill, has a purulent bulging TM, or is younger than 2 years should be treated with antibiotics because this subset of patients is most at risk for complications of AOM. Mastoiditis should always be suspected in any patient with a high fever or who otherwise appears toxic. Mastoiditis is caused by extension of the purulent middle ear process into the mastoid air cells. It will present with redness, tenderness, and swelling behind the auricle severe enough that the auricle may protrude outward away from the skull. It requires prompt treatment with intravenous antibiotics and sometimes surgical débridement.

Prevention

Breast-feeding in the first 6 months of life has been shown to decrease the risk for AOM. Other studies have shown that the influenza vaccine can reduce the risk for AOM during cold and flu season in children older than 2 years. Day care exposure remains the single greatest risk factor for respiratory infections and AOM.

Future Directions

Better randomized clinical trials are needed to identify which antibiotics are most effective and which patients benefit most from antibiotic treatment versus observation. Particularly with the widespread use of the PCV7 vaccine, nontypeable *H. influenzae* is emerging as the predominant organism causing AOM. Thus, amoxicillin may soon be obsolete as the first choice of treatment, losing favor to drugs with better *H. influenzae* coverage such as amoxicillin-clavulanate or second- and third-generation cephalosporins. For prevention, the PCV7 vaccine has been somewhat unimpressive, but ongoing trials of a 9- and an 11-valent conjugate vaccine may show more benefit in preventing AOM and its complications. Additionally, affordable and easy-to-use tools to help clinicians objectively determine the presence of an effusion are needed to make better diagnoses and better determination on whom to treat.

This is an excellent source of evidence for diagnosis and management of AOM. The site provides several summaries of evidence-based reviews ranging from use of decongestants to studies of observation versus antibiotics for AOM.

Hoarseness

Introduction

Hoarseness describes a rough or harsh voice caused by improper vibration of the epithelial covering of the vocal cord. Anything that causes stiffening or improper coaptation of the vocal cords will result in an abnormal voice. If the vocal cords do not coapt properly because of paralysis or bowing, there will often be a breathy and weak nature to the hoarseness, whereas inflammation in and around the vocal cords will result in a coarse sounding voice. Any hoarseness persisting for 2 weeks or more warrants direct examination of the vocal cords by an otolaryngologist (Fig. 14-1).

Etiology, Pathogenesis, and Clinical Presentation

Because hoarseness is the final common pathway for anything that impairs vocal cord vibration, a myriad of entities may cause it (Box 14-1 and Figs. 14-2 to 14-4). Gastroesophageal reflux disease (GERD), laryngopharyngeal reflux (LPR), postnasal drip, and chronic cough are common causes of voice changes. Carcinoma of the glottic larynx is of greatest concern in the adult patient. In otherwise healthy children, nodules of the vocal cords caused by excessive voice use (“screamers’ nodules”) are common. An abnormal cry in the neonate warrants examination for a congenital or acquired abnormality of the vocal cords.

The threshold for what a patient identifies as hoarseness varies with how the voice is used. Professional voice users such as singers, teachers, ministers, and actors may not tolerate even mild degrees of voice disturbance occurring only under certain circumstances.

Diagnostic Approach

Indirect laryngoscopy (see Fig. 14-1) is the mainstay of evaluation. A mirror may be used, but a better examination can be performed using a flexible or rigid fiberoptic telescope. In this manner, the structure and function of the vocal cords can be evaluated in patients of all ages. For subtle cases, and most particularly for the professional voice user with subtle voice problems, fiberoptic laryngoscopy with videostroboscopy is essential. By timing a strobe light to the frequency of the vocalization, this examination

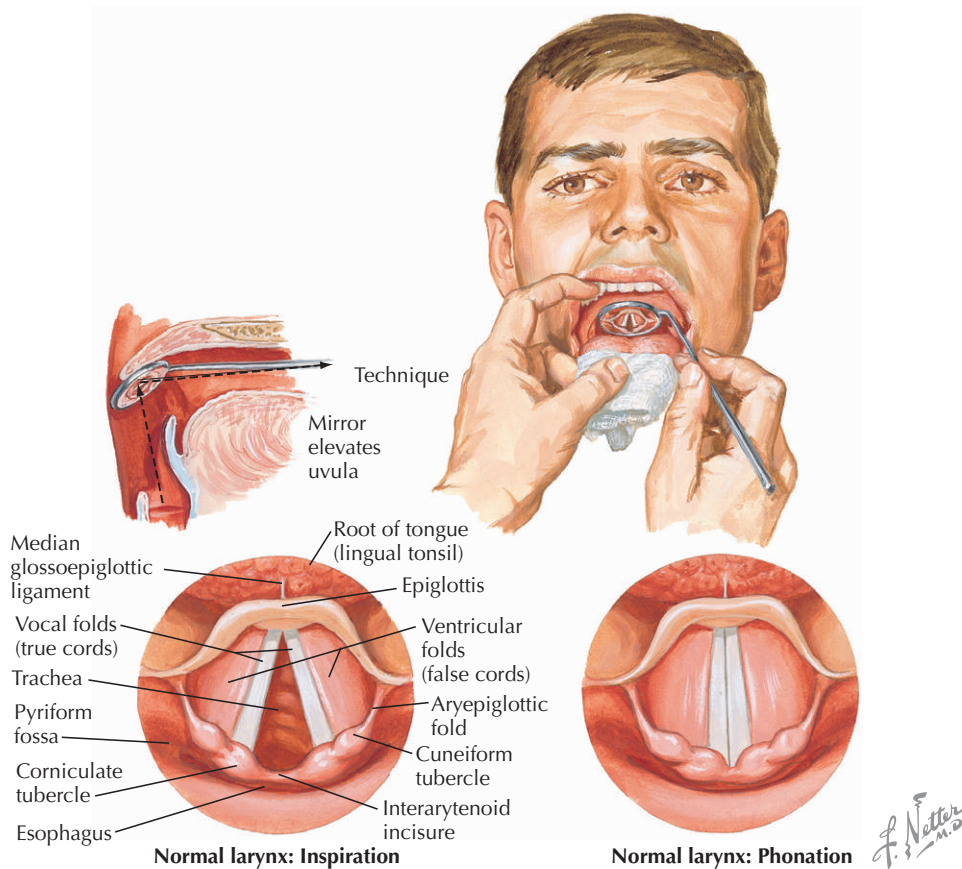

allows visualization of the mucosal wave and is the only method that allows the examiner to appreciate subtle abnormalities in the vibration of the surface epithelium of the vocal cord.

When clinical examination reveals abnormalities that warrant a biopsy, direct laryngoscopy under general anesthesia in the operating room is indicated. Blood tests (e.g., thyroid-stimulating hormone, free T₄) and imaging (e.g., chest x-ray, computed tomography [CT] of the neck) may be appropriate in certain clinical situations. If the airway is in any way impaired, emergent evaluation by an otolaryngologist is indicated.

Management and Therapy

Referral to an otolaryngologist for visualization of the vocal cords is indicated for any patient with hoarseness persisting longer than 2 weeks (Fig. 14-5). Treatment depends on the specific clinical situation, but common interventions consist of voice rest; cessation of tobacco use; treatment for gastroesophageal reflux, chronic rhinosinusitis, and cough; and referral to a speech pathologist for therapy and vocal coaching. Most inflammatory conditions and those caused by voice abuse are best treated nonsurgically if possible. Biopsy may be necessary to exclude malignancy. Before therapeutic surgical intervention for benign disease, it is essential to control the underlying conditions causing the inflammation.

Smoking cessation is often difficult to achieve. The mainstay of treatment is to get all members of the house-

hold to stop smoking and to do so together on a defined timetable. Nicotine substitutes can be helpful, as can bupropion. Alternative medicine approaches such as acupuncture and hypnosis can benefit some patients.

Gastroesophageal Reflux Disease and Laryngopharyngeal Reflux

LPR is increasingly implicated in chronic inflammation of the upper aerodigestive tract. In up to 50% of cases, it is not associated with classic heartburn or GERD symptoms. Initial therapy consists of lifestyle changes, including avoidance of substances known to exacerbate reflux such as caffeine, alcohol, peppermint, and hot spicy foods or those that are associated with symptoms; avoidance of eating for 3 hours before bedtime; elevation of the head of the bed; regular exercise, and weight loss. If such measures are unsuccessful, addition of an over-the-counter H_2 receptor blocker or proton pump inhibitor is indicated. If this is still not successful, initiation of prescription-strength H_2 blockers or proton pump inhibitors is indicated. If the diagnosis remains in question, a 24-hour pH probe study with a concurrent diary performed while off antireflux medication can be helpful, although even this test is not

absolutely accurate if the patient is not symptomatic at the time. Esophageal manometry and a barium swallow are also often performed. If these tests are positive, and medical therapy has been unsuccessful, referral for consideration of surgical fundoplication, which can usually be performed laparoscopically, is indicated.

Chronic Rhinosinusitis and Postnasal Drip

Allergy and sensitivities to pollutants account for most of these cases. Treatment with avoidance, antihistamines, leukotriene inhibitors, topical intranasal corticosteroids or antihistamines, and inhaled cromolyn form the basis of medical management. Antihistamines with a minimum anticholinergic effect are preferable for this indication because the dryness associated with systemic antihistamines can aggravate vocal problems. In severe cases, formal intradermal allergy testing or radioallergosorbent testing and subsequent desensitization may be indicated. Hypertonic buffered saline nasal irrigations and gargle can also prove beneficial. Ipratropium is the treatment of choice for vasomotor rhinitis with postnasal drip. Patients not responding to medical management should undergo a CT

CHF, congestive heart failure; COPD, chronic obstructive pulmonary disease; CT, computed tomography; ENT, ear, nose and throat specialist/otolaryngologist; GERD, gastroesophageal reflux disease; LPR, laryngopharyngeal reflux; PND, postnasal drip; PPI, proton pump inhibitor; URI, upper respiratory infection.

scan of the paranasal sinuses and referral to an otolaryngologist (rhinologist). In some cases, endoscopic surgery to correct obstructions to drainage of the paranasal sinuses can be helpful.

Chronic Cough

The most frequent causes, after excluding chronic bronchitis and chronic obstructive pulmonary disease, cardiac failure, pulmonary infection, and neoplasm, are gastroesophageal reflux, allergy, medications (especially angiotensin-converting enzyme inhibitors), chronic sinusitis with postnasal drip, and reactive airways disease. A chest x-ray should be performed on all patients with persistent

unexplained cough. If the chest film is normal, therapy for GERD, allergy, postnasal drip, and asthma may be instituted one at a time, in a graduated and exploratory manner. Alternatively, formal allergy testing, a methacholine challenge test for reactive airways disease, 24-hour pH probe testing with manometry and a barium swallow or upper endoscopy, and a CT scan of the paranasal sinuses can be undertaken also in a stepwise fashion, to determine a specific etiology.

Optimum Treatment

The treatment of most patients is usually well defined after the evaluation outlined and can be provided by the patient's

primary care physician or otolaryngologist. However, optimal management for the professional voice user may require consultation with a speech therapist to improve vocal hygiene and avoid maladaptive behaviors such as hyperfunctional voice disorder or inappropriate vocal volume or fundamental frequency.

Avoiding Treatment Errors

The most noteworthy potential treatment error in someone with hoarseness is misdiagnosis of a carcinoma of the larynx. For this reason, any patient with symptoms lasting more than 2 weeks should have the larynx visualized by an otolaryngologist or head and neck surgeon. Any abnormality seen on fiberoptic laryngoscopy evaluation not responding to conservative medical therapy should undergo biopsy.

Future Directions

There are many areas of ongoing active research. The neuromuscular control and reflex control of vocal cord function is under study and may lead to new treatment strategies for cough and vocal problems. The causes of GERD, including the physiology of gastric acid production and esophageal sphincter function and the precise substances that cause irritation, especially in the larynx and pharynx, are under intense study. An association between reflux and upper aerodigestive tract malignancy has recently been proposed and deserves further study.

Vocal Cord Dysfunction

Introduction

Vocal cord dysfunction (VCD) was first described in the medical literature by Patterson and colleagues in 1974 as “Munchausen’s stridor” and has subsequently been referred to as factitious asthma, paradoxical vocal fold motion (PVFM), steroid-resistant asthma, laryngeal dyskinesia, functional laryngeal stridor, and functional airway obstruction in the otolaryngology, pulmonology, and emergency medicine literature. Clinically, VCD manifests as episodic, involuntary adduction of the true vocal folds during respiration (primarily inspiration). The varying degree of paradoxical glottal adductory motion causes a spectrum of respiratory complaints ranging from cough to frank respiratory embarrassment. As a clinical entity, VCD is relatively uncommon; however, the impact of this diagnosis can be substantial because patients often experience repeated emergency room visits, hospitalizations, multiple trials of ineffective medications, and potentially invasive measures such as endotracheal intubation or tracheostomy in an attempt to manage their clinical picture of airway obstruction.

The diagnosis of VCD is most often considered in the clinical settings of a patient with severe or chronic respiratory symptoms that prove refractory to common therapeutic interventions. Common presenting complaints include dyspnea or chronic cough without amelioration on standard asthmatic medications. The economic impact of these refractory symptoms is significant. These patients are routinely subjected to numerous tests (chest radiographs, computed tomography scans, bronchoscopy, and spirometry) and multiple pharmacologic therapies (antitussives, antihistamines, bronchodilators, and steroid medications) before receiving the diagnosis of VCD.

Etiology and Pathogenesis

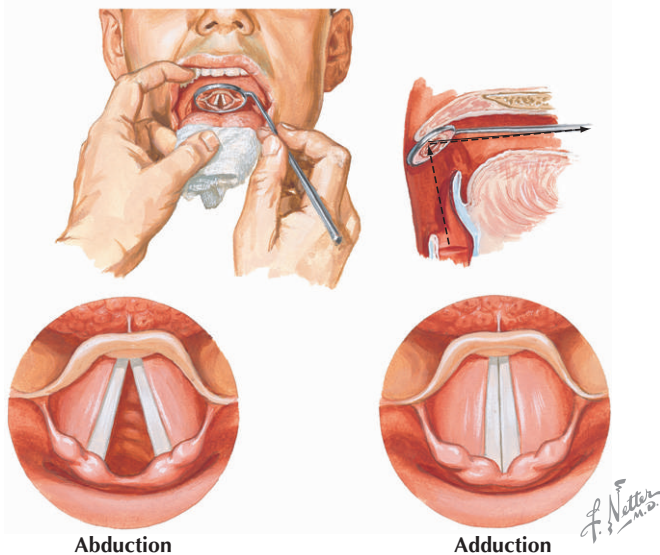

The myriad, descriptive terminology for VCD underscores the lack of a single definitive cause for this disorder. In fact, the cause of VCD is often thought to be multifactorial. Many potential contributing etiologies have been advanced and include brainstem abnormalities, psychiatric or conversion disorders, laryngeal respiratory dystonia, physical exertion, exposure to environmental respiratory irritants, and chronic upper airway irritation or inflammatory processes (i.e., laryngopharyngeal reflux, allergy, and sinusitis). All these factors may lead to a final common pathway of an abnormal glottic closure reflex and subsequent vocal fold adduction (Fig. 15-1) during inspiration, causing symptoms of airway obstruction.

The link between VCD and psychiatric disorders has been well established. In a series of 10 patients with VCD, Altman and associates found that 70% had a diagnosis of anxiety, depression, or personality disorder. Patterson’s

original article supports this finding, as do several case reports in the literature. The theory that a subset of VCD may represent a form of laryngeal, respiratory dystonia is supported by series within the otolaryngology and neurology literature citing clinical responses to intralaryngeal botulinum toxin injected into the thyroarytenoid-vocalis muscles. Laryngeal hypersensitivity from gastroesophageal reflux, uncontrolled allergic rhinosinusitis, and even occupational exposure has also been observed in patients with VCD. Indeed, the presence of reflux as a contributing factor has been reported in as many as 70% of VCD patients in some series. It is hypothesized that the threshold for the laryngeal adductory reflex may be reduced in these patients.

Proposed classification schemes for VCD have focused on etiology (brainstem, upper and lower motor neurons, gastroesophageal reflux, malingering, psychogenic), further subclassifying by the degree of laryngeal overactivity (i.e., chronic cough and episodic laryngospasm).

Figure 15-1 Larynx in Abduction and Adduction. This diagram illustrates the technique of indirect laryngoscopy and the appearance of the larynx in abduction (*lower left*) and in adduction (*lower right*).

Box 15-1 Differential Diagnosis of Vocal Cord Dysfunction

- Exercise-induced asthma
- Airway foreign body
- Allergic anaphylaxis
- Anxiety attack
- Vocal fold polypoid degeneration
- Bilateral vocal fold immobility
- Supraglottitis
- Sensitivity to airborne irritants
- Chronic cough
- Supraglottic lesions
- Extrathoracic airflow obstruction (i.e., subglottic stenosis)

methacholine challenge. Oxygen saturation during dyspneic episodes is within normal ranges, in contrast to that in patients experiencing a significant asthma exacerbation.

Physical examination usually reveals an anxious, stridorous (upper airway inspiratory noise) patient with normal neurologic and pulmonary findings. The patient typically has more difficulty on inspiration than expiration. Flexible fiberoptic laryngoscopy demonstrates vocal fold adduction on inspiration with a classic appearance of a small posterior inspiratory glottic chink. Not uncommonly in the emergency department setting, a patient's respiratory status may clinically worsen and warrant invasive airway management such as endotracheal intubation or tracheostomy. In a 20-patient cohort across two published studies, 12 patients underwent an invasive airway intervention (5 of 20 received tracheotomies).

Clinical Presentation

Patients who present with VCD are typically female and frequently have a past diagnosis of asthma and some type of psychiatric diagnosis (depression or anxiety). The most common complaints are of episodic hoarseness, throat tightness, chronic cough, aphonia, dysphonia, and dyspnea. Many patients may describe certain triggers such as stress, exercise, cold air, discrete odors, or respiratory irritants. Additionally, many patients may comment that they have begun treatment for asthma (without much benefit), suffer from acid reflux, or take allergy medications. It is reported that about 10% of patients with recalcitrant asthma have VCD.

Clinically, there is a recognized subset of VCD patients who are young, high-achieving, female athletes with isolated respiratory exacerbations precipitated by strenuous physical exercise. These patients are often misdiagnosed as having exercise-induced bronchospasm (EIB). Distinctive features differentiating EIB from VCD include cessation of the VCD-associated dyspnea with cessation of exercise and the failure of standard bronchodilators to abort the VCD symptoms. Some authors have advocated the use of exercise laryngoscopy to identify the diagnostic laryngeal behavior that is present only during strenuous exercise.

In symptomatic VCD patients without concomitant pulmonary disease, pulmonary function tests (PFTs) reveal spirometric measures within normal reference ranges and, potentially, flattening of the inspiratory flow loop. PFTs should also fail to show bronchial hyperresponsiveness to

Differential Diagnosis

The differential diagnosis for vocal cord dysfunction is shown in Box 15-1.

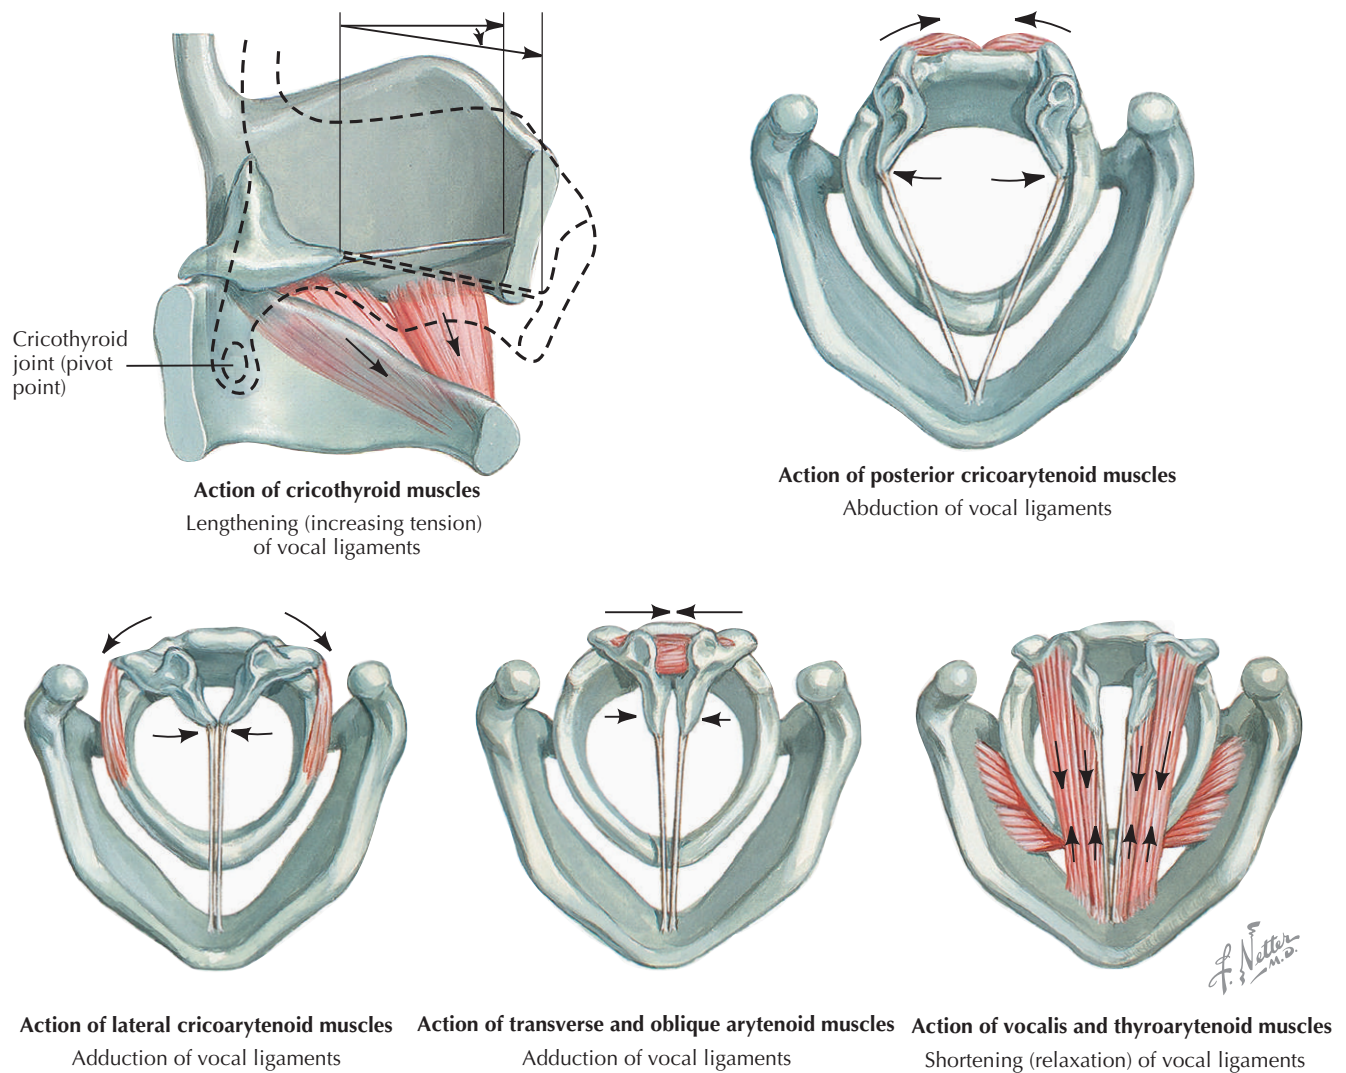

Diagnostic Approach

Because PVFM is often misdiagnosed as asthma or chemical sensitivity, it is important to obtain a thorough history, including the success of previous medical therapy, PFT results, and the frequency of attacks. Routine laboratory studies, such as basic metabolic panel and complete blood count, are typically normal but should certainly be checked to rule out concomitant disease processes. Chest radiographs appear normal without hyperinflation. In anxious patients with tachypnea, the arterial blood gas findings may demonstrate respiratory alkalosis. Additionally, PFTs (typically done on an outpatient basis) do not show significant improvement with bronchodilators and in some cases show a diminished maximum inspiratory flow.

The most useful diagnostic tool is flexible fiberoptic laryngoscopy. This allows the examiner to clearly assess the mobility of the vocal folds throughout the respiratory cycle as well as to rule out obstructing lesions or anatomic laryngeal abnormalities. Supraglottic laryngeal neoplasms

Figure 15-2 Action of Intrinsic Muscles of Larynx.

This diagram illustrates the intrinsic muscles of the larynx. The abductor of the larynx is the posterior cricoarytenoid muscle.

can easily mimic the symptoms of VCD. The resultant intermittent and variable glottic obstruction is caused by their close anatomic relationship above the glottis. Even benign glottic lesions have, on occasion, mimicked these symptoms. Large, edematous, overly mobile vocal folds such as those seen with polypoid degeneration (Reinke's edema) may cause similar symptomatology secondary to the Bernoulli effect, causing intermittent ball-valving of these lesions into the subglottic airway.

Laryngoscopy in patients with VCD confirms paradoxical adduction during inspiration, causing substantial functional airway obstruction, in association with the clinical complaints and laboratory findings mentioned earlier. Because of the episodic nature of this disorder, however, asymptomatic patients examined laryngoscopically may not exhibit pathologic laryngeal motion. In this baseline setting, some authors have reported the use of exacerbating

stimuli or eliciting behaviors (based on patient history) during laryngoscopy in an attempt to increase the diagnostic sensitivity of the exam.

Management and Therapy

Optimum Treatment

Treatment of VCD can be divided into acute and long-term therapies. Initial management should focus on maintenance of a secure and safe airway. This includes supportive measures such as supplemental oxygen, continuous pulse oximetry, nebulized racemic epinephrine, heliox therapy, or continuous positive airway pressure. Invasive airway management with endotracheal intubation or awake tracheostomy is also well recognized in the literature, although with early diagnostic recognition, it can often be avoided.

Once the diagnosis of VCD is established, maneuvers such as sniffing, whistling, or breath-holding may help break the paradoxical vocal fold behavior. Additionally, relaxation techniques may help resolve the airway distress. In specific circumstances, a low dose of sedative-anxiolytic medications is useful in managing psychogenic contributing factors during acute exacerbations.

A personalized, multidisciplinary approach offers the best opportunity for long-term treatment. Medical management should include treatment of underlying psychiatric disorders (including psychological counseling), treatment of reflux, and management of allergic rhinitis. When these conditions are accounted for, the most acknowledged course of treatment involves behavioral speech therapy techniques. The speech pathologist can offer the patient respiratory re-education and relaxation techniques to remove the patient's focus from the inspiratory phase of breathing. Some therapists may also employ the use of laryngeal image biofeedback. First presented by Bastian and Nagorsky, this method employs the flexible fiberoptic laryngoscope and allows the patient to visualize the larynx in real time while performing various exercises with the speech pathologist. These investigators have shown this technique to be a useful instrument for patient re-education.

Although speech therapy has been shown to be beneficial for some patients, there appears to be a group of patients who have true respiratory dystonia. These patients are reasonable candidates for a trial of intralaryngeal botulinum toxin injection (into adductory laryngeal muscles; Fig. 15-2). Patients with psychiatric disorders that prevent them from participating in multidisciplinary treatment plans may also require long-term tracheotomy to mechanically bypass the laryngeal site of airway obstruction. There is yet another subgroup of PVFM patients who have central or brainstem etiologies for whom the previously described treatments are likely to be ineffective. These patients more frequently remain tracheotomy dependent.

Avoiding Treatment Errors

Vocal cord dysfunction remains a rare clinical entity. The clinician's primary focus should be the maintenance of a safe and secure airway. To avoid treatment errors in these patients, one must have a high index of suspicion when presented with patients who fit the historical and physical exam findings described.

Treatment errors include overly aggressive treatment and undertreatment. Overtreatment often results in endotracheal intubation or tracheotomy in an attempt to avoid what the clinician perceives as imminent loss of the patient's airway. Undertreatment arises from a failure to recognize this clinical entity and to appropriately address potential exacerbating factors such as laryngopharyngeal reflux, allergic rhinitis, and mental illness (including depression and anxiety). Otolaryngologic consultation for flexible

fiberoptic laryngoscopy during an attack may lead to earlier diagnosis.

Future Directions

Future directions in the study of vocal cord dysfunction will require the development of a formal medical definition of this clinical entity, including inclusionary and exclusionary criteria. Further research into the neurologic underpinnings of the paradoxical vocal fold activity is necessary. Additionally, refinement of long-term therapy merits randomized, controlled trials examining treatment modalities such as pharmacotherapy, laryngeal biofeedback, and botulinum toxin injection.

Neck Masses in Adults

Introduction

The causes of neck masses include congenital disorders, infection, and neoplastic lesions (Fig. 16-1 and Box 16-1), among others. With careful attention to patient history, physical examination, and properly selected laboratory and imaging tests, the physician can usually arrive at a correct diagnosis quickly and efficiently.

Etiology, Pathogenesis, and Clinical Presentation

Age

The patient's age may give a clue to the diagnosis. Neck masses in infants and children are usually branchial cleft abnormalities, thyroglossal duct cysts, hemangiomas, lymphangiomas, or benign lymphadenopathy. Adolescents and young adults with significant cervical lymphadenopathy, malaise, and pharyngitis often have infectious mononucleosis. Single large, inflamed anterolateral neck masses that develop after upper respiratory infections in this age group suggest branchial cleft cysts. Multiple rubbery, low neck masses, night sweats, fever, and malaise may indicate Hodgkin's disease. Metastatic cancer, primary salivary gland infections or neoplasms, and lymphomas are common causes of neck masses in older adults (see Box 16-1).

History

The history helps to limit the differential diagnosis. Infectious processes usually develop over hours to days and have associated pain, redness, warmth, and fever. Patients often have a preceding upper respiratory tract or dental infection. Infected congenital cysts may have enlarged on earlier occasions and resolved with antibiotic therapy. Submandibular gland infection often waxes and wanes, is exacerbated by eating, and causes a foul taste in the mouth as the gland decompresses. Hodgkin's disease is associated with night sweats, malaise, itching, and fever. Patients with cat-scratch disease give a history of cat contact.

Metastatic squamous cell carcinoma of the upper aerodigestive tract usually occurs in patients with a history of heavy smoking, many of whom also abuse alcohol. Ody-

phagia, dysphagia, dyspnea, otalgia, voice change, and weight loss are indicative of the primary malignancy. Patients with metastatic disease from distant sites may report symptoms of the primary tumor, such as cough, hemoptysis, abdominal pain, hematochezia, abnormal uterine bleeding, or difficulty urinating. Salivary gland neoplasms are usually painless and grow slowly, although high-grade malignancies may enlarge rapidly. Parotid gland malignancies sometimes cause facial nerve paralysis. Schwannomas, paragangliomas, dermoids, and other benign neoplasms typically grow slowly, cause few symptoms, and are noticed only coincidentally.

Physical Examination

The head and neck exam should include thorough visualization of the ears, nose, oral cavity, oropharynx, nasopharynx, hypopharynx, and larynx. In certain instances, general anesthesia may be required to perform an adequate exam in children. The fiberoptic laryngoscope is helpful in patients with brisk gag reflexes. Auscultation of the chest and over the neck mass may yield important data. Palpation for cervical, axillary, and inguinal lymphadenopathy and for liver or spleen enlargement may strengthen a suspicion of lymphoma. Breast, rectal, and pelvic exams are appropriate in many cases.

Mass consistency and location are critical in the neck examination. Metastatic squamous cell carcinoma feels firm and becomes fixed when advanced. Lymphoma or simple lymphadenopathy feels rubbery or soft, whereas branchial and other cysts are fluctuant. Infected lymph nodes or congenital cysts become tense. Infected masses become attached to the overlying skin as they begin to "point," are often warm and tender, and have erythema-

Figure 16-1 Neck Masses in Adults.

tous overlying skin. Capillary hemangiomas are generally flat and appear pink to red, whereas cavernous hemangiomas are raised, are purple to blue, and feel soft and cystic.

Thyroglossal duct cysts lie in or near the midline of the neck; most present below the level of the hyoid bone. Masses in the midline of the submental area can be dermoid cysts or teratomas; plunging ranulae may also present in this area. Masses in the submandibular region may develop secondary to sialadenitis, submandibular gland neoplasia, or enlarged submandibular lymph nodes from infection or metastatic tumor (most commonly squamous cell carcinoma of the oral cavity).

Posterior triangle lymph nodes suggest squamous cell carcinoma of the nasopharynx. The upper jugular lymph nodes are most commonly enlarged in cases of pharyngitis

and are often the first site of metastasis for oropharyngeal cancers. Enlarged supraclavicular lymph nodes suggest Hodgkin's disease or metastases from the thorax or abdomen. Masses in the lower anterior neck often indicate thyroid disease.

Differential Diagnosis

The differential diagnosis of a neck mass is extensive. One helpful way to categorize possible pathologic processes combines tissue of origin and disease type (see Box 16-1).

Congenital Lesions

Congenital neck masses may become apparent in infancy or later in life. Branchial cleft anomalies and thyroglossal duct

Box 16-1 Differential Diagnosis of Neck Masses**Congenital Lesions**

Branchial cleft anomalies
Thyroglossal duct cysts
Lymphangiomas
Hemangiomas
Dermoid cysts

Neoplastic Lesions

Metastatic squamous cell carcinoma and others
Salivary glands
Lymphomas (Hodgkin's and non-Hodgkin's)
Neurogenic (schwannomas and neurofibromas)
Paragangliomas (carotid body tumors and glomus tumors)
Thyroid (carcinomas and goiters)
Parathyroid neoplasms
Teratomas

Inflammatory

Abscess
Ludwig's angina
Bezold's abscess
Suppurative lymphadenopathy
Deep neck space infection
Infectious
Sialoadenitis
Lymphadenitis and benign lymphadenopathy
Atypical tuberculosis
Tuberculosis

Actinomycosis
Fungus
Mononucleosis
Ranulae
Others

Other Lesions

Carotid aneurysm
Epidermal and dermal inclusion cysts
Laryngoceles
Esophageal diverticula

cysts are most common. Branchial sinuses, or fistulas, present at birth as small draining puncta along the anterior border of the sternocleidomastoid muscle or in the preauricular area. Branchial cleft cysts present in young adults, typically during or after an acute upper respiratory infection. The cyst develops as a painful, warm, soft, or fluctuant area in the neck along the anterior border of the sternocleidomastoid muscle; deep neck abscess or cellulitis may complicate this problem. Surgical excision is usually required. Thyroglossal duct cysts occur in or near the midline of the neck, slightly below the level of the hyoid bone, and move superiorly with tongue protrusion. They represent thyroid gland remnants left during the gland's descent from its origin near the foramen cecum of the tongue to its normal paratracheal location. Dermoid cysts often develop in the submental area. These congenital cysts may present acutely when they become infected (usually during or after an upper respiratory infection) or chronically (as cystic neck masses) during young adult life.

Capillary and cavernous hemangiomas are benign tumors, generally obvious at or shortly after birth. Capillary hemangiomas (port wine stains) do not regress significantly with age. Recently, pigment-seeking laser therapy has yielded good results. Cavernous hemangiomas may regress significantly with age and therefore, call for a "watch and wait" approach. Overly aggressive early treatment may result in unnecessary damage to involved normal structures. Surgery is reserved for bleeding lesions or lesions obstructing the airway or digestive tract and hemangiomas that have not regressed significantly by the preschool years.

Cavernous lymphangiomas, or cystic hygromas, appear as soft, fleshy masses. Although benign, lymphangiomas in infants are often infiltrative and may cause obstructive symptoms requiring surgical excision. Total extirpation is not usually possible, so involved normal structures should not be sacrificed at surgery. Adults often manifest less infiltration, permitting more definitive surgical excision.

Neoplastic Lesions

Squamous cell carcinoma of the upper aerodigestive tract metastatic to cervical lymph nodes is the most common cause of a unilateral neck mass in middle-aged or older men with a history of tobacco use. Other common neoplasms include tumors of the parotid and submandibular salivary glands, Hodgkin's and non-Hodgkin's lymphomas, neurogenic tumors (schwannomas and neurofibromas), and paragangliomas (carotid body tumors and glomus tumors).

Squamous cell carcinomas metastatic to the neck often originate in the oral cavity, pharynx, or larynx but may come from the skin or more distant sites. Involved lymph nodes usually feel firm, and although initially mobile, they become fixed to surrounding structures as cancer breaks through their capsules. In advanced cases, there is multiple or bilateral node involvement. Usually, radical surgery with or without radiotherapy and chemotherapy is necessary (see Fig. 16-1).

Salivary gland tumors develop in older individuals. About 80% of parotid gland neoplasms, mostly pleomorphic adenomas, are benign. The most common malignant parotid gland tumor is the mucoepidermoid carcinoma. About 50% of submandibular gland neoplasms are benign. The most common benign submandibular gland neoplasm is the pleomorphic adenoma; the most common malignant tumor is adenoid cystic carcinoma. Surgical excision is usually necessary, with additional postoperative radiation for high-grade malignancies.

Involved cervical lymph nodes in Hodgkin's disease feel softer and more rubbery than those of squamous cell carcinoma. This lymphoma often causes enlargement of multiple nodes in the lower neck. Non-Hodgkin's lymphoma generally presents in older patients. Enlarged nodes are often matted and multiple, again having a rubbery rather than a hard infiltrative feel. It sometimes involves the tissue

of the Waldeyer ring (palatine tonsils, lingual tonsils, and adenoids). Diagnosis is confirmed by biopsy. Treatment consists of radiation therapy, chemotherapy, or both.

Schwannomas usually grow on the vagus nerve or cervical sympathetic trunk. Neural function usually remains normal, as the lesion enlarges very slowly over many years. Surgical removal is frequently recommended. Neurofibromas in the neck, often multiple, can coexist with neurofibromas elsewhere and may involve any nerves. Surgeons generally reserve excision for solitary lesions or those causing obstructive symptoms or severe deformity. Most neurogenic tumors are benign; however, malignant degeneration has been described, usually marked by a rapid growth phase or loss of nerve function.

Paragangliomas are usually benign and occasionally multiple; these highly vascular neoplasms often produce bruits. Carotid body tumors typically splay the internal and external carotid arteries. Glomus jugulare and glomus vagale tumors, originating in specialized paraganglion tissue along the internal jugular vein and the vagus nerve, respectively, often erode the temporal bone and present high in the neck behind the angle of the mandible. Surgical removal is generally recommended.

Infectious Neck Masses

These may be indolent or fulminant. Simple lymphadenopathy often occurs with acute viral or bacterial pharyngitis, sinusitis, or tooth infections. Generally, these nodes feel soft and shrink over days to weeks after the acute infection resolves. Suppurative lymphadenopathy occurs when the center of a node necroses and an abscess develops. Most abscesses require antibiotic therapy and surgical drainage; untreated suppurative lymphadenopathy can lead to deep neck infections with potential for spread to the mediastinum that may be fatal.

Certain infection paths are common enough to have their own identity. Ludwig's angina begins with an infection in the oral cavity of dental origin. Sublingual inflammation and swelling retrodisplace and elevate the tongue, possibly leading to acute upper airway obstruction (see Fig. 16-1). Bezold's abscess develops when a mastoid infection breaks out inferiorly into the deep neck. Deep neck space infections require emergency hospitalization, intravenous antibiotics, and usually surgical drainage.

The parotid and submandibular glands may become infected. Acute parotid sialadenitis afflicts elderly individuals most commonly, especially when they get dehydrated; it may also reflect sialolithiasis. Cystic degeneration of the parotid gland has been described in patients with HIV infection. Acute submandibular sialadenitis often follows sialolithiasis. Patients often note intermittent submandibular swelling associated with eating. Parotitis is usually treated with hydration, intravenous antibiotics, local heat, massage, and sialogogues. Recurrent submandibular sialadenitis is usually treated with resection of

the submandibular gland during a quiescent period (see Fig. 16-1).

Other infectious processes include atypical tuberculosis (scrofula), best treated by surgical excision of the involved lymph nodes; cat-scratch disease, which frequently requires surgical drainage; and actinomycosis, which often causes multiple chronically draining sinus tracts with sulfur granules of matted organisms (see Fig. 16-1). Many patients with HIV infection develop cervical lymphadenopathy; this complication does not generally require specific treatment unless rapid expansion suggests lymphomatous involvement.

Other Common Neck Masses

These include prominent normal structures, such as the (pulsatile) carotid bulb or the (hard) transverse process of the first cervical vertebra. Careful palpation should delineate these bilateral (although frequently asymmetric) structures. Carotid aneurysm, although uncommon, should be suspected if the patient has an expanding neck mass or a history of cervical trauma. Thyroid masses are quite common. Diffuse nodular thyroid enlargement present for many years suggests simple goiter. Solitary thyroid nodules, although usually benign, may represent thyroid cancer and, thus, demand evaluation. Epidermal and dermal inclusion cysts are very superficial and often result from recurrent cutaneous inflammation.

Diagnostic Approach

Laboratory Studies

A variety of studies may prove useful. A heterophil antibody test may reveal mononucleosis in the young patient with pharyngitis and cervical adenopathy out of proportion to that expected in cases of simple upper respiratory infection. Serologic tests for HIV infection may help in the evaluation of an at-risk patient with multiple enlarged cervical lymph nodes or parotid gland enlargement. Intradermal antigen testing for tuberculosis and a control substance, thyroid function tests, and a complete blood cell count with differential can each provide useful data in appropriate situations.

Imaging Studies

Chest x-rays may show lung carcinoma, metastases, findings consistent with lymphoma or tuberculosis, or tracheal deviation. Computed tomography (CT) scanning (or possibly magnetic resonance imaging) can delineate cervical anatomic relationships and reveal a pathologic process, such as a primary aerodigestive tract cancer. Although used less frequently since the advent of fine-needle cytologic examination, thyroid scanning still proves useful in some cases. Anteroposterior and lateral neck x-rays can show tracheal deviation or encroachment on the airway (before or instead of CT scans).

Further Diagnostic Workup

Patients should undergo complete clinical evaluation before any biopsy; the otolaryngologist with head-and-neck surgical training can best evaluate patients with neck masses of concern. Cytologic examination of neck masses by fine-needle aspiration is very helpful. More than 90% sensitive and specific, cytology often aids in counseling patients preoperatively or in directing further diagnostic maneuvers.

Patients with masses that represent metastases should undergo direct laryngoscopy, pharyngoscopy, esophagoscopy, and bronchoscopy under anesthesia before any excisional neck biopsy. If endoscopy reveals no obvious primary lesion, especially if previous cytologic evaluation documented squamous cell carcinoma in the neck, biopsies of the tongue base, the tonsils, and the nasopharynx should be obtained. If negative, the surgeon can perform an open neck biopsy and obtain frozen sections. If no primary tumor is found, but the open neck biopsy reveals unequivocal squamous cell carcinoma, a neck dissection is performed at the time of biopsy. There is a 20% incidence of second primary tumors in patients with upper aerodigestive tract malignancies.

If open neck biopsy does not reveal squamous cell carcinoma, the surgeon and pathologist should be ready to thoroughly evaluate the tissue specimens. Cultures for aerobes, anaerobes, acid-fast bacteria, and fungi should be obtained, and material should be processed for immunohistochemical or electron microscopic study if indicated by the frozen section findings.

Management and Therapy

Optimum Treatment

Optimal therapy demands that a patient presenting with a neck mass have a thorough examination of the upper aerodigestive tract. If no obvious benign reason for the mass is found, a fine-needle aspirate and other diagnostic workup as outlined, is indicated.

Avoiding Treatment Errors

Major errors in treatment include delay in diagnosis of a cancer of the upper aerodigestive tract and inappropriate open incisional biopsy without a thorough examination for a primary tumor. Doing so may result in spread of the tumor or contiguous tissue, which may be detrimental to the patient. Fine-needle aspiration is the preferred initial method of histologic examination.

Future Directions

New treatment modalities for head and neck cancer are needed. The mainstay of treatment for many years has

been surgical excision and radiation. New organ preservation protocols using combinations of chemotherapy and radiation are becoming more popular. New treatments such as gene therapy, adenovirus vectors, antiangiogenesis factors, and immune modulators are on the horizon.

This is a brief and concise overview, from an otolaryngology, head and neck surgery perspective, of a new demographic of patients (those ≤45 years of age) who develop squamous cell carcinoma of the head and neck. This article contrasts this age group of patients with the traditional demographic and reviews the evidence of treatment patterns.

2. Back G, Sood S: The management of early laryngeal cancer: Options for patients and therapists. *Curr Opin Otolaryngol Head Neck Surg* 2:85-91, 2005.

This article, from an otolaryngology, head neck surgery perspective, evaluates the current evidence for optimal treatment of early-stage laryngeal cancer. Multiple therapeutic modalities are available, and treatment choice should take into account post-treatment morbidity, patient quality of life, patient preference, and voice quality.

Cough

Introduction

Cough is the number one reason patients seek medical attention. Although an occasional cough is normal, excessive coughing or chronic coughing that produces blood or thick, discolored mucus is not. Cough is a symptom; its causes exist on a continuum from acute (<3 weeks) to subacute (3 to 8 weeks) to chronic (>8 weeks), and the duration is not linked to the potential seriousness of the underlying condition. Interestingly, smokers rarely report cough as a symptom and may consider it a normal phenomenon. Although they are excluded from most studies of chronic cough, making it difficult to cite an exact figure for how commonly it occurs, smoking and its related diseases are a major cause of acute and chronic cough.

Serious and potentially life-threatening causes include pneumonia, congestive heart failure (CHF), pulmonary embolism, and severe exacerbations of asthma or chronic obstructive pulmonary disease (COPD). Nonserious acute cough stems most commonly from viral upper respiratory infections (URIs) but may also be caused by mild exacerbations of chronic underlying lung diseases or environmental or occupational exposures. URIs are usually viral in nature and are considered benign and self-limiting. Pneumonic cough, usually with purulent sputum and associated fever or chills, chest pain, and dyspnea, is beyond the scope of this chapter (see Chapter 18).

Subacute cough, lasting 3 to 8 weeks, most commonly is postinfectious in nature following a common URI. Because this type of cough is self-limited, it is important not to initiate a complex workup if suspected. Other causes of subacute cough, including asthma, upper airway cough syndrome (previously known as postnasal drip), and gastroesophageal reflux disease (GERD), overlap with the causes of chronic cough and require similar diagnostic workups and treatments. Cough may, by itself, have clinical complications ranging from conjunctival bleeding, epistaxis, tussive or post-tussive syncope or vomiting, stress urinary incontinence, rib fractures, cervical disk herniation, abdominal hernias, esophageal rupture, cardiac arrhythmias and infarction, pulmonary barotrauma, and even cerebral air embolism. In addition, chronic cough takes a toll on quality of life, with significant effects on social relationship, sleep, concentration, mood, and daily activities affecting up to 80% of chronic cough patients. Therefore, chronic cough warrants a thorough evaluation.

Etiology and Pathogenesis

Asthma, upper airway cough syndrome, and GERD are the most common causes of subacute and chronic cough and account for about 75% of all cases. Each can present with cough as the only symptom. Between 75% and 90% of cases of chronic cough are a result of a single cause, 5% to 20% are a result of two causes (e.g., allergic rhinitis and asthma together), and less than 5% are a result of three or more causes simultaneously. Whooping cough (*Bacillus pertussis*) has made a strong resurgence, increasing 10-fold to a prevalence of about 1% in the United States (with a similar prevalence in Western Europe) in the past decade.

Whooping cough now needs to be considered in the differential diagnosis of both adolescents and adults with severe cough, whereas, in the past, it had largely been a disease in infants. In some modern series, it accounts for as much as 20% of the cases of prolonged (≥ 8 weeks) cough.

Statistics regarding the etiology of cough depend, in part, on the source of the information. Experience from general practice suggests that more than 90% of patients with chronic cough had either asthma or upper airway disease. In contrast, specialists in pulmonary medicine find that about 50% of their cough patients have COPD, bronchiectasis, pulmonary fibrosis, or lung cancer. Usually, smokers are excluded from chronic cough studies, a prac-

tice that leads to an underestimate of smoking-related diseases. Interestingly, women are referred to specialists more often than men, and this may be explained by differences in smoking habits or the social consequences of the symptom. Women also appear to have an intrinsically heightened cough response. More than 100 diseases are associated with chronic cough, but most are uncommon. Occupational diseases (especially in miners and tunnel and concrete manufacturing workers) are becoming increasingly linked to chronic cough. In addition, indoor and outdoor air pollutants (ozone, nitrogen dioxide, sulfur dioxide, and particulates) are becoming recognized as the cause of chronic cough. Although the prevalence of air pollution-induced or occupational cough is not known, the clinician should remain vigilant to the role of environmental factors in chronic cough. Finally, a higher percentage of patients being referred for cough in recent studies have unexplained cough (despite a full workup), a problem once referred to as “habit” or “psychogenic” cough.

Clinical Presentation

Chronic productive coughs with purulent sputum are usually seen in chronic bronchitis and bronchiectasis and, less commonly, from lung abscesses. Productive coughs with white to off-white sputum may be seen in asthma or postnasal drip. In the latter conditions, the secretions are usually from the upper respiratory tract. Dry chronic coughs usually result from asthma (many sufferers never report wheezing), interstitial lung disease (ILD), CHF, and the use of angiotensin-converting enzyme (ACE) inhibitors. Whooping cough should be considered when coughing paroxysms or an inspiratory “whoop” is present, especially in those exposed to a confirmed case. Childhood vaccination may not prevent whooping cough in adults but may lessen its severity.

Physical examination may detect some causes of chronic cough, including chronic airway obstruction if expiratory rhonchi or wheezes are present. CHF and ILD present with wet or dry inspiratory crackles, respectively. Inflamed nasal mucosa indicates the diagnosis of chronic rhinosinusitis. Lower extremity edema and an abnormal heart exam point to the diagnosis of CHF, whereas extremity clubbing may lead to the diagnoses of lung malignancy, ILD, or bronchiectasis.

Differential Diagnosis

An adequate history is vital in establishing a diagnosis. In smokers, the cough is considered a consequence of cigarette-related disease until proved otherwise. The most common causes of chronic cough in nonsmokers are asthma, upper airway cough syndrome, and GERD (Table 17-1). Chronic bronchitis is the most common diagnosis in smokers. Determining the precipitating factors for cough provides useful clues to the underlying cause. The

Table 17-1 Etiology of Chronic Cough with a Normal Chest Radiograph

ACE, angiotensin-converting enzyme; GERD, gastroesophageal reflux disease.

timing of cough may be important (e.g., it might occur postprandially in aspiration-induced cough or GERD, or nocturnally in asthma or CHF). Patients with chronic bronchitis or bronchiectasis often cough most vigorously after awakening because secretions have pooled in the lung during sleep. Often, response to specific antitussive therapy is critical to make the final diagnosis of cough (e.g., response to antihistamine or decongestants implicates either the common cold or upper airway cough syndrome, grades A and B*).

Diagnostic Approach

Diagnostic tests are unnecessary if the history or physical examination suggests benign or self-limited causes. Symptoms and signs suggestive of URI (i.e., cold) or upper airway cough syndrome (postnasal drip) warrant a therapeutic trial with an over-the-counter (first-generation) antihistamine-decongestant or a nonsteroidal anti-inflammatory drug before diagnostic testing (grade A). A cough caused by an ACE inhibitor, regardless of the temporal association between the two, is best managed with a trial off the drug or, if mild, observation while therapy continues (grade B). A chronic postinfectious cough is best managed with simple observation because it will probably spontaneously remit, but a short antitussive (inhaled anticholinergic agent or corticosteroid) therapy trial may be helpful (grade B). Otherwise, diagnostic tests should be directed by the history and physical examination. A chest radiograph is essential early in the investigation and has the potential to diagnose many serious parenchymal lung diseases (e.g., bronchogenic malignancy, CHF, ILD, lung abscess, or emphysema with a bronchitic component; Box 17-1 and Fig. 17-1). Symptoms suggestive of asthma or chronic bronchitis are more effectively evaluated with pulmonary function tests (PFTs) than chest

*The grading scale for diagnostics and treatments is evidence based: A, strong; B, moderate; C, weak; D, negative; I, inconclusive.

Figure 17-1 Causes of Chronic Cough with a Normal Chest X-Ray.

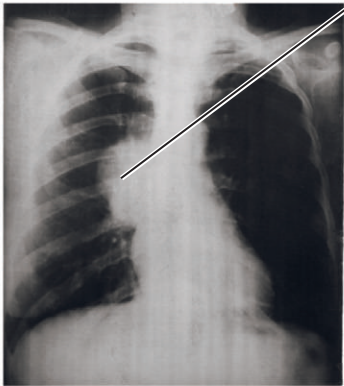

radiography. Patients with chronic cough from advanced lung disease related to the airways or parenchyma should undergo both an anatomic (chest radiograph) and physiologic (i.e., PFTs) workup. Eosinophilic bronchitis should be considered in patients with normal PFTs and sputum or bronchial wash eosinophilia. Whooping cough can be diagnosed clinically or by culture of the organism from nasopharyngeal aspirates or by using polymerase chain reaction techniques, but the latter two are problematic (special culture media needed and good quality controls)

and have the highest yield early in the illness before patients are likely to seek medical attention.

A recommended diagnostic protocol is outlined below, but individualization based on the history and physical examination is important (Fig. 17-2). A chest radiograph is usually the most sensitive test. If a cause is identified from the chest radiograph, the workup proceeds on the basis of the abnormality (see Box 17-1). Sputum cultures are necessary if infection is suspected. Bronchoscopy or lung biopsy can confirm the presence of a malignant or an

Figure 17-2 Diagnostic Testing in Chronic Cough.

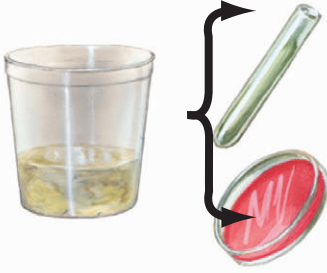

Chest x-ray

- Emphysema and chronic bronchitis
- Congestive heart failure
- Cystic fibrosis and bronchiectasis
- Tuberculosis and nontuberculous mycobacterial infection
- Alveolar hemorrhage syndromes
- Pulmonary hypertension

inflammatory entity. When the chest radiograph is normal or shows signs of a quiescent disease, spirometry before and after bronchodilator therapy should be obtained if airway diseases (e.g., COPD and asthma) are suspected. Many patients with asthma show some evidence of airflow obstruction (forced expiratory volume in 1 second [FEV₁] <80% of predicted; FEV₁/forced vital capacity [FVC] ratio <80% of predicted; low forced expiratory flow 25% to 75%; or a large [>10% increase in FEV₁] bronchodilator response). Additional PFTs, including diffusing capacity and lung volume measurements, may be useful in a subset

of patients with normal spirometry or to better define the extent of disease in those with abnormal spirometry. If the chest radiograph is normal in a smoker or an individual exposed to occupational or seasonal antigens or environmental irritants, the patient should be encouraged to avoid the irritating factor before additional diagnostic testing. Unfortunately, many patients cannot or will not avoid potential irritants, and PFTs may prove useful in defining the disease and its severity (if only to reinforce the need for irritant avoidance).

If the history, physical examination, chest radiograph, and spirometry do not suggest a cause for the chronic cough, pulmonary consultation may be indicated. If asthma remains a possibility with a normal examination and spirometry, home peak flow monitoring or methacholine challenge testing may be helpful to make the diagnosis. High-resolution chest computed tomography (CT) is the best diagnostic test if clinical suspicion for ILD exists based on the chest x-ray or restriction is present on PFTs (total lung capacity <80% predicted or FVC <80%). High-resolution CT is also useful to diagnose bronchiectasis because chest x-rays are insensitive. If GERD is suspected on the basis of symptoms, 24-hour esophageal pH monitoring may prove diagnostic, but many clinicians opt for a trial of therapy to reduce gastric acidity to determine whether the cough improves. Sinus x-rays are rarely helpful when symptoms are not present. If patients give a history of an upper airway source of cough (e.g., a tickle in the throat), laryngoscopy may exclude vocal cord nodules and lesions. Bronchoscopy or cardiac evaluation for left ventricular function is used as a last resort, but the diagnostic yield is low if other testing is negative.

Management and Therapy

The majority (>80%) of patients with subacute and chronic cough benefit from treatment. Because chronic cough has more than one cause in at least 20% of patients, add-on therapy should be considered if there is a poor response to the initial, cause-directed therapy. The management principles for intractable cough of unknown cause are not well defined. Some causes of cough are etiologically related to or trigger other causes of cough. For example, many patients with asthma have been found to have GERD, and in turn, chronic cough from any cause has been found to precipitate GERD. Thus, the potential for a self-perpetuating cycle exists.

Optimum Treatment

Specific Antitussive Therapy

Specific antitussive therapy has a high likelihood of success (>80%) because a specific cause for chronic cough is usually found (>80% based on previous studies). Common colds and upper airway cough syndrome treatments were men-

tioned previously. Allergic rhinitis can be treated with intranasal corticosteroids or combination antihistamine-decongestants (grade B). Asthma therapy guidelines focus on obtaining disease control with inhaled corticosteroids and leukotriene modifiers (e.g., montelukast) (grade A, see Chapter 20) and providing acute relief with bronchodilators. Infectious sinusitis should be treated with antibiotics.

Patients with chronic cough from GERD should use an antireflux regimen (weight loss; elevation of the head of the bed on blocks; avoidance of bedtime snacks, caffeine, and theophylline and antireflux medication) (grade B, see Chapter 50). A trial of medications is appropriate without additional diagnostic testing even if there are no reflux symptoms. H₂ receptor antagonists and proton pump inhibitors are effective in reducing cough in roughly half of the patients. Case reports of the prokinetic agent, metoclopramide, indicate that it is also effective. Other antireflux agents such as antacids and cytoprotective agents (e.g., sucralfate) have been disappointing in the management of cough. Patients with aspiration-induced cough (oral-pharyngeal dysphagia) should be diagnosed by a speech therapist with a swallowing evaluation and treated with either dietary modification or, when especially severe and intractable, gastric tube feedings (grade B).

Chronic bronchitis, chronic cough, and sputum expectoration occurring on most days for at least 3 months and for at least 2 consecutive years is successfully treated with smoking cessation alone in more than 90% (grade A). More than half the time, cough disappears within a month of cessation. For infectious exacerbations of chronic bronchitis or bronchiectasis, antibiotics and bronchodilators are the mainstay of therapy (grade A). There is no role for prophylactic antibiotics or expectorants in stable patients with chronic bronchitis (grade D). Chronic cough from COPD should be treated accordingly (see Chapter 22). The treatment of cough caused by potentially severe diseases, including ILD, CHF (see Chapter 34), and tuberculosis (see Chapter 103), should be directed at the underlying cause. Chest physiotherapy, hypertonic saline, and inhaled tobramycin may help cough in patients with chronic suppurative diseases (e.g., cystic fibrosis and bronchiectasis; grade B).

Eosinophilic bronchitis should be treated with inhaled corticosteroids (grade B). Patients with confirmed or probable whooping cough should receive a macrolide antibiotic for a week and should be isolated for 5 days from the start of treatment (grade A); early treatment within the first few weeks will diminish the coughing paroxysms and prevent spread of the disease; the patient is unlikely to respond to treatment beyond this period. In adults with chronic unexplained cough, common psychosocial problems such as anxiety, depression, domestic violence, and abuse or neglect are often associated with somatization disorders that should be evaluated by a psychotherapist (strongly recommended on the basis of expert opinion).

Nonspecific Antitussive Therapy

Ipratropium bromide is effective in suppressing the cough reflex through the efferent limb or decreasing airway secretions. A trial of inhaled or oral corticosteroids is often used in patients with intractable cough. This therapy may be particularly valuable in undiagnosed asthmatic patients and in patients with eosinophilic bronchitis. Non-narcotic medications, such as dextromethorphan and levopromazine, are useful for acute or chronic bronchitis but are not recommended for cough caused by the common cold or URI because of lack of proven efficacy (grade D). Narcotics (e.g., codeine, morphine) are not very effective antitussive agents and should be used judiciously. Guaifenesin and mucolytic drugs are of unclear benefit. It should be remembered that patients in the placebo arm of many cough studies improve, suggesting a strong “treatment” effect irrespective of drug used.

Avoiding Treatment Errors

Because chronic cough is, in and of itself, a nuisance symptom, the main potential treatment error is to misdiagnose the underlying disease. Thus, for a persistent cough, the diagnostic approach recommended previously is designed to detect important diseases.

Future Directions

Because cough is a common symptom of underlying respiratory and nonrespiratory disease, much of the future research in this area will address the underlying pathologic processes rather than the symptom itself. Studies measuring exhaled nitric oxide and inflammatory mediators in

breath condensate or bronchoalveolar lavage samples may shed important light on the role of lung inflammation in the pathogenesis of chronic cough.

Community-Acquired Pneumonia

Introduction

Community-acquired pneumonia (CAP) is an important source of morbidity and mortality in the United States. Each year, CAP results in about 10 million physician visits, 500,000 hospitalizations, and 45,000 deaths. About 258 cases of CAP per 100,000 population and 962 cases per 100,000 persons older than 65 years require hospitalization. The mortality rate of persons hospitalized is about 14% (range, 2% to 30%).

The following recommendations for the diagnosis and treatment of CAP are largely drawn from guidelines published by the Infectious Diseases Society of America (IDSA) and the American Thoracic Society (ATS), including an update published in 2007.

Etiology and Pathogenesis

Community-acquired pneumonia is an acute infection of the pulmonary parenchyma associated with symptoms of infection and accompanied by the presence of a new infiltrate on a chest radiograph or auscultatory findings consistent with pneumonia (such as altered breath sounds or localized rales). When CAP occurs in a patient who is hospitalized or who is a resident of an extended care facility, the infection is designated as “hospital” and “health care–associated pneumonia” and is treated according to different principles and guidelines. CAP in the normal host is caused by a variety of pathogens, with *Streptococcus pneumoniae* the most commonly identified (Table 18-1). The epidemiology, etiology, pathogenesis, and treatment of CAP differ from health care–associated pneumonia, pneumonia in the immunocompromised host, and pneumonia associated with travel outside the United States.

The lower respiratory tract is constantly exposed to microbes that are present in the upper airways through microaspiration. Usually, the lower airways remain sterile because of the pulmonary defense mechanisms, including the cough reflex and mucociliary clearance. The development of CAP indicates either a defect in defenses (e.g., damage to epithelial cells from smoking), exposure to an especially virulent microbe, or an overwhelming inoculum. Although microaspiration is the most common mechanism

that allows pathogens to reach the lung, hematogenous spread from a distant infected site, direct spread from a contiguous focus, and macroaspiration are other important mechanisms.

Clinical Presentation

Pneumonia should be suspected in patients with newly acquired lower respiratory symptoms such as cough, sputum production, pleuritic chest pain, and shortness of breath. Fever and chills are common. Elderly and immunocompromised patients may not manifest the classic symptoms of CAP such as fever and cough; if such patients exhibit a significant medical deterioration (e.g., decreased responsiveness, poor appetite, low-grade fever), CAP should remain high on the differential list.

Cough is the hallmark of pneumonia. Initially, it may be nonproductive, only to become productive with disease progression. The sputum may be yellow to green as a result of the action of myeloperoxidase produced by neutrophils. Green sputum occurs most commonly as a result of bacterial infection, but it may result from invasive viral illness. Occasionally, pigment-producing *Pseudomonas* species may present with green-colored sputum. The neutropenic patient will not produce purulent sputum even with a life-threatening pneumonia because of the inhibi-

Table 18-1 Most Common Etiologies of Community-Acquired Pneumonia

tion of an inflammatory response to the pathogen. Signs of pneumonia include elevated temperature, elevated respiratory and heart rates, hypoxia, use of accessory muscles, and general ill appearance. Auscultatory signs are secondary to alveolar infiltration and include dullness to percussion, decreased breath sounds, rales, and egophony.

Pneumonia is traditionally divided into typical and atypical categories. Typical pneumonia is caused by extracellular bacterial pathogens such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Klebsiella pneumoniae*, and *Staphylococcus aureus* (Figs. 18-1, 18-2, and 18-3). Its characteristics include sudden onset, prominent pulmonary symptoms and signs, purulent sputum, and clinical and radiographic evidence of lobar consolidation. Atypical pathogens consist of viruses and intracellular bacteria such as *Legionella* (Fig. 18-4) and *Mycoplasma* species and *Chlamydophila pneumoniae* (formerly *Chlamydia pneumoniae*). Pneumonia caused by atypical pathogens is often characterized by a stepwise fever curve, prolonged prodrome, frequent extrapulmonary symptoms and signs, nonpurulent sputum (i.e., dry cough), and diffuse infiltrates on chest radiography, often in an interstitial pattern. Extrapulmonary symptoms include headache and bullous myringitis (blood blebs on the tympanic membrane) with *Mycoplasma* species, headache and myalgias with viral influenza, and gastrointestinal symptoms (e.g., nausea, vomiting, diarrhea) with *Legionella* species. Often, the differentiation of typical from atypical

pneumonia is not clear because patients present with overlapping symptoms.

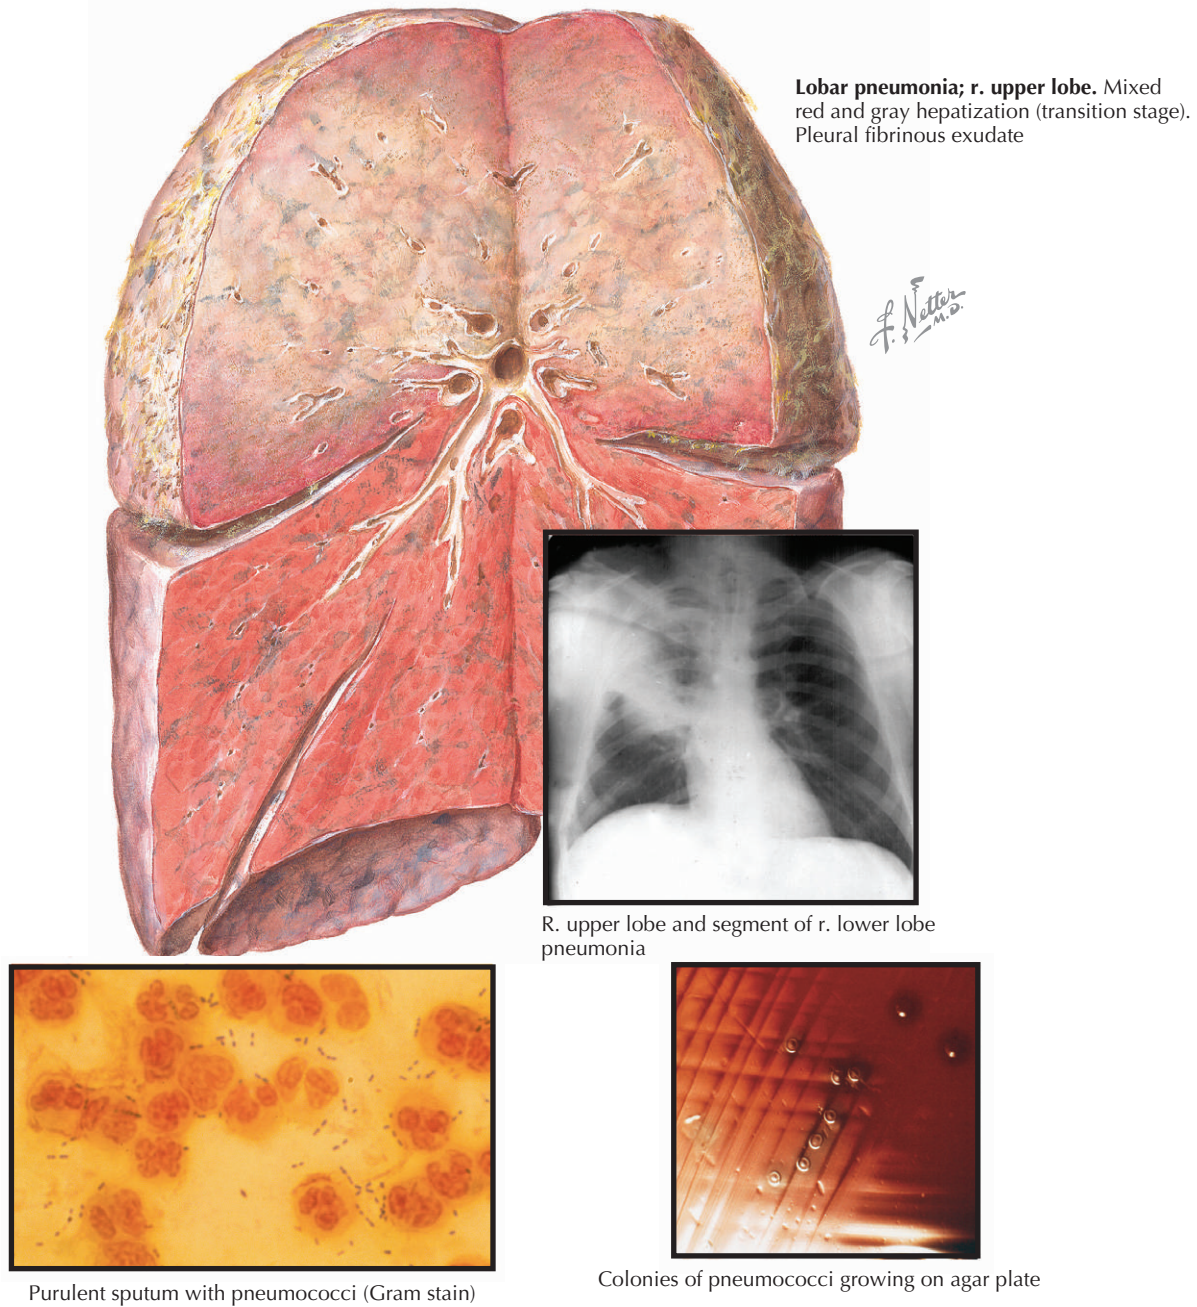

Differential Diagnosis

The differential diagnosis of lower respiratory tract illness is extensive and includes both upper and lower respiratory tract infections as well as noninfectious disorders. Important noninfectious etiologies that can mimic pneumonia include aspiration of blood or gastric contents, pulmonary emboli with or without pulmonary infarction, congestive heart failure, cryptogenic organizing pneumonia, primary pulmonary malignancy, metastatic cancer, acute respiratory distress syndrome, drug toxicity, pulmonary hemorrhage, sarcoidosis, and vasculitis (e.g., Wegener's granulomatosis). Many of these disorders are associated with fever, including aspiration of gastric contents, malignancy, pulmonary emboli with infarction, and vasculitis.

Diagnostic Approach

The diagnosis of CAP requires a combination of clinical and laboratory assessments (including microbiologic data). Differentiation of CAP from upper respiratory tract infection (URI) is important because most URIs and acute bronchitis are of viral origin and do not require anti-infective therapy. However, rapid testing for influenza A and B is indicated during epidemic periods because a positive result warrants treatment with a neuraminidase inhibitor (i.e., oseltamivir, zanamivir). Patients with bacterial pneumonia require appropriate antibiotic therapy. Obtaining a chest radiograph in persons with symptoms and signs suggestive of lower respiratory tract infection helps to substantiate the diagnosis of pneumonia. In addition, a chest radiograph is often useful for determining the etiologic diagnosis and the prognosis; it also raises suspicion for alternative diagnoses or associated conditions. For example, chest radiographs in patients with *Pneumocystis jirovecii* (formerly *Pneumocystis carinii*) pneumonia are normal at the time of presentation (false-negative results) in up to 30% of infected patients.

A few clinical pearls are helpful in evaluating a patient with pneumonia. First, viral infections are most common in the late fall through early spring and generally occur during community epidemics. Awareness of both local (e.g., influenza), national, and worldwide (e.g., severe acute respiratory syndrome) outbreaks is important. Second, clinicians must know the local epidemiology because several pathogens (e.g., *Histoplasma capsulatum*, *Coccidioides immitis*) occur only in selected areas of the United States. Third, *M. tuberculosis* and *B. pertussis* (whooping cough) deserve consideration in patients with prolonged (i.e., >2 to 3 weeks) cough. Fourth, *Pneumocystis* species should remain high on the differential diagnostic list of pneumonia in the immunocompromised host, especially persons with HIV infection, use of corticosteroids, or hematologic malignan-

Figure 18-1 Pneumococcal Pneumonia.

cies. Fifth, community-associated methicillin-resistant *S. aureus* (CA-MRSA) is increasingly recognized as a source of severe, often necrotizing, pneumonia, especially following a viral pneumonia such as influenza.

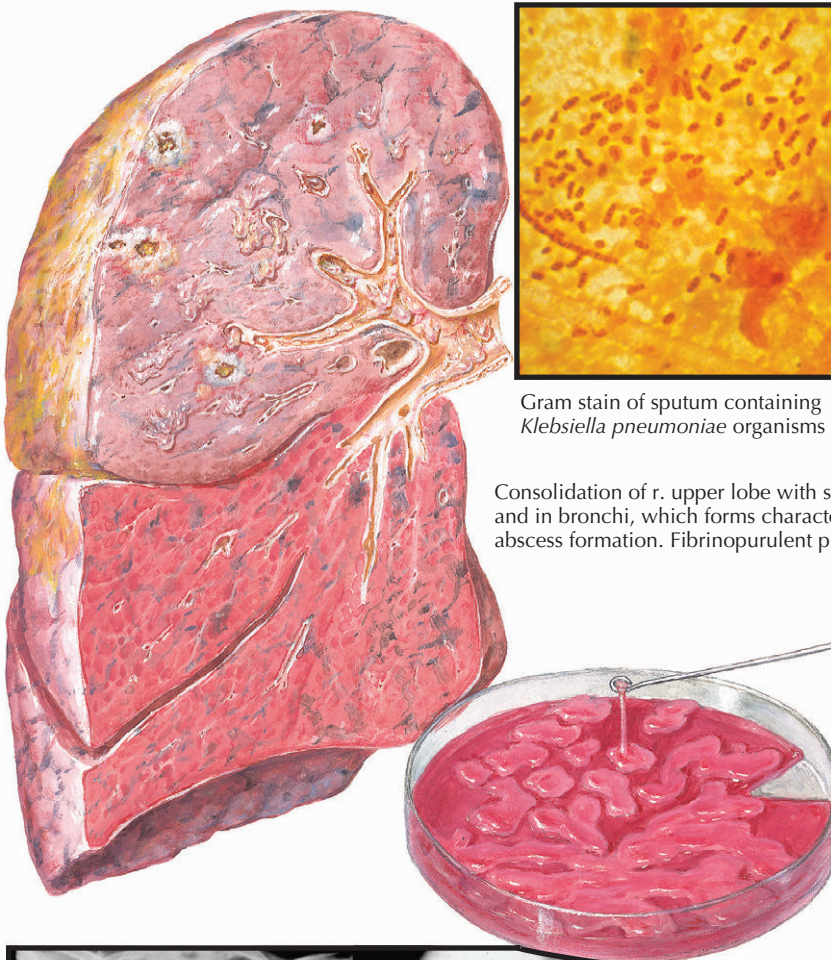

Management and Therapy

Optimal Therapy

The key decision concerning treatment is whether to treat in the outpatient setting or in the hospital. Most patients,

about 75%, can safely undergo therapy with oral antibiotics on an outpatient basis. Failure of recommended empiric therapy in appropriate outpatients is uncommon. The IDSA/ATS guideline recommends using a severity of illness score such as the CURB-65 criteria (confusion, elevated urea, elevated respiratory rate, low blood pressure, and age of at least 65) or prognostic models such as the Pneumonia Severity Index (PSI) as an aid in identifying patients who may be candidates for outpatient therapy. Hospitalization should be strongly considered for patients with two or more CURB-65 criteria: confusion, urea

F. Netter M.D.

PA and lateral chest films; *Klebsiella pneumoniae*, r. upper lobe

≥ 7 nmol/L, respiratory rate ≥ 30 /min, systolic blood pressure ≤ 90 mm Hg, diastolic blood pressure ≤ 60 mm Hg, and age ≥ 65 years. The PSI is more complex, requires a two-step screening process, and places patients into five risk categories. Step 1 requires assessment of 11 risk factors including age, 5 coexisting medical conditions, and 5 abnormalities on physical exam. If any of these 11 risk factors are present, patients are screened using a point scoring system that includes 20 risk factors (age, gender, 5 coexisting diseases, 5 abnormal physical exam findings, and

7 laboratory or radiographic findings). Although much more complex, the PSI score has been more extensively studied and validated than the CURB-65 criteria. The current recommendations are as follows: patients falling into class I (mortality 0.1%) and II (mortality 0.6%) can be treated as outpatients; patients in risk class III (mortality 2.8%) are considered for treatment in an observation unit or with short-term hospitalization, and risk class IV (mortality 8.5%) or V (mortality 31.1%) patients are treated as inpatients. These prediction rules are meant to contribute

Figure 18-3 Staphylococcal Pneumonia.

to rather than supersede the physicians' judgment. Outpatient treatment requires that the patient be able to comply with therapy and to absorb oral antibiotics. Patients with cognitive impairment, history of substance abuse, nausea and vomiting, or underlying disorders that increase the risk for morbidity but are not included in the scoring systems often require hospitalization. The second-level decision is whether to admit the patient directly to an intensive care unit (ICU) or high-level monitoring unit rather than to a general medical ward. About 10% of hospitalized patients with CAP require ICU admission. Patients with a major criterion or with three or more minor criteria warrant direct ICU admission (Box 18-1).

Clinicians should make every effort to establish an etiologic diagnosis. Doing so permits optimal antibiotic selection specifically directed at the causative agent. Second, it

provides a rational basis for a change from parenteral to oral therapy and for a change in therapy necessitated by an adverse drug reaction. Third, a specific diagnosis permits antibiotic selection that limits the consequences of antibiotic use in terms of cost, inducible resistance, and adverse drug reactions. Finally, this allows identification of pathogens of potential epidemiologic significance, such as *Legionella* species, *B. pertussis*, and CA-MRSA. A detailed history may be helpful in suggesting a diagnosis (Table 18-2).

After a clinical diagnosis has been made, a microbiologic diagnosis using bacteriologic cultures of sputum and blood should be attempted in hospitalized patients. Ideally, initial studies should include a sputum sample from a deep-cough specimen for Gram stain (and culture) to aid in initial selection of antimicrobial therapy. Sputum is acceptable for culture if, under low-power microscopy, there are

F. Netter M.D.

more than 25 polymorphonuclear cells and less than 10 to 25 squamous epithelial cells. The Gram-stain appearance of *S. pneumoniae* (lancet-shaped gram-positive diplococci), *H. influenzae* (small gram-negative coccobacilli), and *S. aureus* (clusters of gram-positive cocci) are sufficiently distinctive to allow a tentative diagnosis. Blood culture results are positive in 5% to 14% of patients hospitalized with pneumonia. Additional diagnostic tests including rapid tests for respiratory syncytial virus and influenza, special smears (acid-fast smears) and culture for *M. tuberculosis*, urine antigen for *Legionella* species, and serologic tests for

Mycoplasma pneumoniae or *Legionella* or *Chlamydia* species may be indicated, depending on the presence of epidemiologic clues, chest radiographic pattern, severity of illness, and host defense abnormalities. Many additional tests are available to diagnose less common pathogens.

Computed tomography (CT) or magnetic resonance imaging (MRI) is rarely required for the routine diagnosis of CAP. However, a CT scan, especially using high-resolution CT, is more sensitive than plain films for the evaluation of interstitial disease, bilateral disease, cavitation, empyema, and hilar adenopathy. Thus, a chest radio-

Box 18-1 Criteria for Severe Community-Acquired Pneumonia**Major Criteria**

- Invasive mechanical ventilation
- Septic shock with need for vasopressors

Minor Criteria^a

- Respiratory rate^b ≥ 30 breaths/min
- PaO₂/FiO₂ ratio^b ≤ 250
- Multilobar infiltrates
- Confusion, disorientation
- Uremia (BUN level ≥ 20 mg/dL)
- Leukopenia^c (WBC ≤ 4000 cells/mm³)
- Thrombocytopenia (platelet count $< 100,000$ cells/mm³)
- Hypothermia
- Hypotension

^aOther criteria to consider include hypoglycemia (in nondiabetic patients), acute alcoholism and alcohol withdrawal, hyponatremia, unexplained metabolic acidosis or elevated lactate level, cirrhosis, and asplenia.

^bA need for noninvasive ventilation can substitute for respiratory rate ≥ 30 breaths/min or PaO₂/FiO₂ ratio^b ≤ 250 .

^cAs a result of infection alone.

graph is the preferred method for initial imaging, with CT scan or MRI reserved for further anatomic definition (e.g., detecting cavitation, adenopathy, or mass lesions). If radiographic studies demonstrate an effusion, consideration should be given to a diagnostic aspiration to exclude an empyema, which would require drainage.

Bronchoscopy is rarely indicated in immunocompetent patients with CAP. It should be considered in patients with a fulminant course without a clear etiology who require admission to the ICU or who have complex pneumonia unresponsive to antimicrobial therapy. Bronchoscopy is particularly useful for the detection of selected pathogens, such as *Pneumocystis*, *Mycobacterium*, and *Legionella* species and cytomegalovirus. Standard hematologic tests, chemistries, and oxygen saturation help assess the physiologic status of hospitalized patients and the need for intensive care.

Empiric antimicrobial therapy is guided by knowledge of likely pathogens (see Tables 18-1 and 18-2) and local resistance patterns. Therapy guidelines have undergone recent changes due to the increase in antimicrobial resistance of common pathogens (e.g., *S. pneumoniae*). Therapy may need to be altered or modified by host factors including age, pregnancy, liver or renal dysfunction, use of other medications that interact with planned antimicrobial therapy, and drug allergies. When possible, the least expensive effective therapy should be chosen. For oral therapy, important considerations include the frequency of

dosing (better compliance is achieved with once- or twice-daily administration), taste, and the frequency of gastrointestinal irritation.

Antimicrobial therapy should be initiated promptly after the diagnosis is established with radiography, and ideally after Gram stain results are available to facilitate antimicrobial selection. For patients admitted to an inpatient unit through the emergency department, therapy should be initiated in the emergency department (preferably after blood culture specimens have been obtained). Antibiotic therapy should not be withheld from acutely ill patients because of delays in obtaining appropriate specimens or the results of Gram stains and cultures. The empiric therapy recommended by the IDSA and ATS is summarized in Box 18-2. If an etiologic agent is isolated, therapy should be altered based on the known susceptibilities of the pathogen or in vitro testing. Drug resistance is a growing problem with *S. pneumoniae* (especially resistance to β -lactam antibiotics, macrolides, and tetracyclines) and *S. aureus* (especially resistance to β -lactam antibiotics, macrolides, quinolones). The duration of therapy is based on the pathogen, response to therapy, comorbid illness, and complications. Patients should receive therapy for at least 5 days (longer therapy required for *S. aureus* and enteric gram-negative bacteria). In general, hospitalized patients can be switched from intravenous therapy to oral therapy when they are hemodynamically stable and improving clinically, are able to ingest medications, and have a normally functioning gastrointestinal tract. Criteria for clinical stability include temperature $\leq 37.8^\circ\text{C}$, heart rate ≤ 100 beats/min, respiratory rate ≤ 24 breaths/min, systolic blood pressure ≥ 90 mm Hg, arterial oxygen saturation $\geq 90\%$ or PO₂ ≥ 60 mm Hg on room air, ability to maintain oral intake, and normal mental status.

Avoiding Treatment Errors

CAP is not difficult to diagnose in patients presenting with typical symptoms of fever, cough, sputum production, and shortness of breath. However, it is important to realize that pneumonia in elderly patients may present as confusion, lethargy, and poor feeding.

Both overtreatment and undertreatment for suspected pneumonia are common. Antibiotics should only be prescribed for patients with proven or highly suspected bacterial pneumonia. Although most patients can be treated as outpatients, many are inappropriately admitted to the hospital. However, the failure to admit appropriate patients should also be avoided. The CURB-65 criteria and PSI score are helpful guides in making admission decisions.

Empiric therapy is successful in most patients; nevertheless, a complete history and appropriate laboratory tests should be obtained for hospitalized patients to define the most appropriate therapy. A wider spectrum of pathogens, including multidrug-resistant pathogens, must be considered in immunocompromised patients or residents in an

Table 18-2 Epidemiology Clues Related to Specific Pathogens with Selected Community-Acquired Pneumonia

Epidemiologic Clue	Pathogen (Disease)
	Associated with Specific Pathogen
Poor dental hygiene; risk for aspiration (e.g., seizure disorder)	Anaerobes
Cough >2 weeks with whoop or post-tussive vomiting	<i>Bordetella pertussis</i>
Exposure to birds (especially psittacine birds)	<i>Chlamydia psittaci</i> (psittacosis)
Exposure to infected farm animals or cats, especially parturient animals	<i>Coxiella burnetii</i> (Q fever)
Exposure to rabbits or infected ticks	<i>Francisella tularensis</i> (tularemia)
Exposure to bats or soil enriched with bird dropping in an endemic area	<i>Histoplasma capsulatum</i> (histoplasmosis)
Hotel or cruise ship stay in previous 2 weeks	<i>Legionella</i> spp. (legionnaires' disease)
Exposure to cats and less commonly to dogs	<i>Pasteurella multocida</i> (pasteurellosis)
Exposure to infected fleas or host animals (e.g., ground squirrels) in an endemic area, or to persons with pneumonic plague	<i>Yersinia pestis</i> (plague)
	Associated with Multiple Pathogens
Alcoholism	<i>Streptococcus pneumoniae</i> , <i>Klebsiella pneumoniae</i> , anaerobes, <i>Acinetobacter</i> spp., <i>Mycobacterium tuberculosis</i>
Bioterrorism	<i>Bacillus anthracis</i> (anthrax), <i>Yersinia pestis</i> (plague), <i>Francisella tularensis</i> (tularemia)
Chronic obstructive pulmonary disease or smoking	<i>Haemophilus influenzae</i> , <i>Pseudomonas aeruginosa</i> , <i>Legionella</i> spp., <i>S. pneumoniae</i> , <i>Moraxella catarrhalis</i> , <i>Chlamydophila pneumoniae</i>
HIV infection (early)	<i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>M. tuberculosis</i>
HIV infection (late)	Above plus <i>Pneumocystis</i> , <i>Cryptococcus</i> , <i>Histoplasma</i> spp., <i>Aspergillus</i> , nontuberculous mycobacteria (especially <i>M. kansasii</i>), <i>Pseudomonas aeruginosa</i> , <i>H. influenzae</i>
Influenza active in community	Influenza, <i>S. pneumoniae</i> , <i>S. aureus</i> , <i>H. influenzae</i>
Lung abscess	Community-associated methicillin-resistant <i>S. aureus</i> , oral anaerobes, endemic fungal pneumonia, <i>M. tuberculosis</i> , nontuberculous mycobacteria
Residence in an extended care facility	<i>S. pneumoniae</i> , gram-negative bacilli, <i>H. influenzae</i> , <i>Staphylococcus aureus</i> , anaerobes, viral influenza, <i>Mycobacterium tuberculosis</i>
Structural abnormalities of the lung (e.g., cystic fibrosis, bronchiectasis)	<i>Pseudomonas aeruginosa</i> , <i>Burkholderia cepacia</i> , <i>S. aureus</i>
Travel to or residence in Southwestern U.S.	<i>Coccidioides</i> species, Hantavirus
Travel to or residence in Southeast and East Asia	<i>Burkholderia pseudomallei</i> , avian influenza, severe acute respiratory syndrome

extended care facility, and for this reason there is a separate IDSA/ATS guideline to address this patient population.

The optimum treatment of CAP requires at least 5 days of antibiotic therapy. Although some regimens are successful using 5 days of therapy (e.g., levofloxacin 750 mg each day for 5 days), most antibiotic agents are approved for 7 to 14 days. Patients should be discharged only when they demonstrate clinical improvement. Influenza and pneumococcal vaccines should be offered to appropriate patients per recommendations by the Advisory Committee on Immunization Practices (ACIP).

Prevention

The annual impact of viral influenza is highly variable. During years in which the infection is epidemic, its impact on CAP is sizeable as a result both of primary influenza

pneumonia and secondary bacterial superinfection. Persons 50 years of age or older, those at high risk for complications of illness, and all health care workers should receive the influenza vaccine as recommended by ACIP. The currently available 23-valent pneumococcal capsular polysaccharide vaccine is about 50% effective in preventing hospitalization and about 80% effective in preventing death from pneumococcal disease in immunocompetent adults. All adults who are older than 65 years and all younger persons who are at high risk for pneumococcal infection, such as those with HIV infection, should receive the pneumococcal vaccine.

Future Directions

Recommendations for the therapy of CAP are likely to require frequent modifications based on the emerging

Box 18-2 Empiric Therapy for Patients with Community-Acquired Pneumonia**Outpatients**

- Previously healthy and no use of antimicrobials within previous 3 months
 - A macrolide: erythromycin, azithromycin, clarithromycin (strong recommendation)
 - Doxycycline (weak recommendation)
- Presence of comorbidities such as chronic heart, lung, liver, or renal disease; diabetes mellitus; alcoholism; malignancy; asplenia; immunosuppressing conditions or use of immunosuppressive drugs; or use of antimicrobials within the previous 3 months (in which case an alternative from a different class should be selected)
 - A respiratory fluoroquinolone (levofloxacin [750 mg], moxifloxacin) (strong recommendation)
 - A β -lactam (high-dose amoxicillin [e.g., 1 g 3 times per day] or amoxicillin-clavulanate [2 g 2 times per day] is preferred; alternatives include ceftriaxone, cefpodoxime, and cefuroxime [500 mg 2 times per day]) *plus* a macrolide (strong recommendation)
- In regions with a high rate (>25%) of infections with high-level (MIC ≥ 16 $\mu\text{g/mL}$) macrolide-resistant *Streptococcus pneumoniae*, consider use of alternative agents for patients without comorbidities (moderate recommendation)

Inpatients, non-ICU Treatment

- A respiratory fluoroquinolone (strong recommendation)
- A β -lactam plus a macrolide (strong recommendation)

Inpatients, ICU Treatment

- A β -lactam (cefotaxime, ceftriaxone, or ampicillin-sulbactam) *plus* either azithromycin or a fluoroquinolone (preferred) (for penicillin-allergic patients, a respiratory fluoroquinolone and aztreonam are recommended)

Special Concerns

- If pseudomonas is a consideration (moderate recommendation)
 - An antipseudomococcal, antipseudomonal β -lactam (piperacillin-tazobactam, cefepime, imipenem, or meropenem) plus either ciprofloxacin or levofloxacin (750 mg), *or*
 - The above β -lactam plus an aminoglycoside and azithromycin, *or*
 - The above β -lactam plus an aminoglycoside and an antipseudomonal fluoroquinolone (for penicillin-allergic patients, substitute aztreonam for above β -lactam)
 - Generally preferred are: an extended-spectrum cephalosporin or β -lactam/ β -lactamase inhibitor plus either fluoroquinolone or macrolide
- If community-associated methicillin-resistant *S. aureus* (CA-MRSA)
 - Add vancomycin or linezolid (moderate recommendation)

Pleural Effusion and Pneumothorax

Introduction

Typically, pleural effusions and pneumothoraces are secondary manifestations of other underlying disease states, such as empyema with pneumonia or spontaneous pneumothorax with emphysema. Less commonly, the pleura can be the primary site of disease, as with mesothelioma. Although many different diseases may cause a pleural effusion (Box 19-1), the most common causes in the United States are pneumonia, congestive heart failure (CHF), and cancer. The diagnostic approach in a patient with a pleural effusion largely depends on the probable etiologies of the effusion in that patient. Much is known about the clinical patterns of pleural diseases, but surprisingly little is understood about their pathogenesis.

Etiology and Pathogenesis

The pleural space, 10 to 20 mm in diameter, is filled with a thin layer of pleural fluid that acts as a lubricant. Both the visceral and parietal pleura are lined with a single layer of mesothelial cells overlying a layer of connective tissue and derive their blood supply from the systemic capillaries.

Pleural fluid can originate in the interstitial spaces of the lung, the pleural capillaries, the intrathoracic lymphatics, or the peritoneal cavity. In normal individuals, the origin of most pleural fluid is the capillaries in the parietal pleura, and the amount of fluid produced each day is about 0.1 to 0.2 mL/kg of body weight. The pleural space is in communication with the lymphatic vessels by means of stomas in the parietal pleura. The capacity for lymphatic clearance of fluid is 20-fold to 30-fold greater than the rate of fluid influx. Normal fluid has a pH of 7.6, protein of less than 1.5 g/dL, and a cell count of about 1500 cells/mL with a predominance of monocytes.

Fluid accumulates when the rate of formation exceeds the rate of absorption; the most common cause is increased interstitial fluid in the lungs. Mechanisms for pleural fluid accumulation include increased hydrostatic pressure, decreased oncotic or pleural pressure, increased vascular permeability, transdiaphragmatic movement of ascitic fluid, and disruption of the thoracic duct. Obstruction of the lymphatics draining the parietal pleura and an eleva-

tion of systemic vascular pressures are the most common causes of decreased fluid absorption.

Clinical and Radiologic Presentation

Patients may present asymptotically or with pleuritic chest pain, nonproductive cough, and dyspnea. Examination of the chest reveals decreased tactile fremitus and diminished or absent breath sounds. When pleural effusions diminish in size spontaneously or because of treatment, a pleural rub may develop.

Obliteration of the posterior costophrenic angle by a meniscus-shaped homogeneous shadow is a common finding on the upright chest radiograph. As more fluid accumulates, the diaphragm silhouette on the affected side is lost, and the fluid extends upward around the anterior, lateral, and posterior thoracic walls. The lateral decubitus radiograph helps to quantify the size of the effusion. Fluid that exceeds 10 mm in diameter from the inside margin of the rib to the outside margin of the lung is amenable to thoracentesis.

At times, substantial amounts of pleural fluid can be present in a subpulmonic location without spilling into the costophrenic sulci. The radiographic characteristics of a subpulmonic effusion include elevation of the diaphragm, lateral displacement of the dome of the diaphragm,

Box 19-1 Differential Diagnosis of Pleural Effusion and Pneumothorax**Transudates**

Congestive heart failure, urinothorax, cirrhosis and ascites, myxedema, nephrotic syndrome, pulmonary embolism, peritoneal dialysis, malignancy, superior vena caval obstruction, atelectasis

Exudates

Infectious diseases: parapneumonic, empyema, tuberculosis, aspergillosis, blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis, viral infections, nocardiosis, actinomycosis, paragonimiasis, amebiasis

Gastrointestinal diseases: pancreatitis, pancreatic pseudocyst, esophageal perforation, abdominal surgery, postsclerotherapy, abscess

Collagen vascular diseases: rheumatoid arthritis, systemic lupus, Sjögren's syndrome, Churg-Strauss vasculitis, familial Mediterranean fever, immunoblastic lymphadenopathy

HIV disease: Kaposi's sarcoma, parapneumonic, tuberculosis, opportunistic infections, other malignancies

Malignancy: metastatic carcinoma, lymphoma, mesothelioma, leukemia, multiple myeloma

Lymphatic diseases: chylothorax, yellow nail syndrome, lymphangiomyomatosis

Drugs: nitrofurantoin, amiodarone, dantrolene, methysergide, procarbazine, drug-induced lupus, bromocriptine, minoxidil, bleomycin, methotrexate, mitomycin

Miscellaneous: pulmonary embolism, sarcoidosis, benign asbestos effusion, uremia, Meig's syndrome, radiation therapy, hemothorax, post-thoracotomy

diaphragmatic flattening, and if the effusion is on the left side, a gap greater than 2 cm between the left hemidiaphragm and the gastric bubble.

When the patient is in the supine position, pleural fluid gravitates to the posterior parts of the thoracic cavity. The supine radiograph reveals blunting of the costophrenic angle, loss of the hemidiaphragm silhouette, and increased homogeneous density superimposed over the lung.

When the entire hemithorax is opacified because of a pleural effusion, the mediastinum shifts to the contralateral side. Shifting of the mediastinum toward the ipsilateral side implies either complete obstruction of the ipsilateral mainstem bronchus or a trapped lung as in mesothelioma. If no shift is evident, the mediastinum is likely fixed as a result of fibrosis or malignant infiltration.

Diagnostic Approach, Management, and Therapy

A diagnostic thoracentesis is performed when a clinically significant effusion (thickness of pleural fluid on the lateral decubitus radiograph greater than 10 mm) is present or when loculated fluid is demonstrated on ultrasound. If a

patient has typical clinical signs of CHF and bilateral pleural effusions, and is afebrile, a trial of diuresis can be undertaken. If the effusions persist for more than 3 days, thoracentesis is indicated.

Appearance of the Pleural Fluid

The gross appearance of the pleural fluid often provides useful information. Turbid fluid is usually associated with a chylothorax, elevated levels of cholesterol (pseudochylothorax), or empyema. Chocolate-brown fluid suggests amebiasis with a hepatobiliary fistula. Clear or bloody viscous fluid (increased hyaluronic acid level) is suggestive of malignant mesothelioma. Yellow-green fluid is described with rheumatoid pleural effusions, and black fluid with *Aspergillus* species infection. A bloody effusion with a red blood cell count of more than 100,000/mm³ suggests trauma, malignancy, or pulmonary embolism. When the pleural fluid hematocrit exceeds 50% of that of the peripheral blood, a hemothorax is present, and chest tube thoracostomy should be considered (Fig. 19-1). A feculent odor indicates an anaerobic infection; an ammonia scent is associated with urinothorax.

Pleural Fluid Analysis

Routine tests performed on all effusions include protein, lactate dehydrogenase (LDH), glucose, pH, and differential cell count. Additional studies include Gram stain and culture, potassium hydroxide preparation and fungal culture, acid-fast bacteria smear and culture, and cytology. In the appropriate clinical context, additional studies such as amylase, triglycerides, cholesterol, rheumatoid factor, and antinuclear antibody may be helpful.

Differential white blood cell count is one of the most informative tests on pleural fluid. Neutrophils predominate (>50% of the cells) in pleural fluid resulting from acute inflammatory processes such as bacterial infection, pancreatitis, and pulmonary embolism. Lymphocyte predominance indicates that the patient most likely has a malignancy or tuberculosis, although predominance of lymphocytes can also be seen in pleural effusions after coronary artery bypass surgery. The most common cause of pleural fluid eosinophilia (>10% eosinophils) is the presence of air or blood in the pleural space; other causes include asbestos, drugs (dantrolene, nitrofurantoin, bromocriptine), parasitic infections (paragonimiasis, amebiasis), and Churg-Strauss syndrome. Pleural fluid eosinophilia is uncommon in patients with cancer or tuberculosis, unless the patient has undergone repeated thoracenteses. Basophilia (>10%) is most common with leukemic pleural involvement. The presence of mesothelial cells (>5%) excludes tuberculosis.

Specific tests may provide additional insight. A markedly elevated fluid protein (>7 g/dL) implies a paraproteinemia or multiple myeloma. A low pleural fluid glucose

Figure 19-1 Hemothorax.

level (<60 mg/dL) indicates rheumatoid disease, empyema, a complicated parapneumonic effusion, malignancy, esophageal rupture, and occasionally tuberculosis. Pleural fluid amylase above the upper limits for serum indicates one of four problems: pancreatic disease, esophageal rupture, malignancy, or ruptured ectopic pregnancy. A pH below 7.30 is seen in esophageal rupture, empyema, rheumatoid effusion, malignant effusion, lupus pleuritis, tuberculosis, and systemic acidosis. In the evaluation of collagen vascular disease, measurement of a rheumatoid factor and antinuclear antibodies often provides very useful information.

Transudate versus Exudate

A transudative effusion develops when systemic factors (hydrostatic or oncotic pressures) influencing the forma-

tion of fluid are altered. Vascular permeability is normal. Exudative effusions develop when the pleural surfaces or the capillaries in the location where the fluid accumulates are altered. Exudative pleural effusions meet at least one of the following criteria (Light's criteria): (1) fluid-to-serum protein ratio of more than 0.5; (2) fluid-to-serum LDH ratio of more than 0.6; and (3) pleural fluid LDH greater than two thirds the upper limit of normal for serum LDH. Transudative effusions meet none of the criteria.

A confounding factor encountered with the diagnostic separation of transudates and exudates is seen in diuretic-treated CHF, in which the fluid protein can be elevated in the range of 3 to 4 g/dL. In this instance, the pleural fluid-to-serum albumin gradient is useful; a gradient greater than 1.2 g/dL greatly increases the probability that the pleural fluid is a result of CHF.

(Right) Diffuse lesion (involving both medial and lateral aspects of limb)

Transudative Effusions

CHF is the most common cause of pleural effusions; most patients (88%) have bilateral effusions. Unilateral right- and left-sided effusions are reported in 8% and 4%, respectively. About 25% of patients with unilateral effusions attributable to CHF have concomitant pneumonia or pulmonary embolism. Patients with bilateral effusions and the accompanying physical findings of left ventricular dysfunction can safely be observed without thoracentesis. Failure of the effusion to respond to heart failure management or the presence of pleuritic chest pain or fever mandates evaluation of the pleural fluid. Other causes of transudative effusions are listed in Box 19-1.

Exudative Effusions

The differential diagnosis of exudative pleural effusions is extensive (see Box 19-1). The most common causes are infectious processes and malignancy (Fig. 19-2).

Parapneumonic effusions, associated with bacterial pneumonia or lung abscess, are the most common cause of exudative effusions in the United States. About 40% of cases of pneumonia have an associated pleural effusion. The bacteriology of empyema or complicated pleural effusions includes a predominance of gram-positive aerobes (*Streptococcus pneumoniae*, *Staphylococcus aureus*), gram-negative aerobes (*Klebsiella* species, *Pseudomonas* species, *Haemophilus influenzae*), and anaerobes (*Bacteroides* species,

Peptostreptococcus). *S. pneumoniae* is still responsible for most bacterial pneumonias, and an associated pleural effusion occurs in 40% to 53% of patients. Patients with anaerobic bacterial infections that involve the pleural space frequently present with a subacute illness. Many patients have a history of alcoholism, an episode of unconsciousness, or another factor that predisposes to aspiration. Typically, uncomplicated parapneumonic effusions have a pH greater than 7.30, glucose greater than 60 mg/dL, and LDH greater than 1000 IU/L and resolve spontaneously with appropriate antibiotic therapy. In addition to treatment with appropriate antibiotics, the main management decision is whether to insert a chest tube, a decision that is made after analysis of the pleural fluid obtained with a diagnostic thoracentesis. An empyema is pus in the pleural space and warrants immediate drainage with tube thoracostomy. A complicated parapneumonic effusion is defined by one or more of the following: pleural fluid pH greater than 7.0, glucose less than 40 mg/dL, LDH greater than 1000 IU/L, and Gram stain or culture positivity. These effusions are not likely to respond to antibiotic therapy alone, and drainage with tube thoracostomy (chest tube) is necessary. Inadequate drainage of an empyema or lack of clinical improvement requires aggressive management with computed tomography (CT) imaging and further intervention. The CT is useful to evaluate for the progressive development of a loculated effusion (pleural fluid that becomes encapsulated by adhesions anywhere between the parietal and the visceral pleura or in the interlobar fissures). Although individual studies of intrapleural installation of thrombolytics such as streptokinase have reported successful lysis of loculations and improved drainage through chest tube, a recent meta-analysis did not support routine use of fibrinolytics in all patients who required chest tube drainage for empyema or complicated parapneumonic effusions. Surgical options include decortication and open drainage.

Tuberculous pleural effusions are rare; typically, they present as an acute illness. Purified protein derivative skin test results are negative in about one third of patients. Fluid examination reveals a lymphocyte-predominant exudate. Mesothelial cells and eosinophils are uncommon. Typically, the fluid protein is greater than 5 g/dL, LDH is mildly elevated, and the glucose is less than 60 mg/dL. The acid-fast bacteria smears are rarely positive, and less than 40% of patients have positive pleural fluid cultures. Alternative tests to aid in the diagnosis of tuberculous pleurisy include adenosine deaminase (>40 U/L), interferon- γ (level of 140 pg/mL is comparable to an adenosine deaminase level of 40 U/L), or polymerase chain reaction for mycobacterial DNA. Pleural biopsy is reported to have a high diagnostic yield. Most tuberculous effusions resolve spontaneously; however, treatment with standard tuberculous therapy is indicated to prevent recurrent disease. Serial thoracentesis has not been shown to improve outcome.

Malignant pleural effusions are due most commonly to lung (30%) and breast (25%) cancer. Lymphoma is responsible for 20% of malignant effusions. Mechanisms for these effusions include direct pleural involvement by tumor, reduced pleural pressure associated with bronchial obstruction, pulmonary embolism, or sequelae of chemotherapy or radiation therapy. Malignant effusions are usually moderate in size and associated with dyspnea, show a lymphocyte predominance, and have red blood cell counts greater than 1,000,000/mm³. Large tumor burden is associated with a low pH (<7.30) and glucose (<60 mg/dL) as well as shortened survival time. Pleural fluid cytology is diagnostic in about 65% of cases. The yield can increase when three separate fluid specimens are submitted. Closed pleural biopsy (CPB) is only diagnostic in about 50% of cases. Thoracoscopy provides a higher diagnostic yield of 93%. Therapeutic options include treating the underlying cancer, drainage with pigtail catheter or chest tube, and chemical pleurodesis.

Chylothorax is characterized by a milky-white effusion with an elevated triglyceride level caused by the accumulation of chyle in the pleural space from disruption of the thoracic duct. The most common cause of chylothorax is lymphoma (37% of cases). Other causes include metastatic cancer, surgical or nonsurgical trauma, lymphangiomyomatosis, and cirrhosis. Thoracentesis is used for diagnosis, and treatment includes a chest tube for drainage and lung expansion, bowel rest, parenteral nutrition, and treatment of the underlying disorder. If chylous drainage from the chest tube persists, repair of the thoracic duct needs to be considered.

Hemothorax is defined as a pleural fluid hematocrit exceeding 50% of the peripheral blood value. Trauma and iatrogenic vascular injury are the most common causes, but hemothorax is seen with a variety of disorders, including arteriovenous malformations, ascites, malignancy, coagulopathy, endometriosis, neurofibromatosis, pneumothorax, retroperitoneal hemorrhage, sequestration, and vascular anomalies. Treatment involves large-bore chest tube thoracostomy and thoracotomy if the bleeding persists.

Pneumothorax

Pneumothorax occurs when air escapes into the pleural space. Pneumothoraces can be divided into spontaneous (without antecedent trauma) and traumatic (result of direct or indirect trauma). Spontaneous pneumothoraces are further divided into primary (in otherwise healthy individuals) and secondary (a complication of underlying lung disease). Primary spontaneous pneumothoraces are caused by rupture of apical subpleural blebs. Most secondary spontaneous pneumothoraces are caused by chronic obstructive lung disease, although they have been associated with a variety of disorders (Box 19-2).

Dyspnea and pleuritic chest pain are the most common symptoms. If pneumothorax is suspected, an end-

Figure 19-3 Tension Pneumothorax.

expiratory chest radiograph is the most helpful diagnostic study. Simple observation will suffice as treatment in asymptomatic patients with small (<15% of hemithorax) primary spontaneous pneumothoraces. Supplemental oxygen accelerates the rate of air absorption. Needle aspiration is the initial treatment for symptomatic primary spontaneous pneumothorax. If it is unsuccessful, chest tube thoracostomy should be performed. Chest tube thoracostomy is the treatment of choice for secondary spontaneous pneumothoraces.

Tension pneumothorax, a one-way valve mechanism that results in a progressive rise in pleural pressure, occurs in 3% to 5% of patients with spontaneous pneumothorax and in 5% to 15% of those with barotrauma (patients on mechanical ventilation) (Fig. 19-3). The patient will look extremely distressed, and physical exam will reveal absence of breath sounds on the involved side associated with deviation of the trachea to the contralateral side. Displacement of the trachea and mediastinum along with impaired venous return results in cardiopulmonary distress. Placement of a

large-bore needle or an angiocatheter into the chest anteriorly in the 2nd rib space will decompress the tension. The mortality rate is approximately 30% when treatment is delayed.

Avoiding Treatment Errors

Appropriate initial selection of antibiotic therapy for patients with pneumonia and pleural effusion depends on whether the pneumonia is community or hospital acquired; antibiotic coverage is then guided by the results of pleural fluid cultures. If the patient is thought to have an anaerobic infection, penicillin and clindamycin are the drugs of choice. Prompt recognition of complicated parapneumonic effusions and empyema is of utmost importance because adequate drainage of the pleural space is at least as important in the cure as antimicrobial therapy. Chest tube insertion must occur as soon as it is determined that the patient has an empyema or complicated parapneumonic effusion; the longer the chest tube is delayed, the greater the chance of loculation and the more difficult the pleural drainage becomes. Malnourishment and immunocompromise, major complications in patients with chylothorax, are caused by removal of large amounts of protein, fats, and lymphocytes with repeated thoracentesis or prolonged chest tube drainage. Surgical correction of the thoracic duct needs to be considered if the chylous drainage persists. Tension pneumothorax is a medical emergency that must be treated immediately.

Future Directions

The workup of pleural effusions is often a lengthy process fraught with pitfalls, particularly when dealing with malignant pleural effusions. Several studies suggest that thoracoscopy increases the diagnostic yield in patients with benign and malignant pleural disease when thoracentesis and CPB results are nondiagnostic. Thoracoscopy is a minimally invasive and relatively safe procedure that will likely supplant CPB in the diagnostic workup of malignant pleural effusions.

Asthma

Introduction

Asthma is a syndrome with a chronic but variable clinical course and presentation. Its main features are (1) reversible airflow obstruction, (2) nonspecific airways hyperreactivity, and (3) airways inflammation. The nonspecific nature of the hyperreactivity is perhaps a reflection of airway inflammation. Symptoms are triggered by nonallergic stimuli such as smoke and strong odors and quantified by sensitivity to inhalational challenge to nonallergic stimuli such as histamine. Airway hyperreactivity predisposes patients to symptoms in a variety of environments.

Both children and adults develop asthma. The remission rate in adults is 10% to 15% but is more than 50% in children. Despite advances in the understanding of asthma and better medications, asthma morbidity and mortality have increased. During the past 110 years, our understanding of asthma has changed greatly. It was long considered a disease of “twitchy” airways and a minor ailment that, according to Osler, allowed the patient to “pant into old age.” Now, asthma is considered a disease of chronic fluctuating airways inflammation with a lethal potential of 5000 deaths annually in the United States. It is a major public health problem that results in 1.8 million emergency room visits per year, with about 10% of patients requiring hospitalization at a cost of \$12 billion annually in the United States.

Etiology and Pathogenesis

Asthma manifests as inflammation in the lower airways. Over time, structural changes in the airway called *remodeling* result (i.e., muscle hypertrophy and thickening of the basement membrane) (Fig. 20-1). Acute asthma exacerbations cause airway muscle contraction, edema and sloughing of the airway mucosa, and the accumulation of mucus, cellular debris, and exudative secretions in the airway lumen. These changes degrade airway function, causing respiratory symptoms and even death by suffocation.

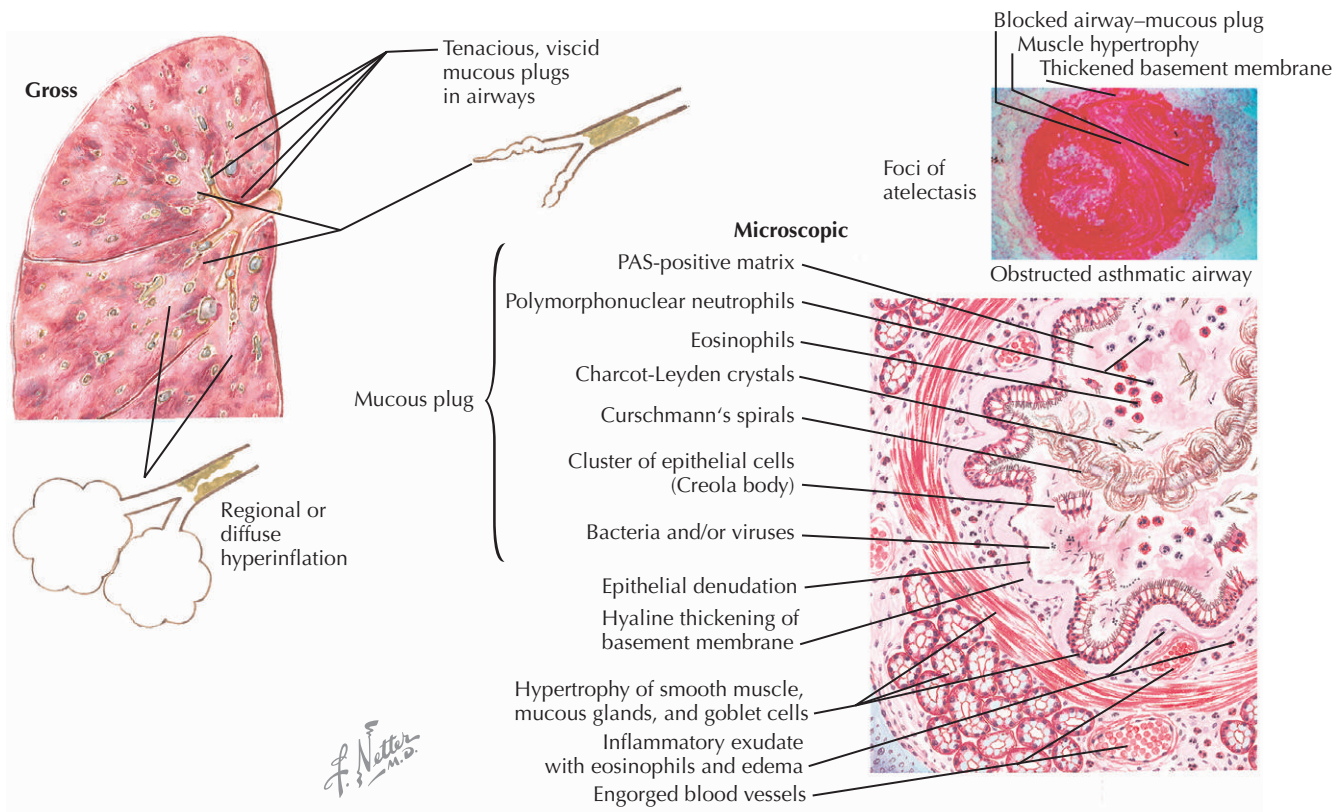

There are clinical and epidemiologic links between asthma and immunoglobulin E (IgE). Transcription factors, such as nuclear factor- κ B and members of the signal transduction-activated transcription (STAT) factor family, act on genes encoding for inflammatory cytokines, such as interleukins (ILs), and appear to initiate and sustain airway (Fig. 20-2) inflammation. Corticosteroids are the most effective *controllers* of asthma. They inhibit these transcription factors and airway inflammation. Asthma refractory to corticosteroids has been linked to the tumor necrosis factor axis. However, the newly described subset of natural killer T (NKT) cells, CD1d-restricted NKT

cells, with potent immunoregulatory functions and associated with asthma, are also resistant to modulation by corticosteroids.

A widely held mechanistic explanation is that inhaled antigen activates mast cells and T helper type 2 (Th2) lymphocytes, causing mediator release that promotes a persistent eosinophilic airway inflammation. There is no clear understanding of which biologic influences lead to chronic eosinophilic airway inflammation and hyperresponsiveness in asthma. Genetic factors (e.g., polymorphism for the IgE receptor, β receptor, matrix metalloproteinase, and CD14), environmental factors (e.g., excessive hygiene, vaccinations), and triggers (e.g., viral infection, exposures to tobacco smoke, pollutants, allergens) have all been implicated in the pathogenesis of asthma (see Fig. 10-3 in Chapter 10). Most asthmatic patients are atopic and have IgE-mediated disease, although there is evidence suggesting that intrinsic or nonatopic asthmatic patients may produce local, as opposed to circulating, IgE. Inflammation in atopic asthma can be demonstrated when the patient is challenged with inhaled allergen. The sensitive patient will show decline in pulmonary function demonstrated by obstruction of airflow with spirom-

etry and decrease in the forced expiratory flow at 1 second (FEV₁) and in the peak expiratory flow rate (PEFR). There is an initial decline within about 20 minutes associated with histamine release from mast cells that is stimulated by allergen binding to IgE on the mast cell surface. This immediate reaction is blocked by antihistamines but not by steroids. Classically, a spontaneous recovery occurs, only to be followed by a second, later decline in flow rates. Steroid pretreatment inhibits this late phase reaction, which is manifest by the recruitment of inflammatory cells into and around the lower airway (Fig. 20-3).

The estimates of the rate of decline in pulmonary function vary from 22 to 35 mL/year in FEV₁ in those with no asthma to 38 to 160 mL/year in FEV₁ in those with asthma. Whether remodeling contributes to or causes the accelerated loss of pulmonary function is not known.

Clinical Presentation

The clinical presentation of asthma is nonspecific (Fig. 20-4). Prototypically, the chief complaint consists of the triad of wheezing, shortness of breath, and chest tightness.

Figure 20-2 Extrinsic Asthma: Mechanism of Type 1 (Immediate) Hypersensitivity.

Symptoms vary in severity with time, sometimes changing in minutes or over many months, but commonly changing daily. Symptoms are typically worse at night. The hyper-reactivity is associated with triggers such as respiratory infections and exposure to strong odors or cold air. Repeated allergen exposures lower the threshold for non-specific hyperreactivity symptoms.

Occasionally, the sole presentation is dyspnea on exertion or cough. The cough with cough-variant asthma is usually unproductive. However, asthmatic patients can occasionally produce copious sputum laden with eosino-

phils and eosinophilic debris, mucus casts of the small airways (Curschmann's spirals), airway epithelial cells (sometimes in clumps referred to as *Creola bodies*), and Charcot-Leyden crystals (protein from eosinophils) (Fig. 20-5). Thirty percent or more of patients with chronic cough have asthma.

Acute exacerbations generally present, by patient history, as a sudden onset of respiratory distress. Following the resolution of the acute event, a history, either from the patient or from others who have observed the patient, often reveals that signs of disease activity have been present

Figure 20-3 Antigen Challenge.

FEV₁, forced expiratory volume in 1 second.

for many hours or days before the acute decompensation. However, actual sudden-onset respiratory failure and death are reported with asthma. At autopsy, these individuals demonstrate less mucous plugging and more neutrophilic, and less eosinophilic, airway infiltration. Death in this setting is associated with suffocation secondary to bronchospasm rather than mucous occlusion of the airways. Objective monitoring of signs of respiratory disease activity such as peak expiratory flows, nocturnal awakenings caused by shortness of breath, chest tightness, and cough can be useful as a guide to early intervention (Fig. 20-6). Occasionally, lung infection or pneumothorax is associated with acute decompensation. These conditions require early detection and therapy in severely affected asthmatic patients to ensure survival. Life-threatening signs include marked accessory muscle use, depressed mental status, diaphoresis, cyanosis, fatigue, pulsus paradoxus greater than 15 mm Hg, peak expiratory flows less than 100 L/min, and CO₂ retention.

Morbidity and mortality from asthma are increased in elderly patients. Generally, there is less reversible airflow obstruction and eosinophilia. IgE concentrations are also less impressively elevated. The signs and symptoms are similar to those of younger patients, and response to therapy is good. Conditions that exacerbate asthma, such as congestive heart failure, hypothyroidism, and gastroesophageal reflux, are more common in this population. Chronic sinus disease should be evaluated in all asthmatic patients with refractory disease.

Asthma has many clinical forms. The syndrome has been classified based on severity by the National Asthma Education and Prevention Program (NAEPP) guidelines:

intermittent asthma, requiring bronchodilator therapy less than twice weekly, and *persistent asthma*, graded as mild, moderate, or severe (Table 20-1). Commonly, individual asthmatic patients move among these levels of disease severity as the activity of their disease varies.

Steroid-dependent asthma, *steroid-resistant asthma*, and *difficult or brittle asthma* are other terms employed to describe categories of severe asthma. Asthma is also classified into groups by presumed cause: *intrinsic asthma* with no apparent allergic sensitization, and *extrinsic asthma* demonstrating elevated IgE and skin test reactions to allergens and seasonal variability (see Fig. 20-2). Other categories separate asthma by the type of trigger of the exacerbation: exercise-associated asthma, nocturnal asthma, and drug-induced asthma (e.g., angiotensin-converting enzyme inhibitors and β blockers).

Sensitivity to nonsteroidal anti-inflammatory drugs (NSAIDs) in asthma is associated with severe disease and nasal polyps (Samter's triad). The proposed mechanism is not linked to anti-NSAID antibody production. Rather, it is proposed that there is enhanced inflammatory leukotriene production when arachidonic acid metabolism to prostaglandins is blocked by the inhibition of cyclooxygenase and shunted to the 5-lipoxygenase pathway (Fig. 20-7). Treatment requires avoidance of all drugs classified as NSAIDs (not just salicylates, or aspirin), salicylate-containing foods (e.g., apricots, dates, and almonds to name but a few), and artificial yellow-red food dyes. Acetaminophen is considered safe. Desensitizing protocols have also been developed and are reported to be clinically beneficial but need to be carried out under careful medical supervision.

Asthmatic bronchitis is associated with an acute respiratory infection causing prolonged cough and sputum production. Allergic bronchopulmonary mycosis reflects a hypersensitivity to airway colonization with a fungus such as *Aspergillus* species. Occupational asthma refers to new-onset asthma caused by workplace exposures and asthma aggravated by exposure to factors in the work environment.

Differential Diagnosis

The causes of cough, wheezing, and dyspnea are legion, and the adage that "all that wheezes is not asthma" is true (Box 20-1).

Establishing the diagnosis of asthma in the setting of chronic obstructive pulmonary disease (COPD), which shares many signs and symptoms with asthma, can be challenging. Also, asthmatic smokers often can develop fixed airflow obstruction. However, even when no reversible airflow obstruction is demonstrated with spirometry, a clinical trial of corticosteroids and bronchodilators is appropriate. Another consideration is bacterial infections causing bronchial hyperreactivity in asthmatic patients, for example, pertussis, mycoplasma, and chlamydia pneumo-

Asthmatic airway—same view as shown in the normal airway

nias. The functional disorder of vocal cord dysfunction is often initially confused with asthma and is diagnosed when inspection of the vocal cords reveals a characteristic paradoxical movement of the vocal cords with respiration (see Chapter 15). Underlying sinus disease, hypothyroidism, and gastroesophageal reflux aggravating asthma also warrant consideration.

Diagnostic Approach

Patients with undiagnosed asthma often present with complaints of episodic attacks of wheezing, cough, or shortness of breath. The suspected diagnosis is supported when examination documents wheezing and when the history of asymptomatic intervals and precipitating triggers is elicited. A chest x-ray is obtained to exclude other pulmonary pathology. Generally, the chest x-ray in asthma is normal. Radiographs may demonstrate hyperinflation during an acute attack, but this finding is more often associated with COPD. Atelectasis with mucous plugging is associated with asthma (see Fig. 20-1). Pneumothorax is more

common in asthmatic patients and can present as an asthma exacerbation.

Spirometry measurements before and after administering a bronchodilator are usually obtained to demonstrate reversible airflow obstruction and to determine the severity of the acute disease (see Fig. 20-4). Chronic cough associated with normal spirometry and an elevated DLCO (carbon monoxide diffusion capacity) suggests the diagnosis of *cough asthma*. Skin scratch testing may be useful diagnostically and provides guidance when prescribing immunotherapy and designing avoidance strategies. Other observations supporting the diagnosis of asthma include variability in home monitoring of PEFs, improving PEFs on asthma therapy, hyperreactivity to challenge testing with histamine or methacholine, peripheral blood eosinophilia, elevated IgE, and the characteristic sputum previously described. Generally, the diagnosis is made correctly using only spirometry and chest radiography to support the physical examination and history. Failure to respond to asthma therapy should prompt a search for other causes.

Table 20-1 Stepwise Approach for Managing Asthma in Adults and Children Older than Five Years of Age: Treatment

<i>Clinical Features before Treatment or Adequate Control</i>			<i>Medications Required to Maintain Long-Term Control</i>
Classification	<u>Symptoms/Day</u> <u>Symptoms/Night</u>	<u>PEF or FEV₁</u> <u>PEF Variability</u>	Daily Medications
STEP 1 Mild intermittent	<2 days/wk ≤2 nights/mo	>80% <20%	No daily medication needed. Severe exacerbations may occur, separated by long periods of normal lung function and no symptoms. A course of systemic corticosteroids is recommended.
STEP 2 Mild persistent	>2/wk but <1×/day >2 nights/mo	≥80% 20%-30%	<i>Preferred treatment:</i> Low-dose inhaled corticosteroids <i>Alternative treatment:</i> Cromolyn, leukotriene modifier, nedocromil, <i>or</i> Sustained-release theophylline to serum concentration of 5-15 µg/mL
STEP 3 Moderate persistent	Daily >1 night/week	>60%<80% >30%	<i>Preferred treatment:</i> Low- to medium-dose inhaled corticosteroids and long-acting inhaled β ₂ agonists <i>Alternative treatment:</i> Increase inhaled corticosteroids within medium-dose range, <i>or</i> Low- to medium-dose inhaled corticosteroids and either leukotriene modifier or theophylline <i>If needed</i> (particularly in patients with recurring severe exacerbations): <i>Preferred treatment:</i> Increase inhaled corticosteroids within medium-dose range and add long-acting inhaled β ₂ agonists <i>Alternative treatment:</i> Increase inhaled corticosteroids within medium-dose range and add either leukotriene modifier or theophylline
STEP 4 Severe persistent	Continual Frequent	≤60% >30%	<i>Preferred treatment:</i> High-dose inhaled corticosteroids, <i>and</i> Long-acting inhaled β ₂ agonists, <i>and, if needed,</i> Corticosteroid tablets or syrup long term (2 mg/kg/day, generally do not exceed 60 mg per day). (Make repeat attempts to reduce corticosteroids and maintain control with high-dose inhaled corticosteroids.)
QUICK RELIEF All patients	Short-acting bronchodilator: 2-4 puffs short-acting inhaled β ₂ agonists as needed for symptoms. Intensity of treatment will depend on severity of exacerbation; up to 3 treatments at 20-min intervals or a single nebulizer treatment as needed. Course of systemic corticosteroids may be needed. Use of short-acting β ₂ -agonists >2×/wk in intermittent asthma (daily, or increasing use in persistent asthma) may indicate the need to initiate (increase) long-term control therapy.

Management and Therapy

Optimum Treatment

Asthma therapy focuses on the management of airway inflammation. The goal is to prevent exacerbations, minimize symptoms, and maintain near-normal lung function. Informed patient self-management with the goal of early

intervention, allergen and inhaled irritant avoidance strategies, and repeated review of the proper techniques for employing inhaled medications are keys to controlling asthma. Anti-inflammatory agents (e.g., inhaled corticosteroids [ICS]) are the pharmacologic cornerstones for controlling asthma. ICS therapy should be initiated when asthma symptoms occur even once or twice during a week.

Figure 20-7 Leukotriene Modifiers.

AA, arachidonic acid; LT, leukotriene; NSAID, nonsteroidal anti-inflammatory drug; HETE, hydroxyeicosatetraenoic acid; PGs, prostaglandins; Tx, thromboxane.

Bronchodilators such as β agonists, however, remain the cornerstone of acute management of exacerbations. Severe exacerbations may require monitoring in an intensive care unit and mechanical ventilation. Grading chronic asthma severity, however, is difficult. It is clear that physical examination, symptoms, and pulmonary function tests lack adequate predictive value. Even asthmatic patients with increasing PEFs have died suddenly of their disease. Asthma deaths are equally distributed among asthmatic patients classified by NAEPP guidelines as mild, moderate, or severe. Classification of severity by monitoring β_2 -agonist rescue use has identified *severe* asthmatic patients in the group defined as *mild* by NAEPP guidelines. A careful assessment of β_2 -agonist use is easily accomplished with many patients and provides a practical management tool. Titrating anti-inflammatory therapy to eliminate sputum eosinophils or nonspecific bronchial hyperreactivity, as measured by inhaled histamine challenge testing, produces better asthma control compared with NAEPP guidelines.

Soon-to-be-released guidelines will therefore incorporate strategies to better address the potential for asthma exacerbations and define the present status of asthma disease activity. Integral to each individual patient plan will be accurately judging how responsive the patient will be to available therapies over the long run.

 β_2 Agonists

β agonists reverse smooth muscle bronchospasm regardless of the stimulus, inhibit histamine and other mediator release from inflammatory cells, inhibit cholinergic neuro-

transmission, inhibit airway vascular leakage, and increase mucociliary clearance. Although the anti-inflammatory effects of β agonists in asthma have been difficult to demonstrate clinically, no other class of drug is as effective at relieving the acute symptoms of asthma. Racemic albuterol (R-albuterol) is a commonly used short-acting bronchodilator drug. Levalbuterol, the active component in R-albuterol, is available and may prove superior to R-albuterol. Short-acting β agonists are used on an as-needed basis to relieve symptoms and not routinely in an effort to prevent them. The frequency of as-needed use, therefore, is a marker of disease control. A metered dose inhaler (MDI) with a spacer is as effective as wet nebulizer delivery of the drug when airflow is not extremely restricted. Parenteral β -agonist or wet-nebulizer delivery should be considered if there is little air movement and if the MDI technique is inadequate. Intravenous epinephrine poses a cardiovascular risk in adults.

Long-acting β agonists, such as salmeterol and formoterol, are used in conjunction with inhaled steroids as preventive agents. This combination is more effective than doubling the dose of steroid. In vitro work demonstrates enhanced transport of the steroid receptor into the nucleus in the presence of a β agonist. Whether this is an explanation for the clinical observation is not clear. Monotherapy with long- or short-acting β agonists does not control the clinical expression of persistent asthma, is associated with an increased risk for asthma death, and should not be used. There is a controversial U.S. Food and Drug Administration black-box warning that cautions patients and physicians against the use of any β -agonist therapy for asthma.

Box 20-1 Differential Diagnosis of Common Diseases That Produce Signs and Symptoms Associated with Asthma

Recurrent Episodic Dyspnea

- Chronic obstructive pulmonary disease
- Coronary artery disease
- Congestive heart failure
- Mitral stenosis
- Pulmonary emboli
- Recurrent gastroesophageal reflux with aspiration
- Recurrent anaphylaxis
- Systemic mastocytosis
- Carcinoid syndrome
- Muscle weakness

Chronic Cough

- Rhinitis
- Sinusitis
- Otitis
- Bronchitis (chronic or postviral)
- Bronchiectasis
- Gastrointestinal reflux with or without aspiration
- Cystic fibrosis
- Pneumonia
- Pulmonary fibrosis
- Eosinophilic pneumonia, parasitic infections
- Drugs (e.g., angiotensin-converting enzyme inhibitors)

Airflow Obstruction

- Chronic obstructive bronchiolitis and emphysema
- Bronchiolitis obliterans
- Cystic fibrosis
- Organic or functioning laryngeal narrowing
- Extrinsic or intrinsic narrowing of trachea or main-stem bronchus
- Airway tumors
- Churg-Strauss vasculitis
- Hypothyroidism aggravating asthma

Adapted from Murray JF, Nadel JA (eds): Textbook of Respiratory Medicine, 3rd ed. Philadelphia, WB Saunders, 2000, p 1269.

Steroids

Steroids are the most effective agents for preventing asthma symptoms through their role as inhibitors of inflammatory mediator production. They are the only class of medication demonstrated to decrease asthma mortality. Inhaled steroids are recommended to control chronic asthma when as-needed β -agonist rescue is required more than once or twice weekly. Potent inhaled steroids take days to weeks to produce significant clinical improvement. There is, however, reported effect in 2 hours with 4 puffs (1000 μ g) of flunisolide every 10 minutes for 3 hours by MDI with spacer. This suggests a role for inhaled steroids in acute exacerbations.

Inhaled steroids dosing by NAEPP guidelines is established by PEFr measurements, the frequency of use of rescue short-acting albuterol, and symptoms (see Table 20-1). If, instead, inhaled corticosteroid dosing is based on normalization of hyperreactivity, defined by challenge

testing with histamine, much higher doses of inhaled steroid are required. However, at these doses, asthma control is superior, and asthmatic lung remodeling improves (see Fig. 20-1).

A dose of 60 mg of prednisone orally to 125 mg of methylprednisolone intravenously is commonly used to initiate therapy in severely ill asthmatics. Generally, there is good bioavailability of steroids orally; however, intravenous administration is used to ensure delivery in the acute situation. The onset of action is uncertain, and variability is reported as 1 to 24 hours. Oral prednisone as outpatient therapy following a severe exacerbation is generally used at a dose of 40 mg orally each morning for 2 weeks. Morning dosing of systemic steroids is recommended to minimize adrenal suppression. Tapering schedules are the norm. However, this dose is generally tolerated without a taper for 3 weeks. Intramuscular dosing has not been studied as a long-term maintenance therapy but has rare indications—it may be useful for patients unable to comply with oral medications upon discharge from the emergency department.

Leukotriene Modifiers

Leukotrienes (LTs) are elevated in asthmatic patients and are linked to relevant inflammatory changes in the lung. (For a discussion of montelukast and zileuton, see Chapter 10.) This class of agents blocks aspirin-induced asthma. LT modifiers improve lung function in chronic asthma and decrease β -agonist rescue, inhaled corticosteroid use, and exacerbations requiring oral steroids. They are no longer recommended as first-line monotherapy in mild persistent asthma but may be useful additions to therapy when inhaled steroids alone fail or when inhaled steroids cannot be used. There is an unclear association between the use of LT modifiers to treat asthma and the risk for developing Churg-Strauss vasculitis. Although ICS are strongly preferred for any degree of persistent asthma, LT modifiers are an acceptable second-line choice when the use of ICS is not possible. Adding long-acting bronchodilators (β agonists) is recommended when inhaled steroids do not control symptoms; LT modifiers are an acceptable second choice when long-acting bronchodilators cannot be used. Triple therapy with inhaled steroids, long-acting β agonists, and LT modifiers is also prescribed for daily use to control asthma. Short-acting β agonists should be reserved for rescue therapy and monitored carefully as an index of asthma control. Neither short- nor long-acting bronchodilators should ever be used as monotherapy for persistent asthma.

Anti-immunoglobulin G Antibodies (Omalizumab)

Omalizumab is a humanized recombinant monoclonal anti-IgE antibody that binds only to circulating IgE, preventing IgE binding to mast cells and treating allergic asthma (Fig. 20-8). It does not bind to IgE bound to mast

Figure 20-8 Omalizumab Mechanism of Action in IgE-Mediated Asthma.IgE, immunoglobulin E. *Adapted from Am J Health-Syst Pharm 61(14):1449-1459, 2004.*

cells and is not associated with anaphylaxis. Omalizumab reduces early and late phase reactions to allergen challenge. In moderate to severe asthma, it reduced exacerbations and showed other clinical benefits. In more severe asthma, there was no reduction of exacerbations, but the drug again showed some clinical benefit. There are no guideline recommendations for its use at this time. Omalizumab is indicated in the treatment of poorly controlled asthma when other therapies have failed. The asthmatic patients selected for therapy should ideally have IgE levels of 30 to 700 IUs and be sensitive to at least one allergen by scratch skin testing or radioallergosorbent test (RAST).

Omalizumab is relatively expensive (\$4000 to \$20,000/year; average \$12,000/year) compared with \$1200/year for montelukast, \$2160/year for combination fluticasone dipropionate and salmeterol, and \$680/year for a theophylline preparation. Given the high costs involved, before starting omalizumab, health care providers should exclude specific causes of treatment failure, including compliance issues and poor understanding of inhaler technique.

Ipratropium Bromide

Ipratropium bromide is a bronchodilator, but is not as potent as β agonists in asthma; its most accepted role in asthma therapy is as a rescue in asthmatic patients receiving β blockers. It may prove useful in children and for severe adult exacerbations when routine agents fail.

Other Agents

Cromolyn and nedocromil are anti-inflammatory agents used primarily in children. Magnesium, 2 g intravenously

over 15 minutes, is used in severely ill asthmatic patients to reverse bronchospasm. The phosphodiesterase inhibitor theophylline is a bronchodilator that also enhances respiratory muscle contraction and mucociliary clearance, decreases hypoventilation, and has anti-inflammatory properties. Its narrow therapeutic window and lack of dramatic efficacy limit its use. Mixtures of helium and oxygen, inhaled furosemide, inhaled anesthetics, tetracyclines—most recently telithromycin—and mucolytic agents have been reported to be beneficial.

Avoiding Treatment Errors

β Agonists should never be used as monotherapy for persistent asthma. Inhaled steroids are the cornerstone therapy for persistent asthma.

Before additional therapies are prescribed to improve management or asthma control, the issues of compliance and adequate inhaler technique must be resolved. Each patient interaction should include a review to ensure compliance and more importantly adequacy of inhaler technique. With good inhaler technique, 10% to 15% of the medication reaches the airway; with poor technique, no medication is inhaled.

It is important to remember that “all that wheezes” is not asthma and that the patient’s environment may abound in disease triggers that, until addressed, will make control very difficult. Triggers are legion and include gastroesophageal reflux disease, sinus disease, cigarette smoke, medications, foods, food additives, industrial exposures, and season aeroallergens such as pollens and fungal blooms.

Future Directions

The focus for drug development in asthma is on interrupting its inflammatory cascade. Much effort is being made at the molecular level. Anti-IL-5, while able to reduce blood eosinophilia, had no effect on clinical disease. Soluble IL-4 receptor, on the other hand, shows clinical promise. Other efforts target other cytokines, transcription factors, arachidonic acid metabolites, platelet-activating factor, cell-adhesion molecules, phosphodiesterase-4, and T-cell markers. Also, a mutation on chromosome 10, involving the metalloproteinase matrix protein (MMP) ADAM-33, has been linked to bronchial hyperactivity and presumptively to airway smooth muscle hypertrophy. MMPs were formally thought to be involved only with remodeling of the extracellular matrix. Recent observations, however, suggest a role for MMPs in the clearing of cytokines and their receptors, and thus a role in immune modulation. Perhaps the most promising development in asthma research has been the link between asthma and the recently described subgroup of potent immunoregulatory CD1d-restricted NKT cells. These cells have become an interesting potential therapeutic target in asthma.

More importantly, efforts are emerging that may allow manipulation of the immune system to prevent the development of the asthmatic phenotype or to reverse the abnormal inflammatory response and prevent the chronic airway inflammation that we now call asthma. Interesting efforts include using bacterial DNA repeats, rather than aluminum sulfate, as adjuvants for vaccines to direct inflammatory responses away from pathways that produce pathologic chronic atopic inflammation.

Markers of asthmatic inflammation, for example, exhaled nitrous oxide (NO), may prove helpful in predicting exacerbations, grading disease severity, and judging therapeutic success.

This clinical problem-solving exercise focuses on defining the role of omalizumab in treating refractory asthma.

Bronchitis: Acute and Chronic

Introduction

Bronchitis, the clinical term for inflammation of the bronchi, is divided into acute and chronic forms. It presents as cough, with or without sputum production, and has the potential for airway infection and no evidence of pneumonia on physical examination or chest x-ray.

Acute bronchitis (AB) and chronic bronchitis (CB) are distinct entities, although the original presentation of the patient can appear similar in both cases. The main distinguishing feature clinically is the duration of cough; however, AB must also be distinguished from acute exacerbations of CB because the underlying pathophysiology is different. Although both are diseases of the lower airways, CB is clinically defined as a productive cough for at least 3 months of the year for at least 2 years in a row. It is one component of the spectrum of chronic obstructive pulmonary disease that is discussed in more detail in Chapter 22. The remainder of this chapter focuses primarily on AB.

Epidemiology and Pathogenesis

AB affects about 5% of adults annually and is the ninth most common illness in outpatients in the United States. Cough is the most common symptom resulting in any outpatient visit, and AB is the number one cause of cough in this setting. Although concurrent airway infection is part of the definition, up to 90% of these infections are thought to be viral and do not warrant antibiotic treatment. In fact, AB is considered the number one cause of antibiotic abuse in this country. The usual viral causes include influenza A and B, parainfluenza, coronavirus, rhinovirus, respiratory syncytial virus, and human metapneumovirus. There are also some bacterial causes of AB, including *Mycoplasma pneumoniae*, *Chlamydomphila pneumoniae*, *Bordetella pertussis*, and *Bordetella parapertussis*. In addition, patients with CB can develop acute exacerbations of their CB with *Streptococcus pneumoniae*, *Moraxella catarrhalis*, and *Haemophilus influenzae*, but these are not commonly proved to be a cause of uncomplicated AB. It is unclear whether these organisms are only colonizers or act as pathogens.

The cause of the cough is thought to be multifactorial, but histologically there is epithelial cell damage with

release of proinflammatory mediators, which lead to transient bronchial hyperresponsiveness and airflow obstruction. Although some pathologic changes occur, the symptoms and the physical effects resolve completely in 3 to 6 weeks. Repeated attacks of AB can result in CB.

Clinical Presentation

Patients with AB present with a sudden onset of cough in the absence of fever, tachycardia, and tachypnea. By definition, patients should not have asthma, a common cold, or other upper respiratory tract infection. Uncomplicated AB is not an exacerbation of CB. Simple upper respiratory tract infections include rhinitis, laryngitis, pharyngitis, and sinusitis. They can be caused by both bacteria and viruses but are distinguished from AB by the lack of inflammation of the lower respiratory tract (trachea, bronchi, and bronchioles). The absence of lower tract inflammation explains why cough is rarely present in simple upper respiratory tract infections.

Some patients with AB may complain of soreness in the chest or mild shortness of breath, but the primary symptom is cough, with or without increased sputum production. AB

warrants consideration in any patient who presents with a cough lasting more than 5 days. It is not unusual for a cough to last 10 to 20 days; however, the mean cough duration, taking all causes into account, is 18 days, with an occasional duration of 4 to 5 weeks. Only half of patients report purulent sputum. The physical exam is usually negative for a specific finding other than cough; hence, the presence of crackles or egophony on exam, especially when associated with fever, warrants further evaluation with chest x-ray to rule out pneumonia. If a patient presents with a fever and cough and a negative chest x-ray, influenza and pertussis are two potential causes of AB. Otherwise, other illnesses must be considered because 90% of AB cases are viral and only one virus—*influenza*—causes fever.

Influenza has the potential for high morbidity and mortality, and 93% of these patients present with a cough as well as weakness (94%), myalgia (94%), and fever (68%). During influenza season (primarily winter), the sudden onset of fever and cough suggests influenza.

Of the other viral infections that cause AB, coronavirus, rhinovirus, and adenovirus often present with an upper respiratory infection with the associated nasal congestion, rhinorrhea, and pharyngitis, as well as the cough.

Differential Diagnosis

Because the primary symptom of both acute and CB is cough, the differential diagnosis is large. The history and physical exam alone allow the exclusion of many of the diagnoses.

The differential of AB includes pneumonia or pneumonitis, asthma, upper airway cough syndrome (formerly postnasal drip syndrome), gastroesophageal reflux, CB with an acute exacerbation, and medication reaction. Many of these other diagnoses often last more than 3 weeks and are more likely to present with a chronic cough. Therefore, the primary differential diagnosis for the acute cough of AB is pneumonia and an acute exacerbation of CB. The associated mortality and required treatment for these diagnoses are different. As previously noted, fever is uncommon in AB unless it is associated with influenza or pertussis or unless it is complicated by pneumonia. Another cause of acute cough is severe acute respiratory syndrome (SARS) virus, which has a high morbidity and mortality rate and quickly develops into pneumonia.

Causes of subacute cough (3 to 6 weeks' duration) include upper airway cough syndrome, asthma, gastroesophageal reflux disease, pertussis, pneumonia, and an acute exacerbation of CB. Many of these diagnoses can be distinguished by history and physical examination alone. Upper airway cough syndrome often presents with upper airway congestion and the sensation of a “drip” in the posterior oropharynx and has often been present for longer than 6 weeks. Asthma is often intermittent or chronic, with acute “spells” of worsening shortness of breath or chest

pain, associated with wheezing and exacerbated by change in season, temperature, or climate. If the patient has a chronic cough and a smoking history but presents with an acute change in the baseline cough with increased sputum production or change in color, the underlying problem is probably an exacerbation of CB. Gastroesophageal reflux disease most often presents as a chronic cough, with a history of heartburn or a cough that exacerbates at nighttime or with meals. Pertussis is a cause of cough with fever, but it is often associated with a more prolonged cough, lasting as long as 10 to 12 weeks, and coughing paroxysms. Adults with pertussis often have a milder illness than children, do not always have the characteristic “whoop,” and have post-tussive emesis in up to 40% of cases. As previously noted, pneumonia often presents with cough and fever and typical physical exam findings of tachycardia, lung crackles, or egophony. In contrast, only 30% of elderly patients aged 75 years or older with community-acquired pneumonia presented with a fever, and only 37% had tachycardia.

Excluding the specific laboratory diagnosis of influenza or pertussis, the specific cause of AB is often not determined (i.e., type of virus or bacterium), but it can occasionally be elucidated by a careful history. Exposure to ill contacts, duration of cough, associated symptoms, and vaccination history can be helpful. If AB associated with fever and pneumonia is excluded, then pertussis and influenza are the two main causes.

See Chapter 17 on cough for further discussion and differential diagnoses.

Diagnostic Approach

The routine use of laboratory tests to define the specific pathogen in AB is not cost effective; as a result, routine evaluation with sputum Gram stain and culture and routine serum tests is not recommended. The exceptions are influenza and pertussis, if clinically suspected. The rapid test for influenza is cost effective because it allows for the use of antiviral agents and improves the understanding of the epidemiology of outbreaks. Nevertheless, routine screening for influenza in AB is not recommended unless the patient presents with influenza-like symptoms during the influenza season. If pertussis is suspected, a routine complete blood count is helpful to look for the severe leukocytosis associated with this diagnosis. There are complicated serum and nasal culture recommendations based on the stage of the infection. Whether these tests are warranted can be debated because most cases of AB are not pertussis. Several diagnostic tests can determine other specific pathogens but are not cost effective in simple AB and are not recommended.

Obtaining a chest x-ray (if warranted by history and physical exam) to rule out pneumonia is usually helpful, especially given the significant morbidity and mortality rates associated with this diagnosis.

Management and Therapy

Optimum Treatment

Most cases of AB are viral or self-limited, and only symptomatic therapy is recommended.

Antimicrobial therapy is not indicated in most cases because multiple trials have demonstrated only minor reduction in the duration of cough (0.6 days) and no difference in the time of return to work, school, or usual activities at home on day 3 or 7. If a specific treatable pathogen is identified, antimicrobial therapy is more likely to be beneficial. The use of anti-influenza agents can reduce the duration of cough by 1 day if the agent is started within 48 hours of symptom onset, and treatment of pertussis is indicated to limit transmission. Although there are current recommendations to consider antimicrobial therapy for *M. pneumoniae* and *C. pneumoniae*, there are no data suggestive of improved outcomes with antimicrobial treatment.

Other therapies for AB include the use of antitussive agents, β_2 agonists, mucolytic agents, and corticosteroids. There are limited data and support for the use of β_2 agonists, mucolytics, and oral corticosteroids. A recent Cochrane Database review did not support the use of β_2 agonists based on five trials, including patients with airflow obstruction. There are also no significant clinical trials to support the use of antitussive agents, but they are routinely used for the acute symptomatic benefit of the patient.

The current guidelines released by the American College of Chest Physicians (ACCP) do not recommend the use of antibiotics. The ACCP recommends β_2 agonists only in the subgroups of patients with chronic airflow obstruction at baseline or wheezing at presentation. There is no role for mucolytic agents or anticholinergic agents. For the treatment of pertussis, both the ACCP and the Centers for Disease Control and Prevention recommend macrolides as first-line therapy and, for influenza, oseltamivir or zanamivir. Newer generations of influenza are resistant to amantadine and rimantadine.

Avoiding Treatment Errors

As previously stated, the major treatment error is the use of antimicrobial therapy for AB. Because of rising microbial resistance, physicians are encouraged to use only

symptomatic therapy in patients with simple AB unless specific microbials are identified or suspected.

Future Directions

AB is highly prevalent in primary care practice. The careful history and physical examination remain the most helpful diagnostic tools. Other diagnostic modalities are likely to become available, including the use of the procalcitonin test to discriminate between patients with pneumonia and bronchitis. The chest physical exam remains the most useful tool to distinguish between these two types of pulmonary infection. The use of antibiotics is not recommended for most cases; however, more than 70% of patients who seek care receive antibiotics. This observation has led to a campaign to dissuade physicians from this practice. Limiting the overprescribing of antimicrobials should decrease the cost of health care and reduce the emergence of resistant pathogens.

Chronic Obstructive Pulmonary Disease

Introduction

Chronic obstructive pulmonary disease (COPD) is a heterogeneous disorder that includes emphysema, chronic bronchitis, obliterative bronchiolitis, and asthmatic bronchitis. The definition of COPD includes the following: a disease state characterized by airflow limitation that is not fully reversible. The airflow limitation is usually progressive and is associated with an abnormal inflammatory response of the lungs to noxious particles or gases. COPD is a preventable and treatable disease with important systemic consequences.

Etiology and Pathogenesis

COPD affects more than 30 million people in the United States; only 10 million have been diagnosed, 6 million of whom are on therapy, whereas 20 million have impaired lung function. Cigarette smoking is the major risk factor for COPD. More than 20% of chronic smokers develop COPD, and more than 80% of cases in the United States can be attributed to smoking. Other important risk factors include occupational and environmental insults such as bronchitis related to the workplace and to air pollution.

COPD is characterized by chronic inflammation throughout the airways, parenchyma, and pulmonary vasculature. Macrophages, CD8 lymphocytes, and neutrophils are increased. Activated inflammatory cells release a variety of mediators, including leukotriene B₄, interleukin-8, and tumor necrosis factor- α , all of which damage lung structures. Also important in the pathogenesis of COPD are an imbalance of proteinases and antiproteinases in the lung and oxidative stress. This inflammation is attributable to exposure to inhaled noxious particles and gases, including cigarette smoke and indoor air pollutants. These irritants directly inflame and damage the lungs. Oxidative stress results in further damage. For reasons poorly understood, inflammation and oxidative stress may persist long after smoking cessation occurs.

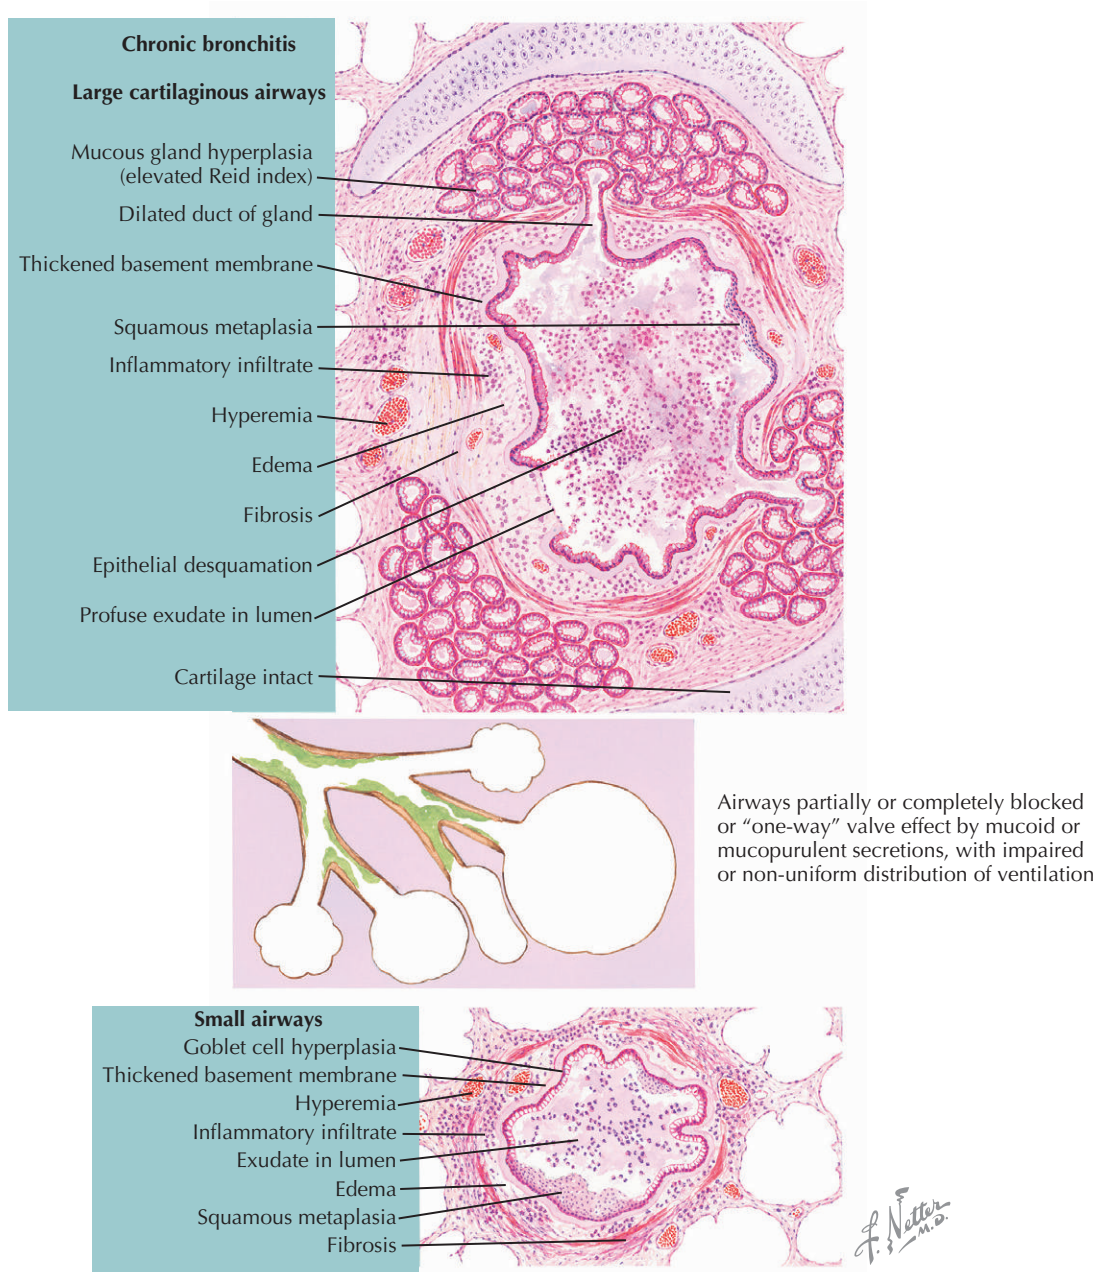

Pathologic changes are found in the central airways, pulmonary vasculature, peripheral airways, and lung parenchyma (Fig. 22-1). In the central airways, there are enlarged

mucus-secreting glands and an increase in the number of goblet cells, plus a marked increase in inflammatory cells infiltrating the surface epithelium. Chronic inflammation also affects the peripheral airways, with repeated cycles of injury and repair of the airway walls leading to remodeling. Inflammatory nodules with exudate are the characteristic lesion in the small airways. Structural remodeling of the airway wall, with increased collagen content and scar tissue formation, results in narrowing and fixed obstruction. In the parenchyma, there is often centrilobular emphysema plus dilation and destruction of the respiratory bronchioles. In α_1 -antitrypsin deficiency, these changes are usually panlobular and involve the lower lobes. In cigarette smokers, centrilobular emphysema involves the upper lobes. The pulmonary arteries are thickened with increased smooth muscle mass, and infiltration of the vessel wall by inflammatory cells is noted.

Clinical Presentation

The clinical course of COPD is affected by multiple factors, including genetic susceptibility, low birth weight, maternal smoking, poor maternal nutrition, infections in the first years of life, asthma in childhood, exposure to inhaled irritants in the workplace, and environmental air pollution. Lung function in most nonsmoking adults decreases gradually throughout life, with a loss of 20 mL/year in forced expiratory volume in 1 second (FEV₁) in

Figure 22-1 Bronchitis.

nonsmokers. Susceptible smokers may lose 60 mL/year in FEV₁, ex-smokers about 30 mL/year, and those who have α₁-antitrypsin deficiency may lose more than 100 mL/year. Young smokers at risk for future COPD often have frequent colds with lower respiratory symptoms that persist for weeks during their 20s and 30s (Fig. 22-2). Usually, middle-aged smokers begin to lose the ability to exercise, and laborers may lose the ability to work in their late 50s. There is a loss of quality of life and functional performance as the COPD patient approaches age 60 years. Many

patients can lose more than 10 years of life expectancy because of this disease. Smokers with COPD are also at increased risk for dying from lung cancer or coronary artery disease.

With far-advanced disease, structural changes result in chronic alveolar hypoxia, which in turn produces pulmonary hypertension and cor pulmonale (see Fig. 23-2). These patients, described as “blue bloaters,” have cyanosis, edema, cardiomegaly, recurrent respiratory failure, hypoventilation, and carbon dioxide retention (Fig. 22-3).

Figure 22-2 Interrelationship of Chronic Bronchitis and Emphysema.

Patients at this stage require frequent hospitalization and have a poor prognosis. The more obese patients may have overlapping obstructive sleep apnea syndrome.

Patients in whom emphysema predominates are hyperinflated, resulting in severe dyspnea, and are called “pink puffers” (Fig. 22-4). They maintain relatively normal arterial oxygen and carbon dioxide tensions despite advanced lung disease but have clear evidence of systemic disease, including a cachectic appearance with marked weakness, fatigue, and poor muscle function. Pink puffers are usually thin and barrel-chested without cyanosis or edema, until the terminal stage of the disease. Most patients with COPD fall into a mixed bronchitis-emphysema clinical category (see Fig. 22-2).

Differential Diagnosis

There is a considerable overlap between COPD and asthma. Both conditions are characterized by obstruction, airway inflammation, and bronchial hyperresponsiveness, and there is an overlap in the response to inhaled β -adrenergic agonist bronchodilators. However, unlike obstruction in asthma, the obstruction in COPD is not completely reversible, and the inflammation is character-

Figure 22-3 The Blue Bloater.

ized predominantly by neutrophil, macrophage, and CD8 cellular infiltrates rather than eosinophils and CD4 lymphocytes. Hyperresponsiveness, although greater than that in the general population, is not nearly as marked as in asthma. Other obstructive lung diseases that may mimic COPD include bronchiectasis with dilation and inflammation of the airways complicated by recurrent respiratory infections. Cystic fibrosis, an inherited disease primarily affecting children and younger adults, is characterized by an abnormal sweat chloride test, susceptibility to repetitive infections with organisms like *Pseudomonas aeruginosa*, much thicker mucopurulent secretions, and a lack of a relationship to cigarette smoking. Obliterative bronchiolitis with obstruction of the small airways is another obstructive lung disease sometimes seen spontaneously, but it is also a complication of transplant rejection. This entity shares features with COPD, as does panbronchiolitis, a small airway obstructive disease primarily seen in Asia.

Diagnostic Approach

A diagnosis of COPD warrants consideration in any patient who has symptoms of cough, sputum production, or dyspnea or a history of exposure to risk factors. The diagnosis is usually confirmed by spirometry. The standards for staging by spirometry continue to evolve. The

Figure 22-4 The Pink Puffer.

recent Global Initiative for Chronic Obstructive Lung Disease (GOLD) guidelines used the presence of a postbronchodilator FEV₁ of less than 80% of the predicted value in combination with an FEV₁/forced vital capacity (FVC) ratio of less than 70% to confirm the presence of airflow limitation that is not fully reversible. Clinical symptoms and signs, including progressive shortness of breath, hyperinflation, and increased forced expiratory time, are useful to support the diagnosis.

The diagnosis of COPD should be considered in a middle-aged patient with symptoms of cough, sputum production, or dyspnea or a history of exposure to risk factors. Women in their 50s are frequently misclassified as asthmatic. Spirometry confirms the diagnosis and is useful for assessing severity (Fig. 22-5). Bronchodilator testing of reversibility is indicated to rule out asthma. The management of COPD is largely symptom driven, and there is a correlation between the degree of airflow limitation and the presence of symptoms.

GOLD Guidelines

The recent GOLD guidelines classify patients with COPD in four stages:

Stage I: Mild COPD—with mild airflow limitation with an FEV₁/FVC ratio of less than 70% but with an FEV₁ greater than 80% of predicted. Some have cough and sputum production.

Stages II and III: Moderate COPD—*stage II* is characterized by worsening airflow limitation with an FEV₁ between 50% and 80% of predicted and *stage III* with an FEV₁ between 30% and 50% of predicted. Usually there is progression of symptoms with shortness of breath, typically on exertion. Patients in stages II and III seek medical attention. Exacerbations occur more frequently in patients who have an FEV₁ below 50% and impact quality of life as well as decrease survival.

Stage IV: Severe COPD—characterized by severe airflow limitations with an FEV₁ less than 30% of predicted or the presence of respiratory failure and clinical signs of right heart failure. Patients who have an FEV₁ less than 30% have poor quality of life, more frequent exacerbations, and shortened life expectancy.

Laboratory Tests

Spirometry reveals an FEV₁/FVC ratio of less than 70% that does not completely reverse to normal following bronchodilator therapy. Lung volumes in emphysema demonstrate hyperinflation, and diffusing capacity for carbon monoxide is low.

The chest radiograph appears normal early in COPD and is not useful in diagnosis. Lower-lobe lung markings are increased in chronic bronchitis, so-called dirty lungs. Findings in emphysema include hyperinflation with a low flattened diaphragm, enlarged anterior-posterior retrosternal space, hypovascularity, areas of hyperlucency, and bullae formation.

Arterial blood gases are usually measured in patients with COPD with more severe disease, usually when the FEV₁ is less than 40%. However, baseline values are commonly benchmarked for comparison during subsequent exacerbations. Mild hypoxemia is often seen during the early stages of COPD. In stages III and IV, because of ventilation-perfusion ratio abnormalities, severe arterial hypoxemia, respiratory acidosis, and hypoventilation are typical findings. The routine use of nocturnal oxygen has made secondary polycythemia a rare occurrence. Surprisingly, more than 20% of patients are chronically anemic.

Electrocardiogram findings are nonspecific in COPD. With severe disease, patients develop changes of right ventricular hypertrophy and atrial arrhythmias. Many have concurrent coronary artery disease.

All patients with COPD, particularly those with early onset or those with a family history of either lung or liver disease, should be screened for α_1 -antitrypsin deficiency, a clinical problem that occurs in 1% to 2% of patients with emphysema. Affected patients are those who have less than 15% of normal serum levels.

Figure 22-5 Pulmonary Function in Obstructive Disease.

FEF_{25-75%}, forced expiratory flow, midexpiratory phase; FVL, forced vital capacity; FEV₁, forced expiratory volume in 1 second; MEFV, maximal expiratory flow volume; TLC, total lung capacity.

Maximal expiratory flow-volume curves. TLC increased in obstruction, but expiratory flow rate decreased. In severe obstruction, tidal breathing may coincide with MEFV curve

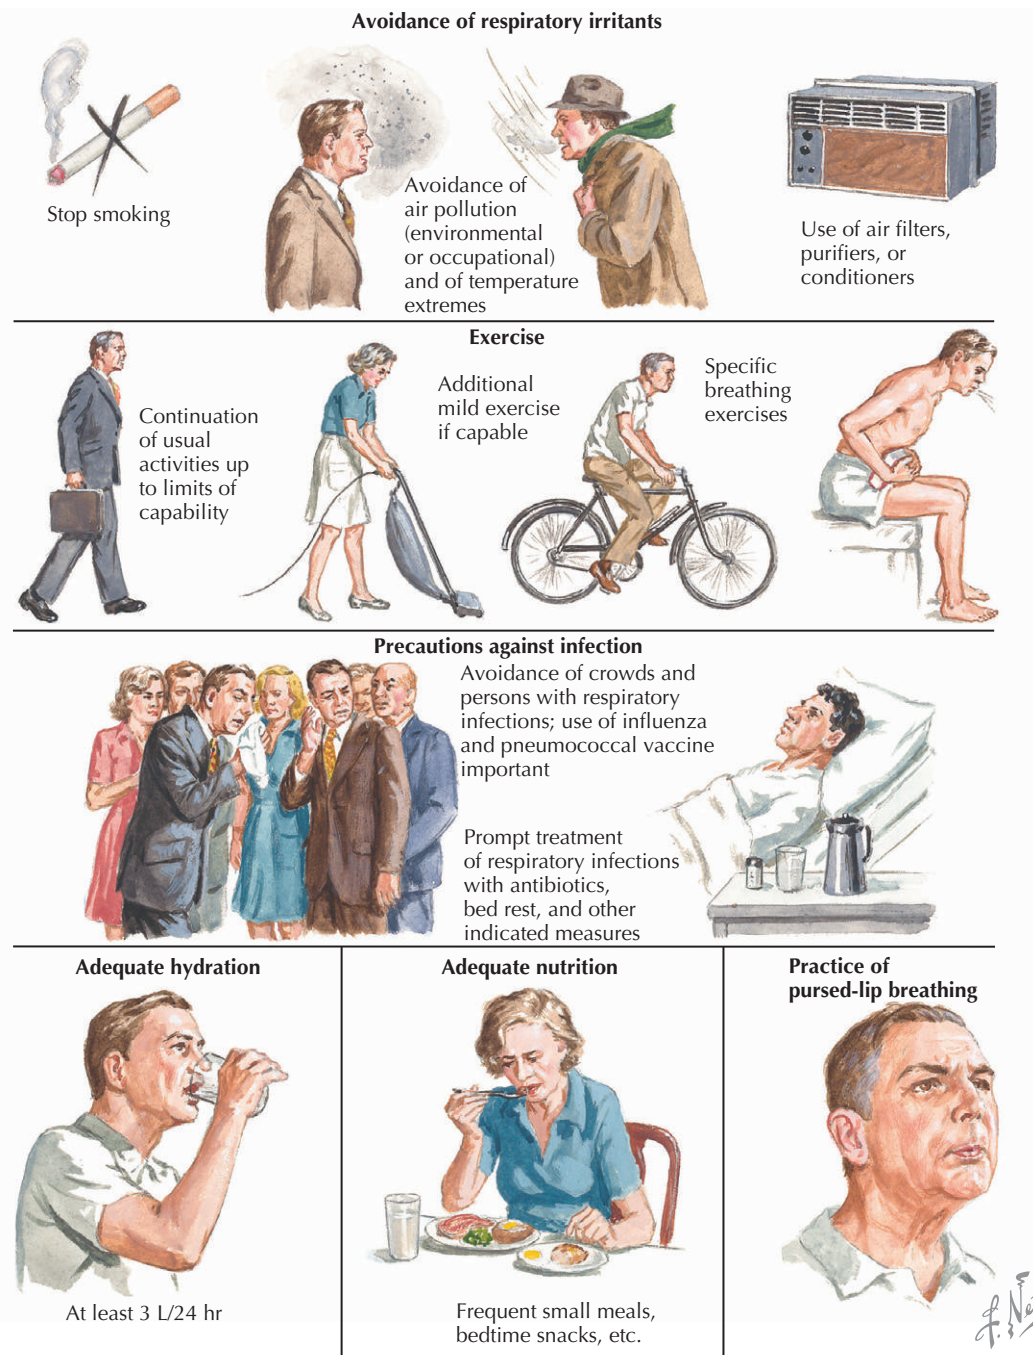

Management and Therapy

Optimum Treatment

Optimal management of COPD requires (1) educating patients and family; (2) retarding the progression of airflow limitation by early disease recognition and avoidance of risk factors; (3) minimizing airflow limitation by reducing the production and increasing the elimination of secre-

tions; (4) performing bronchodilation; (5) correcting the secondary physiologic alterations including hypoxemia, hypercapnia, and pulmonary hypertension; and (6) optimizing functional lung capacity through exercise conditioning, muscle training, rest, nutrition, and psychosocial rehabilitation (Fig. 22-6). The overall approach to managing stable COPD involves a stepwise increase in treatment, dependent on the severity of the disease. Smoking cessa-

Figure 22-6 Management of COPD.

tion is of paramount importance. Counseling, nicotine replacement therapy, and newer agents like varenicline or bupropion should be offered.

Pharmacologic Therapy

Bronchodilator medications are central to the symptomatic management of COPD. They are administered on an as-needed basis or on a regular basis to prevent or reduce

symptoms. The aerosol route using longer-acting bronchodilators is preferred. Frequently, bronchodilators such as long-acting β_2 -agonists, anticholinergics, and theophylline are combined. For mild COPD, a short-acting as-needed bronchodilator like albuterol or ipratropium is often sufficient. For those with stages II, III, and IV disease, regular treatment with an inhaled long-acting β_2 -agonist bronchodilator such as salmeterol and formoterol or an anticholinergic agent such as tiotropium bromide,

either alone or combined, is usually recommended. A short-acting bronchodilator is often added for rescue. Short-acting β_2 agonists like albuterol can be used either regularly or on an as-needed basis, often in combination with ipratropium. These agents are frequently given by metered dose inhaler; however, elderly patients with COPD commonly have difficulty using these devices. Nebulized albuterol-ipratropium is often helpful in patients with more severe disease. With increasing doses of these agents, signs of cardiac toxicity require careful monitoring. Newer long-acting bronchodilators such as arformoterol and formoterol are now available in aerosol solution.

Anticholinergic medications include ipratropium bromide and tiotropium bromide, a new long-acting agent that is a 24-hour antimuscarinic antagonist. Anticholinergics are particularly useful in COPD, especially in patients who have smoked for many years and in those with a low FEV₁. These agents are poorly absorbed systemically, do not cross the blood-brain barrier, and do not adversely affect ciliary activity. The main side effects are dry mouth and cough. Because of their slow onset of action, they are not particularly useful in the rescue mode. However, these are excellent and safe medications in chronic maintenance programs for patients with COPD. Ipratropium can be administered either by metered dose inhaler or by a nebulized solution. It is also effective in acute respiratory failure. Usually long- and short-acting anticholinergics are not used concurrently. Tiotropium is often combined with a long-acting β agonist and at times with an inhaled corticosteroid (ICS).

Salmeterol and formoterol are 12-hour *long-acting bronchodilators* used as chronic maintenance therapy for patients with COPD. Both of these agents are highly effective and are safe in stable patients. The doses, in general, should not be increased. Formoterol has a more rapid onset of action. Salmeterol may be better tolerated. The risk of long-acting β_2 agonists (LABAs) in asthma does not seem to apply to COPD. These agents can easily be combined with theophylline, tiotropium, ipratropium bromide, or an ICS.

Theophylline was previously used in COPD as the first-line therapy but is now secondary therapy. This agent has some anti-inflammatory effects, improves the strength of diaphragmatic contractility, and improves mucociliary clearance and cardiac output. However, theophylline has substantial toxicity in patients with COPD. Elderly patients with preexisting abnormal cardiac function are at risk for cardiac arrhythmias, even if levels are in the high therapeutic range. Theophylline has important interactions with other drugs that are frequently used for COPD, such as macrolide antibiotics, ciprofloxacin, and cimetidine. Clearance may change with concomitant conditions like pneumonia, congestive heart failure, and liver disease. The recommended therapeutic level is 8 to 12 $\mu\text{g}/\text{dL}$. Most patients require a total dose of between 100 and 400 mg per/day.

Prolonged treatment with oral glucocorticosteroids is not recommended in COPD because of the associated severe side effects, including steroid myopathy, osteopenia, and cataracts. *Oral steroids* are very useful in acute exacerbations.

Prolonged treatment with *inhaled corticosteroids* does not modify the long-term decline in FEV₁ in patients with COPD. The GOLD guidelines recommend regular treatment with inhaled steroids in those with an FEV₁ less than 50% of predicted or in those with stage III or IV disease with frequent exacerbations requiring treatment with antibiotics and oral corticosteroids. In this setting, there is preservation of quality of life and a reduced number of exacerbations with ICS. A therapeutic trial of up to 3 months with inhaled corticosteroids may identify patients who would benefit. A recent 3-year study revealed an improvement in all-cause mortality when ICSs were added to LABAs in COPD.

Pulmonary Rehabilitation

Pulmonary rehabilitation is useful for all patients. This includes exercise training, nutrition counseling, and education in a program that usually improves exercise tolerance and overall health, especially in patients whose FEV₁ is below 1.5 L. The goals of pulmonary rehabilitation are to reduce symptoms, improve quality of life, decrease disability, and increase physical and emotional participation in everyday activities. The methods include anxiety management, relaxation, identifying and changing beliefs about exercise and health-related issues, and exercise management. Patients benefit with respect to both exercise tolerance and symptoms of dyspnea and fatigue. The minimum length of an effective rehabilitation program is 2 months, but the longer the program continues, the more effective the results are. There seems to be no effect on survival, and data on reduction in hospitalization rates are inconsistent.

Surgical Therapy

In carefully selected patients, *bullectomy* may reduce dyspnea and improve lung function. The procedure is based on a thoracic computed tomography scan showing a bulla with significant compression of adjoining lung, a large bulla occupying a substantial part of the thorax, or respiratory embarrassment due to an enlarging bulla. Often, a video-assisted thoracoscopy approach is selected.

The National Emphysema Therapeutic Trial of *lung volume reduction surgery* gave mixed results. For patients with very low lung function (FEV₁ <20%), low diffusing capacity (<20%), and diffuse disease, the mortality rate with surgery was greater than in the controlled population treated medically. However, in patients with predominant upper lobe emphysema and low baseline exercise toler-

ance, functional capacity and survival improved over 5 years of follow-up.

In carefully selected patients with advanced COPD, especially those with deficiency of α_1 antitrypsin, *lung transplantation* may improve quality of life and functional capacity. Selected patients are usually those with an FEV₁ of less than 35%, Pao₂ of 55 to 60 mm Hg, and Paco₂ of more than 50 mm Hg. Single-lung transplantations were previously offered, but double-lung transplantation is becoming more popular.

Treatment of Exacerbations

An acute exacerbation of COPD is defined as a subjective increase from baseline in some combination of dyspnea, sputum production, and sputum volume over a 2-day period. Exacerbations are often the defining clinical events in the life of a patient with COPD. There are multiple causes of an exacerbation, including infection, air pollution, exposure to allergens, and ozone. The most common symptoms are increased breathlessness accompanied by wheezing, chest tightness, increased cough and sputum, change in the color or tenacity of sputum, and fever. There may also be nonspecific systemic complaints, such as malaise, insomnia, fatigue, depression, and confusion. The outcome of an exacerbation is influenced by the disease's severity and the patient's previous exposure to antibiotics or recent use of oral corticosteroids. Simple lung function studies are helpful but are often very hard to perform. In the hospital setting, arterial blood gases are useful to guide oxygen therapy and prevent sedation in a patient with impending respiratory failure.

The differential diagnosis of an acute exacerbation includes congestive heart failure, pneumothorax, pleural effusion, pulmonary embolism, and arrhythmias, diagnoses that can be excluded using clinical assessment, chest radiography, electrocardiography, spiral computed tomography scan, and other diagnostic procedures. The presence of increased cough or purulent sputum is sufficient evidence to warrant antibiotic therapy. The most common pathogens are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. More severely affected patients may have infections with gram-negative rods such as *Klebsiella* or *Pseudomonas*, which typically cause more severe lung involvement. Rarely, atypical bacteria such as mycoplasma, *Chlamydia pneumoniae*, or *Legionella* species, are the underlying pathogens. Many exacerbations are due to viruses, but the findings cannot be distinguished from bacterial infection. Similarly, air pollution due to ozone or particulates can cause exacerbations that are indistinguishable from those associated with bacteria.

Most exacerbations of COPD are treated at home. The dose or frequency of β agonists can be increased if no contraindication exists. An additional bronchodilator can be recommended. If the patient is using only metered

dose inhalers, high-dose nebulized therapy deserves consideration.

Usually, patients with acute exacerbations of COPD benefit from *systemic corticosteroid therapy*, with alleviation of symptoms and improved lung function. For patients with moderate COPD, most controlled clinical trials have shown that short-term systemic corticosteroid therapy in combination with other effective therapies leads to small but clinically significant improvement and fewer treatment failures. The usual starting dose is about 30 to 40 mg of prednisone for 5 to 10 days with or without a taper. Increasing the dosage of inhaled corticosteroids is less effective.

Unless the patient is hospitalized or has pneumonia, sputum cultures are not usually necessary. The choice of *antibiotics* is based on the community patterns of bacterial resistance plus factors such as the patient's stage of disease and recent exposure to antibiotics and systemic corticosteroids. Antibiotics directed at the common pathogens are used. Second- and third-generation cephalosporins, newer macrolides, amoxicillin-clavulanate, or fluoroquinolones may be necessary for those who do not respond to simple oral antibiotics, or in cases of the known presence of β -lactamase-producing organism in the sputum.

Avoiding Treatment Errors

The first treatment error is to assume that exacerbations and chronic bronchitis are merely bacterial or viral infections and not an integral feature of the chronic underlying disease. A second error is to misdiagnose COPD as asthma and to use therapies appropriate for asthma but inappropriate for COPD, such as leukotriene receptor antagonists. Administering systemic corticosteroids on a chronic basis, even in the face of evidence that the side-effect profile of chronic oral steroids outweighs any benefits, is another ill-advised treatment decision. A fourth error is to avoid measuring pulmonary function and, as a result, fail to understand how severely impaired your patient is and the corresponding risk for elective surgery, as well as the corresponding prognosis.

Future Directions

Progress in COPD research is accelerating. Characterizations of human lung tissue by advanced molecular, biochemical, microbiologic, and histopathologic methods have revealed important observations on ongoing inflammation, oxidative stress, and apoptosis. Identification of novel biomarkers and clinical end points is essential for the development of new anti-inflammatory agents that might be highly effective. Knowledge of genetic determinants of COPD could lead to recognition of biochemical pathways that contribute to the disease and allow targeting of public health interventions to individuals at greatest risk. The causes and consequences of exacerbations need to be identified, and therapy directed at mucus gland metaplasia and

excess mucus secretion is necessary. Finally, therapy that results in stimulation of alveolar regeneration is an exciting possibility for disease-modifying therapy of emphysema. Clinically, additional work is needed to identify better tools for disease monitoring, as well as more studies to validate or revise current clinical practice.

Restrictive Lung Disease

Introduction

Diseases of the chest resulting from pathologies distal to the conducting airways produce restrictive lung disease (RLD). Collectively, this broad array of disorders manifests clinically as a reduction in the vital capacity (VC) of the lungs. Although less common than obstructive lung diseases such as asthma and chronic obstructive pulmonary disease, RLDs have the potential to progress to respiratory failure and death if not recognized and treated before fibrosis ensues. Therefore, it is essential that physicians are aware of this heterogeneous group of disorders because timely diagnosis and treatment can substantially influence morbidity and mortality.

Etiology and Pathophysiology

RLDs can be grouped into four distinct etiologic categories: chest wall disorders, pleural disease, neuromuscular disease, and diffuse parenchymal lung disease (DPLD). DPLD and interstitial lung disease (ILD) are used interchangeably in the literature; however, DPLD is a more appropriate term because many of these diseases involve the alveolar epithelium, alveolar space, and pulmonary vessels and are not truly limited to the interstitium of the lung. Refer to Chapter 19, which focuses on pleural disease, for a discussion of those disorders.

Although heterogeneous in their pathogenesis, all RLDs result in reductions in VC of the lungs. A restrictive pattern of spirometry is characteristic with reduced forced vital capacity (FVC), reduced forced expiratory volume in 1 second (FEV_1), and normal FEV_1/FVC ratios ($>75\%$) (Fig. 23-1). Decreased compliance of the lungs in DPLDs and decreased compliance of the pleura and chest wall in pleural and chest wall diseases are mechanistically responsible for the reduction in VC observed in these disorders. Lung volume measurements show a reduction in total lung capacity (TLC), functional residual capacity (FRC), and residual volume (RV) (see Fig. 23-1). In contrast, compliance of the lungs, pleura, and chest wall is normal in neuromuscular diseases, and VC is reduced because of diaphragmatic weakness, which prevents full inflation of the lungs to a normal TLC. Because FRC is determined by the balance of forces between the chest wall and lungs, both of which are unaffected by neuromuscular disease,

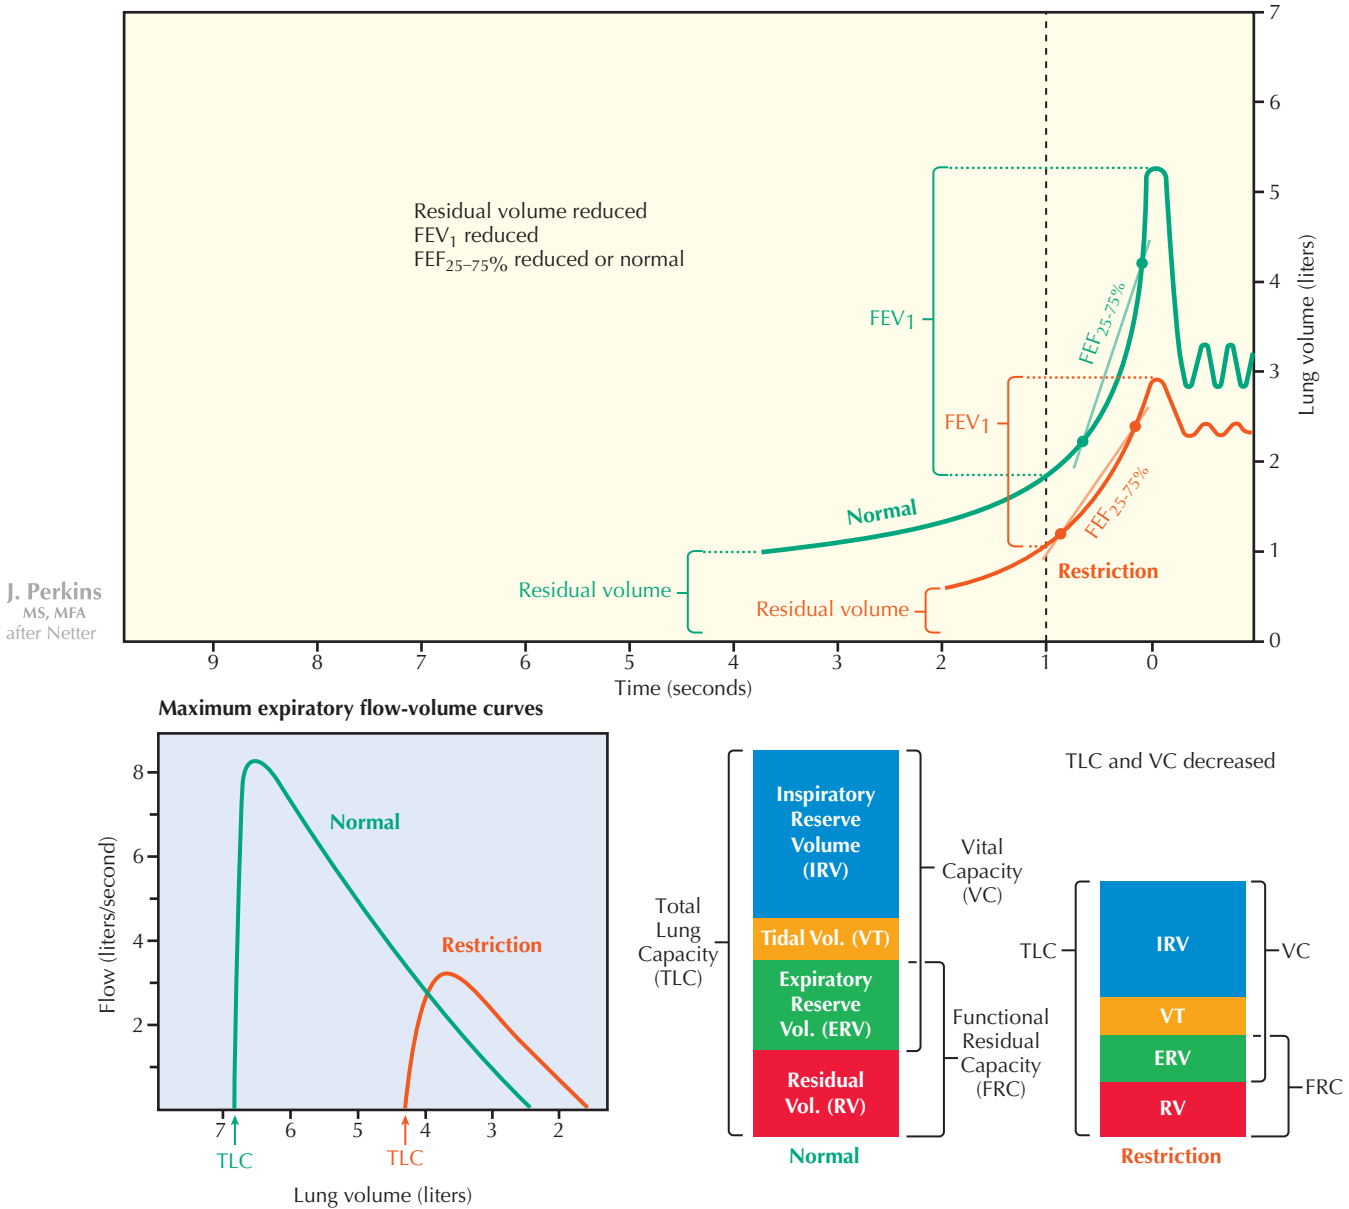

FRC usually remains normal. The RV may be elevated in neuromuscular disease because of weakness of the expiratory muscles, resulting in the inability of the patient to forcefully exhale to a normal RV. These characteristic patterns of lung volumes are useful for the initial differentiation of RLDs. As weakness progresses or as compliance worsens with significant pleural fibrosis or chest wall deformity, hypercapnic respiratory failure can develop. Because the pulmonary parenchyma is normal in these patients, hypoxemia is uncommon unless a secondary process (e.g., atelectasis due to retention of secretions in patients with neuromuscular disease) is superimposed, or hypercapnia is severe.

In contrast to other RLDs, hypoxemia is a common feature of DPLDs. Hypoxemia results from ventilation-perfusion mismatching and diffusion impairment, and it is typically more severe with exertion as red blood cell transit through the pulmonary vascular bed is increased, reducing the available time for hemoglobin loading with oxygen. Hypercapnia is not seen in most DPLDs until end-stage disease is present.

Destruction of alveolar-capillary units by inflammation or fibrosis and hypoxemia act in concert to increase pulmonary vascular resistance. Right ventricular hypertrophy and dilation occur as a consequence of this increase in right ventricular afterload, and cor pulmonale ensues with associated peripheral edema (similar to changes occurring secondary to pulmonary emphysema; Fig. 23-2). Left ventricular diastolic dysfunction can occur from displacement of the septum into the left ventricular cavity as a

result of marked increases in right ventricular pressures, and pulmonary edema can result. The clinical implications of these pathophysiologic changes are discussed under “Management and Therapy.”

Clinical Presentation

Patients with RLD most commonly complain of dyspnea on exertion. The degree of breathlessness usually depends on the etiology of restriction and the severity of lung dysfunction. Some patients notice only mild decreases in exercise tolerance. Patients with severe disease may present

debilitated, unable to ascend a small flight of stairs without significant discomfort. As lung function worsens, patients may complain of dyspnea at rest. Patients with RLD, particularly DPLD, may also present with complaints of cough, which is usually nonproductive. Associated symptoms may include nonspecific chest discomfort depending on the etiology of disease. Because many diseases have similar presentations, a detailed history and thorough physical exam are critical to determining the etiology of restriction. Features of the history and physical exam that may aid in narrowing the differential diagnosis are covered under “Diagnostic Approach.”

Figure 23-2 Cor Pulmonale.

When a neuromuscular disease is the cause of RLD (Box 23-1), patients can present with other neuromuscular complaints. Patients often complain of generalized weakness or fatigue. In some cases, they have objective findings of weakness on physical exam. If the diaphragm is affected, patients may experience worsening dyspnea while laying flat and may exhibit paradoxical breathing as evidenced by the abdominal wall moving inward instead of outward during inspiration. Physical exam may reveal musculoskeletal weakness; however, respiratory muscle weakness may occur in isolation.

Diseases of the chest wall (Box 23-2) usually are apparent on physical exam, and patients may present with more localized complaints. Included in this group are abdominal

processes that interfere with the downward displacement of the diaphragm during inspiration. Tense ascites, an abdominal mass, and a massive pannus are common causes of restriction and may be evident at the bedside. Pectus excavatum is a common congenital disorder affecting the anterior chest wall. Patients with this deformity have a concave depression of the sternum. Younger patients rarely have symptoms. As they age, however, they may complain of mild dyspnea on exertion and pain at the site of deformity. Some patients with pectus excavatum develop mitral valve prolapse and complain of palpitations due to associated arrhythmias. Patients with deformities of the spine have specific findings on physical exam. An anteroposterior angulation is seen in patients with kyphosis. Patients with

scoliosis have lateral displacement or curvature of the spine. If severe rib distortion is present, a patient may report exercise intolerance, but patients are often asymptomatic at rest. With chest wall or spine deformities, children are usually asymptomatic because of the lack of rib rigidity. Adults may be asymptomatic as well until burdened with a superimposed insult such as bacterial pneumonia. RLD that is not manifest clinically when the patient is well can predispose to hypercapnic respiratory failure. Patients with morbid obesity often are asymptomatic at rest but may notice profound dyspnea with exertion due to the combination of deconditioning and pulmonary restriction.

The clinical presentation and physical findings associated with DPLD are important clues to the etiology of a patient's pulmonary disease. Most patients will present with shortness of breath with or without cough. Occasionally, early DPLD may be first brought to clinical attention by a chest x-ray (CXR) or chest computed tomography (CT) performed for other reasons. A sudden onset of respiratory failure, however, must be quickly diagnosed. Acute interstitial pneumonia, a form of idiopathic intersti-

tial pneumonia (Box 23-3), presents with a prodrome of fever, malaise, and cough that precedes the development of hypoxemic respiratory failure by days to weeks. This entity must be recognized quickly because these patients may progress to respiratory failure and require mechanical ventilation. Chest pain is uncommon in most DPLDs, but when present, it is usually due to a systemic inflammatory disorder such as systemic lupus, mixed connective tissues disease, rheumatoid arthritis, or sarcoidosis. Patients with severe or progressive DPLD may develop pulmonary hypertension and present with complaints of dizziness, syncope, or lower extremity edema. Some DPLDs produce wheezing as the result of small airways involvement. Two examples are sarcoidosis and Churg-Strauss syndrome. Churg-Strauss syndrome is one of the pulmonary vasculitides that causes DPLD. This autoimmune disease has an asthma component, and affected patients may complain of wheezing.

Although the idiopathic interstitial pneumonias (see Box 23-3) are often limited to the lung, other DPLDs are part of a systemic illness in which additional organs are also affected. For example, DPLD may occur with many connective tissue diseases (Box 23-4), and other organ-specific complaints typical of the rheumatic process may be present and helpful in diagnosis. For example, patients with connective tissue diseases may complain of fatigue, weakness, joint pain, muscle pain, dry eyes, or dry mouth.

The physical exam findings in patients with DPLD are abnormal but nonspecific. The auscultatory examination of the chest usually reveals "Velcro" or dry inspiratory crackles. Interestingly, the lungs frequently sound clear in pulmonary sarcoidosis, despite the presence of significant parenchymal lung disease. Cyanosis and clubbing are

usually late manifestations of disease and suggest advanced lung disease. Pulmonary hypertension also develops with advanced DPLD, and patients may present with a right-sided heart gallop or an abnormally accentuated P2. Elevated jugular venous pulse, hepatomegaly, and lower extremity edema may result from the development of right ventricular failure—cor pulmonale (see Fig. 23-2).

Extrapulmonary manifestations of disease can help to narrow the extensive differential of DPLD. Systemic hypertension may be seen in connective tissue diseases and vasculitides. Skin changes are common in connective tissue disorders like scleroderma. Sarcoidosis, neurofibromatosis, dermatomyositis, drug-induced DPLD, and systemic vasculitides may also have classic skin findings. When patients with DPLD report eye symptoms, sarcoidosis, ankylosing spondylitis, scleroderma, and the systemic vasculitides should be entertained. Objective findings of muscle weakness on physical exam may be a clue to an underlying connective tissue disease. The absence of extrapulmonary findings, however, should not exclude any particular etiology as the cause of DPLD because pulmonary disease can occasionally be the first manifestation of these systemic illnesses.

Diagnostic Approach

The evaluation of patients suspected of having RLD should include a detailed history with an extensive review of systems, physical exam, spirometry, and a posteroanterior (PA) and lateral CXR. An algorithm for approaching the

patient with suspected RLD is presented in Figure 23-3. Vital signs should include a measurement of room air pulse oximetry. Pulse oximetry with exertion is a very useful test for detecting the presence of DPLD because exercise-induced hypoxemia is a common feature of these disorders. Although a comprehensive history and physical exam, imaging studies, and selected labs may suggest RLD, the diagnosis is based on pulmonary function testing. A diagnosis of restriction should be documented by spirometry and lung volumes before embarking on an extensive radiographic and pathologic workup. Patients with suspected lung disease should first have simple spirometry. If FEV₁, FVC, and the FEV₁/FVC ratio are suggestive of restriction (see Fig. 23-1), then lung volumes and diffusion capacity (DLCO) should be measured. Lung volumes are essential for the diagnosis and initial differentiation of RLDs because the volume compartments are differentially affected by the various classes of RLD.

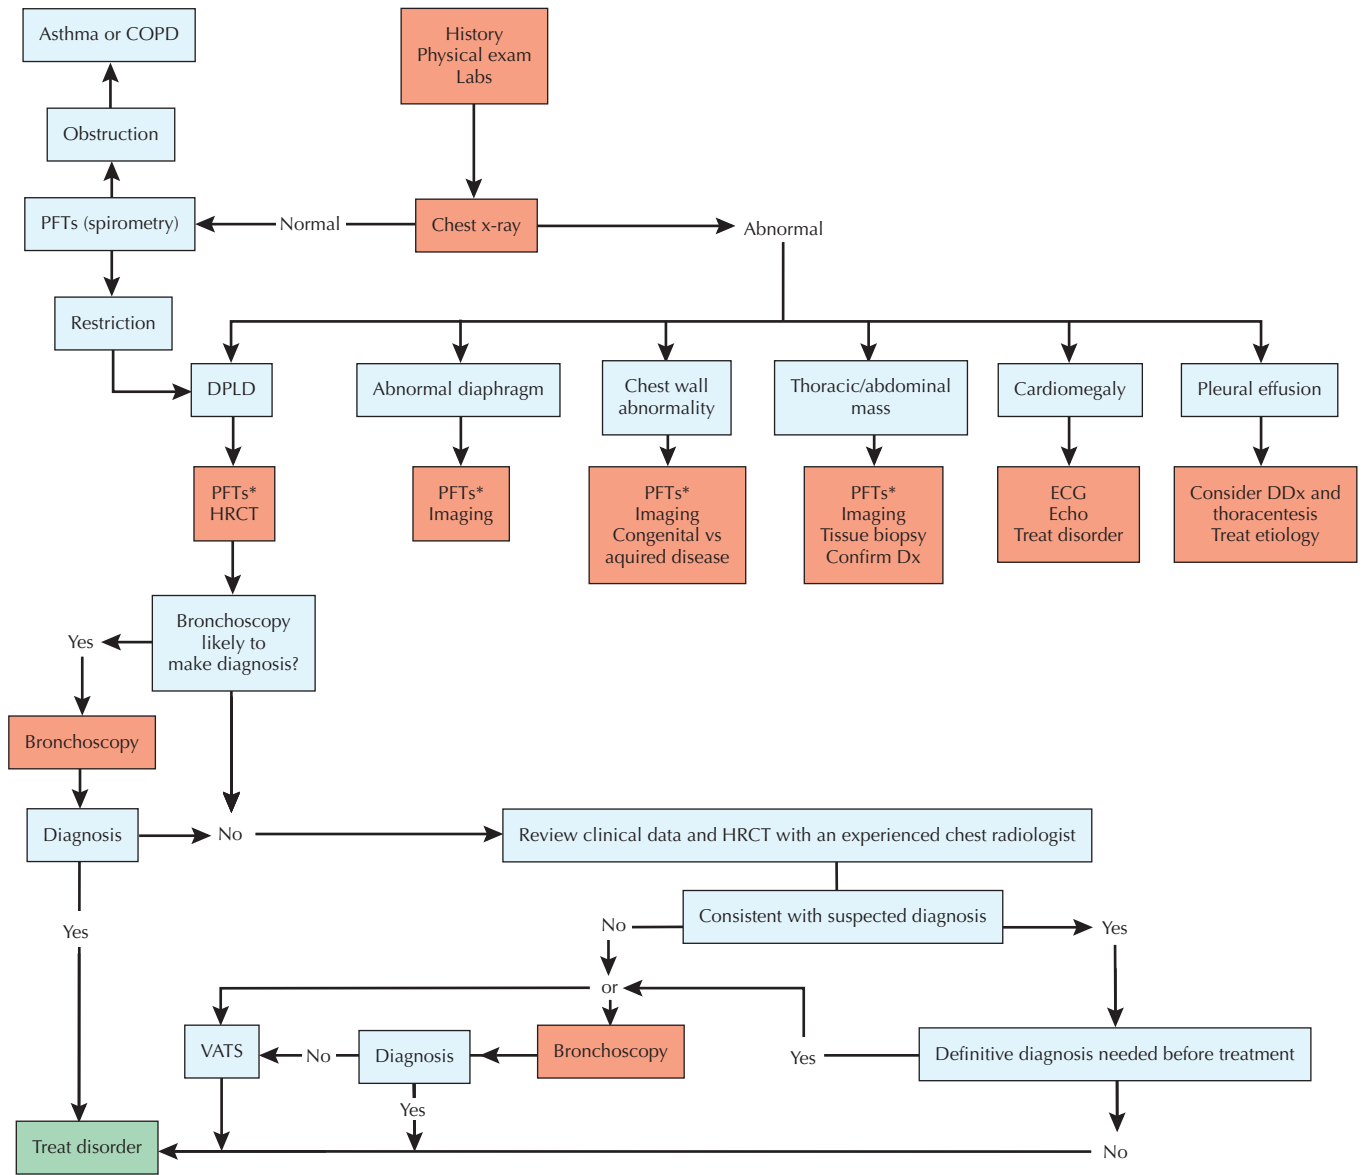

In neuromuscular and chest wall disease, an extensive history, physical exam, and pulmonary function testing may be all that is necessary to generate a differential diagnosis (see Box 23-1). Patients with muscle weakness affecting the diaphragm typically have a decrease in TLC, a preserved FRC, and a mild increase in RV, as previously described. Muscle pressure measurements reveal a decrease in maximal inspiratory and expiratory pressures. Diffusion capacity is typically normal. A PA and lateral CXR may display an elevated hemidiaphragm in cases of diaphragm weakness or injury. Fluoroscopic visualization, however, is often necessary to document abnormal diaphragm movement. Nerve conduction studies and muscle biopsy may be necessary to diagnose neuromuscular disease. A diagnostic plan should be coordinated with an experienced neurologist.

Box 23-2 lists RLDs resulting from chest wall abnormalities. An isolated reduction in FRC is characteristic of obesity-induced RLD. With morbid obesity, TLC may also be reduced. In the absence of concomitant parenchymal lung disease, the DLCO may be normal in patients with a restrictive ventilatory dysfunction from chest wall disease. Chest imaging will often reveal the underlying bony pathology responsible for chest wall disease. Serologic studies typically are not needed. If pleural plaques or chest wall tumors are present, tissue biopsy using CT guidance, video-assisted thoracoscopy, or open surgical procedures may be needed for definitive diagnosis. Depending on the etiology and severity of chest wall disease, patient care should be coordinated with a thoracic or orthopedic surgeon.

The list of causes of DPLD is extensive (see Boxes 23-3 and 23-4), and an approach to diagnosing these disorders is outlined below and in Figure 23-3. Individualization based on the clinical presentation and an extensive history is important. It is essential, as in any medical interview, that the clinician obtain a detailed history of disease onset and extensive review of systems. Information concerning

smoking history is vital because some diseases, including respiratory bronchiolitis–interstitial lung disease (RB-ILD), desquamative interstitial pneumonia (DIP), and Langerhans cell histiocytosis, can improve with smoking cessation. The clinician must inquire about any current or previous occupational or recreational exposures (see Box 23-4) because avoidance of these factors can result in disease remission. Hypersensitivity pneumonitis (Fig. 23-4) is an important DPLD that may only be suspected by a detailed exposure history (e.g., pet bird). A complete list of current and previous medications is essential because a number of drugs have been associated with the develop-

ment of DPLD (see Box 23-4). A detailed family history may reveal clues to the diagnosis of diseases with well-established genetic components (e.g., sarcoidosis). Finally, a thorough physical exam may reveal clues to both the severity (e.g., signs of cor pulmonale) and etiology (e.g., skin findings such as lupus pernio, which may be suggestive of sarcoidosis) of DPLDs.

The CXR is an important diagnostic test when evaluating patients with suspected DPLD. The characteristic CXR in DPLD shows increased linear markings with or without small nodules—a reticular-nodular pattern. However, alveolar filling is seen in some of these disorders,

Figure 23-4 Hypersensitivity Pneumonitis.

Farmer's lung results from inhalation of dust from moldy hay containing thermophilic actinomycetes

emphasizing the basis for the change in nomenclature from ILD to DPLD. Chest imaging may show other findings associated with underlying disease such as hilar adenopathy or pleural abnormalities. Hilar adenopathy is a common feature of pulmonary sarcoidosis (Fig. 23-5). Normal CXRs have been reported in up to 10% of patients with DPLD; therefore, a normal CXR does not exclude the diagnosis. High-resolution computed tomography (HRCT) of the chest should be performed in all patients with suspected DPLD. HRCT is useful for (1) detecting subradiographic disease, (2) distinguishing active inflammation from fibrosis, and (3) suggesting a specific diagnosis. Some reports suggest that an accurate diagnosis can be made in a large percentage of cases when clinical data are combined with the radiographic pattern seen on HRCT.

The pathophysiologic features of DPLD are similar in that most of these diseases result in restrictive pulmonary

physiology. Spirometry and lung volumes in DPLD usually show a pattern of decreased TLC, FRC, and RV. However, pulmonary sarcoidosis, hypersensitivity pneumonitis, and RB-ILD may present with a mixed restrictive-obstructive pattern, and pulmonary sarcoidosis can occasionally present as pure obstruction. A reduced DLCO is common in DPLD but is a nonspecific finding. Changes in DLCO and FVC, however, are strong predictors of prognosis early in disease. These values should be followed closely over the course of a patient's illness to monitor disease progression and response to therapy. The extent of lung involvement on HRCT correlates with a patient's functional capacity. Hypoxemia with an elevated alveolar-arterial oxygen gradient supports the diagnosis of DPLD. With early disease, an A-a gradient may become manifest only with exertion. Exercise pulse oximetry is a useful test for detecting DPLD and for monitoring disease progression and response to

Figure 23-5 Sarcoidosis.

treatment. The physiologic workup will support the diagnosis DPLD but rarely is suggestive of a particular etiology.

Serologic studies are a useful part of the evaluation of patients with suspected DPLD. On initial evaluation, complete blood count with differential, reticulocytes, basic chemistries, urinalysis, and liver function tests (LFTs) should be ordered. Peripheral lymphopenia and elevated

LFTs may be seen in sarcoidosis. An elevated serum angiotensin-converting enzyme (ACE) level may support the diagnosis of sarcoidosis; however, other granulomatous diseases can also produce an elevated ACE. Renal abnormalities may be present in pulmonary-renal syndromes such as Goodpasture's and Wegener's granulomatosis. Serum precipitins against antigens associated with hypersensitivity pneumonitis can be obtained if the history is

Box 23-5 Diseases that Mimic Diffuse Parenchymal Lung Disease

- Cardiac disease (mitral stenosis, left ventricular failure)
- Chronic aspiration of gastric contents (severe gastric reflux)

suggestive of this disease. When an underlying inflammatory process is suspected, a sedimentation rate may be helpful. All patients with DPLD of undetermined etiology after initial evaluation should undergo testing for anti-nuclear antibodies (ANA), antineutrophilic cytoplasmic antibodies (ANCA), extractable nuclear antigen (ENA), creatinine kinase (CK), and aldolase because lung disease can occasionally be the first presenting features of connective tissue disease and vasculitides. When the serologic studies support a specific diagnosis, invasive studies may not be necessary for diagnosis.

Bronchoalveolar lavage (BAL) by fiberoptic bronchoscopy is a minimally invasive procedure that allows for sampling of the cells in the alveolar space. Evaluation of the lavage fluid for cell count, cultures for microorganisms, and cytology may be helpful in diagnosing some DPLDs. Elevated lymphocytes in the BAL suggests sarcoidosis, hypersensitivity pneumonitis, or bronchiolitis obliterans organizing pneumonia (BOOP). Elevated eosinophils in the BAL may be seen in eosinophilic pneumonia and Churg-Strauss syndrome. In addition, BAL may be useful in diagnosing diseases that mimic DPLD (Box 23-5).

When the clinical presentation, pattern of disease on HRCT, and serologic testing are nonspecific and inconclusive, lung biopsy may be necessary to determine the etiology of DPLD. Histopathologic evaluation of lung tissue is the most sensitive and specific way to determine the etiology of DPLD. An accurate diagnosis is necessary to initiate the proper treatment. The therapies for DPLD often have serious side effects, and treatment should not be initiated without a confident diagnosis. Fiberoptic bronchoscopy with BAL and transbronchial lung biopsy is the procedure of choice when sarcoidosis, eosinophilic pneumonia, or lymphangitic carcinomatosis is suspected. However, the small lung sample size obtained by this method is often inadequate for differentiating other DPLDs, particularly the idiopathic interstitial pneumonias (see Box 23-3). If transbronchial lung biopsy is nondiagnostic, or if an idiopathic interstitial pneumonia is suspected, surgical lung biopsy may be necessary. The histopathologic analysis, in combination with the clinical presentation and radiographic pattern on HRCT, ensures the highest level of diagnostic accuracy in patients with DPLD. Recently, it has been suggested that a diagnosis of idiopathic pulmonary fibrosis (IPF), the most common

DPLD of older adults, can be reasonably established without lung biopsy, if clinical presentation and HRCT are characteristic.

Management and Therapy

Optimum Treatment

Therapy for RLD is designed to halt or reverse the disease process responsible for producing restrictive physiology. Although simple physical measures can sometimes be dramatically effective for diseases affecting chest wall mechanics (e.g., weight loss for obesity), neuromuscular diseases are often progressive. Myasthenia gravis is an exception, and specific therapy for this disorder is discussed in Chapter 134.

Treatment of DPLD is tailored for each specific disease entity, highlighting the necessity of an accurate diagnosis of these disorders. For example, RB-ILD and DIP, two idiopathic interstitial pneumonias, may improve with smoking cessation. Immunosuppressive therapy is highly effective for pulmonary vasculitis and diseases in which acute or chronic inflammation is believed to drive disease pathogenesis (e.g., eosinophilic pneumonia, BOOP). However, diseases with active fibroblast proliferation such as IPF are poorly responsive to immunosuppressive therapy, and frequently side effects from these therapies in patients with IPF may outweigh the modest benefit that might be gained. For patients with IPF, and other DPLDs resulting in end-stage lung disease, lung transplantation should be considered. IPF is a uniformly fatal disease with a 2.5-year median survival; therefore, referral for lung transplantation evaluation should be considered early for these patients.

Nonspecific supportive care is an important component of treatment of RLDs including DPLD. Noninvasive positive pressure ventilation can be highly effective for neuromuscular disease and other nonparenchymal diseases affecting pulmonary mechanics. Oxygen therapy is essential to prevent hypoxemia and retard the development of cor pulmonale in these patients. Accordingly, assessment of oxygen requirements at rest, with exertion, and during sleep is warranted. Cor pulmonale should be treated initially with oxygen, which often prompts a spontaneous diuresis. If edema persists despite adequate oxygenation, diuretics can be added. Novel drugs initially developed for primary pulmonary arterial hypertension (PAH) may be available in the future for treating PAH and cor pulmonale secondary to DPLD.

Avoiding Treatment Errors

Sarcoidosis and IPF are the most common DPLDs affecting younger and older adults, respectively. Therefore, these disorders are sometimes treated by the primary care physician. One of the most common treatment errors

related to sarcoidosis is the decision to initiate therapy in the first place. Most patients presenting with sarcoidosis, particularly Löfgren's syndrome (fever, bilateral hilar adenopathy, erythema nodosum), do not need treatment because the disease process has a high propensity for spontaneous remission. Another common treatment error in sarcoidosis is the use of high-dose prednisone. The granulomatous inflammation of sarcoidosis usually responds to an initial dose of 30 to 40 mg/day of prednisone, and can be suppressed with lower doses of 10 to 20 mg/day.

IPF responds poorly to corticosteroid therapy, and trials of high-dose prednisone are no longer indicated for patients with a definitive diagnosis. The need for oxygen therapy, particularly with exertion, should not be overlooked. Oxygen should be prescribed immediately if hypoxemia is present at rest, with exertion, or during sleep. Because novel antifibrotic agents with disease-modifying potential are on the horizon and currently available through clinical trials, consultation with a pulmonologist or IPF referral center should be considered given the lack of other truly effective therapies for this disease, other than lung transplantation. Because patients with IPF can deteriorate rapidly, early referral for lung transplantation evaluation is prudent.

Future Directions

Although the physiologic impairment produced by RLDs have been well recognized for many years, the pathogenesis of individual DPLDs remains poorly understood. Advances in our knowledge of IPF as a disorder of fibroblast proliferation rather than an inflammatory pneumoni-

tis has fueled interest in the development of antifibrotic drugs for this condition. A better understanding of the pathogenesis of specific DPLDs through modern genetic and molecular research with animal models and human tissue should identify new pathways and uncover novel therapeutic targets for this interesting group of diseases producing restrictive disease in the chest.

Environmental Lung Disease

Introduction

Air pollution has presented a challenge to humans for millennia. This was initially of crustal and plant origin but later included particles generated from burning biomass in indoor spaces for heating and cooking. Larger anthropogenic contributions to ambient air pollution arrived with industrialization and accelerated with the development of automotive transport in the 20th century. Episodes of extremely high levels of ambient air pollution such as that in the Meuse Valley of Belgium in 1930 and Donora, Pennsylvania in 1948 were accompanied by acute elevations in morbidity and mortality in the exposed populations. Between 1948 and 1962, eight wintertime air pollution episodes occurred in London, England with the most clearly described being that in December of 1952. Excess deaths during this episode numbered 12,000 and were largely among infants and the elderly (with the majority of the latter suffering from chronic respiratory disease). Increasing concerns regarding the health consequences of air pollution in the United States culminated in the Clean Air Act of 1970 (and subsequent amendments). Despite reductions in air pollution, epidemiologic investigation during the 1980s and 1990s repeatedly demonstrated an association between the daily mean concentration of ambient particulate air pollution in cities both in the United States and worldwide with indices of acute morbidity and mortality. Likewise, associations between fluctuations in daily summertime ozone (O_3) levels and respiratory morbidity were demonstrated.

Etiology and Pathogenesis

Significant anthropogenic contributions to ambient air pollution result in large part from combustion of fossil fuels. This can include emissions from motor vehicle engines (mobile sources), power plants (stationary sources), and area sources (wood burning stoves, fireplaces, and grills). Tailpipe emissions are a major contributor of carbon monoxide (CO), nitrogen oxides (NO_x), hydrocarbons, diesel, and other airborne particles. Power plant emissions are largely responsible for atmospheric sulfur dioxide (SO_2), which is oxidized in the atmosphere to sulfuric acid and various particulate sulfates. Waste incinerators, smelters, steel mills, and other industrial activities may be responsible for emissions of a variety of acidic, organic, and metal compounds that cause local changes in air quality. Gaseous and particulate pollutants can undergo long-range transport in the atmosphere.

Particulate Matter

From the standpoint of adverse health effects, particulate matter (PM) is arguably the most important of the “Criteria Air Pollutants” defined in the Clean Air Act of 1970 (Table 24-1). PM is measured and reported in gravimetric units (micrograms) per cubic meter of ambient air and includes all PM that is respirable—that is, particles small enough to be inhaled into the lower respiratory tract by humans. The upper size limit for globular respirable particles is an aerodynamic diameter of 10 μm . Respirable PM is somewhat arbitrarily divided into size fractions, such as coarse (2.5 to 10 μm), fine (0.1 to 2.5 μm), and ultrafine (<0.1 μm); the last category includes so-called nanoparticles. Coarse particles are thought to arise mainly from the earth’s crust and include compounds like aluminum silicates. They also contain biologic materials like endotoxin. Fine particles are thought to arise from

Table 24-1 U.S. Ambient Air Quality Standards (2006)*

PM ₁₀	150 µg/m ³ (24 hr)	50 µg/m ³ (annual)
PM _{2.5}	65 µg/m ³ (24 hr)	15 µg/m ³ (annual)
Ozone	0.12 ppm (1 hr)	0.08 ppm (8 hours)
NO ₂		0.053 ppm (annual)
SO ₂	0.14 ppm (24 hr)	0.03 ppm (annual)
CO	35 ppm (1 hr)	9 ppm (8 hours)

*Lead is excluded from this list because it is not addressed in this chapter.

combustion processes in mobile and stationary sources. They include elemental carbon, organic carbon, metal compounds, and sulfates and nitrates. Some fine particles are primary emissions, but many represent particles generated from primary gaseous emissions by chemical or photochemical and physical processes occurring in the atmosphere. Fine particles do not sediment readily (unlike coarse particles) and therefore enjoy a long atmospheric lifetime. Ultrafine particles can be primary emissions from combustion processes and can also be generated *de novo* from volatile organic compounds undergoing oxidation in the atmosphere to poorly volatile oxy-organic species. Ultrafine particles agglomerate readily and contribute to the generation of more stable fine particles (sometimes referred to as the accumulation mode). Fine particles generally comprise a substantial fraction of the PM₁₀ mass. Ultrafine particles, on the other hand, contribute little to PM₁₀ mass. However, they account for most of the particle number, sometimes more than 10⁶/cm³, and (in aggregate) have a very large surface area, a property that may confer a high degree of reactivity in biologic as well as physical systems. Decreasing the diameter of PM also reduces uptake by professional phagocytes and enhances penetration into other cells following their deposition on respiratory surfaces.

Time series analyses of short-term associations between fluctuations of daily gravimetric PM₁₀ levels in ambient air and daily nontraumatic mortality statistics, as well as indices of morbidity, have demonstrated significant associations in older adults. Death in older individuals appears to be a result of cardiovascular causes, including acute myocardial infarction, as well as respiratory causes. Morbidity is observed across the age spectrum and is primarily respiratory. There are several current hypotheses to account for PM-associated health effects and their causative agents. These hypotheses are not mutually exclusive.

1. Organic compounds and metals generate reactive oxygen species leading to oxidant stress in the lung and to systemic as well as local effects.
2. Biologic materials like endotoxin may act through high-affinity receptors (e.g., toll-like receptors) to prime the innate immune system and generate enhanced reactivity to other inhaled substances.

3. Ultrafine particles per se may provoke oxidant stress leading to proinflammatory and proliferative effects.
4. Particles (especially ultrafine) may cross the epithelium and gain access to the vascular system.

Some evidence for each of these mechanisms has been published; that for the direct passage of naked particles into the vascular system is least convincing.

With improved techniques for fractionation of the components of ambient air PM, observational studies have been able to assess temporal relations between these fractions and adverse health effects. Size fractionation has suggested that fine particles (PM_{2.5}) are the important agents, but some studies are not in accord with this exclusion of coarse PM.

Identification of the components of ambient air PM responsible for acute and subacute health effects, and of the mechanisms involved, is important to support the biologic plausibility of the reported associations and to pinpoint the source of the toxic components (and their precursors) for more effective monitoring and regulation. In addition, defining components and mechanisms could suggest approaches to identify susceptible individuals and to prevent effects in such persons. Unlike O₃, where indoor levels are substantially less than ambient concentrations and ambient air exposure avoidance strategies are effective, outdoor PM penetrates and persists indoors.

Ozone

O₃ is a second pollutant with a significant impact on human health. O₃ was first identified as a gaseous component of photochemical pollution (smog) in sunny Los Angeles, California during the 1940s. This gas is one of several photochemical oxidants formed in the troposphere as a secondary pollutant by the action of solar radiation on nitrogen dioxide (NO₂) in the presence of volatile organic compounds. Tropospheric O₃ pollution should be distinguished from that in the stratosphere, where O₃ prevents harmful ultraviolet radiation from reaching the surface of the earth. O₃ present at the Earth's surface, however, is detrimental to human health as well as to crops and materials.

O₃ pollution is worse from late spring to early fall, with levels typically rising in midmorning, several hours after the morning rush hour, peaking in the late afternoon, and declining in the evening. O₃ measurements are expressed as either ppb or µg/m³ (1 ppm ≈ 2000 µg/m³). Because the precursors of O₃ (i.e., NO₂ and organic compounds) share common origins with other pollutants, including PM and SO₂, the concentrations of these pollutants frequently correlate with each other.

O₃ causes ozonation and peroxidation of lipids in human lung epithelial lining fluid. Dietary antioxidant supplementation may provide some protection against O₃-induced acute reductions in lung function, but apparently

not against the accompanying inflammatory response. Increased ventilation (exercise), exposure duration, and concentration enhance the health effects of O₃. These include substernal chest pain worsened by deep inspiration, decreased inspiratory capacity, increased bronchial reactivity to specific allergens as well as to methacholine or histamine, altered mucociliary clearance, and neutrophilic airways inflammation. These effects regress more or less rapidly after cessation of exposure. Whether repeated exposures to O₃ cause irreversible change is not clear. However, consecutive daily exposures to O₃ produce marked blunting of the initial spirometric effect and symptoms.

Nitrogen Oxides

During high temperature combustion, NO_x is generated. The significance of low concentrations of NO_x and the need for its regulation in ambient air derives from its role as an O₃ precursor rather than from direct effects on human health.

Sulfur Dioxide

Because of regulations included in the Clean Air Act of 1970, SO₂ concentrations in the United States have declined. This is a direct result of changing fuel quality (sulfur content) and use. High concentrations of SO₂ can still be observed in other parts of the world (e.g., China, where high sulfur coal is used for domestic cooking and heating).

Carbon Monoxide

CO is produced by an incomplete combustion of carbon. Individual exposure to CO occurs during motor vehicle travel, and concentrations of this gas can be high in road tunnels and indoor garages. National Ambient Air Quality Standards (NAAQS) are set to prevent levels of carboxyhemoglobin in the blood reaching 2.5% and above. An increase of 7 ppm CO in inspired air causes an equilibrium elevation of 1% blood carboxyhemoglobin above baseline (which is 0.5% to 1.0% in the healthy nonsmoker).

Clinical Presentation

We have chosen to discuss the individual criteria pollutants in this section. Nevertheless, interactive effects of different classes of pollutants and of other environmental agents (notably allergens) are receiving increasing attention.

Particulate Matter

The clinical presentation following exposure to elevated ambient air pollution PM levels includes an increased

prevalence of respiratory symptoms (i.e., cough, phlegm, and wheeze) as well as hospitalizations for exacerbations of chronic obstructive pulmonary disease (COPD), bronchitis, and asthma. Elevation in ambient air PM levels can also be associated with increases in respiratory infections. Although not found in all studies, small, reversible decrements in pulmonary function as well as modest neutrophilia in the bronchoalveolar lavage have been described following controlled exposure of healthy volunteers to ambient air pollution particles. Such exposures also can elicit modest, acute changes in the peripheral blood, including elevations in white blood cell counts and increases in C-reactive protein, fibrinogen, and blood viscosity. The last two might possibly contribute to the epidemiologic association of ambient PM with thrombotic coronary artery events. Daily hospital admissions for cardiovascular diseases are also associated with PM levels, and the incidence of acute myocardial infarction has been reported to be increased within 2 hours of elevation in PM and to remain elevated for 24 hours.

Ozone

Exposure to low levels of O₃ can be accompanied by neutrophilic airways inflammation as early as within 1 hour (and can persist for 24 hours), even in the absence of either respiratory symptoms or lung function decrements. Prolonged controlled exposures of healthy, exercising volunteers to levels as low as 0.08 ppm caused pulmonary function changes (decreased inspiratory capacity and increased nonspecific airway reactivity) as well as evidence of airway inflammation. Spirometric reactivity to a given inhaled dose of O₃ appears to decrease with increasing age and possibly with antioxidant status and decreasing body mass index. However, most of the large range of interindividual response variability remains unexplained. Genetic polymorphisms may play a role. Ambient daily mean levels of O₃ above 0.02 ppm have been associated with increased daily hospitalizations for respiratory diseases, and levels above 0.05 ppm have been associated with increased respiratory symptoms, school and work absences, emergency department visits, physician visits, and medication use. Recent investigation suggests that mortality may increase with ambient O₃ exposure.

Although there is little evidence to support an induction of an atopic state or asthma by exposure to O₃, symptoms in patients with established asthma are clearly worsened. Panel studies in asthmatic children found an association of low ambient concentrations of O₃ with respiratory symptoms, increased bronchodilator use, and hospitalizations for asthma 1 day later.

Nitrogen Oxides and Sulfur Dioxide

Regarding the acute effects of exposure to NO_x and SO₂, healthy subjects can demonstrate reduced pulmonary

Figure 24-1 Air Quality Index for Pollution Based on Ozone and Particulate Matter Levels.Adapted from U.S. Environmental Protection Agency at <http://epa.gov/airnow>.

Air-quality index	Air quality	Ozone (ppm)		Particulate matter ($\mu\text{g}/\text{m}^3$)		Health advisory
		8 hours	1 hour	PM 2.5	PM 10	
0 to 50	Good	0-0.064		0-15	0-50	None
51 to 100	Moderate	0.065-0.084		>15-40	>50-150	Unusually sensitive people should consider reducing prolonged or heavy exertion.
101 to 150	Unhealthy for sensitive groups	0.085-0.104	0.125-0.164	>40-65	>150-250	People with heart or lung disease, older adults, and children should reduce prolonged or heavy exertion.
151 to 200	Unhealthy	0.105-0.124	0.165-0.194	>65-150	>250-350	People with heart or lung disease, older adults, and children should avoid prolonged or heavy exertion. Everyone else should reduce prolonged or heavy exertion.
201 to 300	Very unhealthy	0.125-0.404	0.195-0.404	>150-250	>350-420	People with heart or lung disease, older adults, and children should avoid prolonged or heavy exertion. Everyone else should reduce prolonged or heavy exertion.

function and increased airway reactivity, but only at concentrations far greater than those ever observed in an outdoor environment. However, asthmatic people are more susceptible to bronchoconstrictive effects of NO_x and SO_2 . The SO_2 effect has many similarities to exercise-induced bronchospasm and can provoke symptomatic bronchoconstriction during brief exposure to as little as 0.25 ppm.

Carbon Monoxide

Health effects of CO result from its high affinity for hemoglobin (which is 200 to 250 times that of O_2). Exposures to very high levels of CO can cause rapid uptake and acute poisoning, but such exposures are not encountered in outdoor settings. Carboxyhemoglobin levels between 2% and 4% cause a shortening of time to onset of exercise-induced angina, and somewhat higher levels cause increased ectopy in patients with coronary artery disease. A few studies have associated CO exposure with cardiac arrhythmia and with hospital admissions for heart disease and mortality, but ambient air CO levels may be surrogates for other pollutants rather than acting directly.

Diagnostic Approach

The air pollution-associated clinical events are essentially indistinguishable from the more common causes of these events. Therefore, the clinician must look for evidence of an association between the development of symptoms (or pathophysiologic changes) and exposure to elevated levels of ambient air pollution, especially in susceptible individuals. The mean daily levels of pollutants in a given region

can be ascertained employing a U.S. Environmental Protection Agency website called AIRNOW.

Management and Therapy

Optimum Treatment

Therapies directed at adverse respiratory effects of air pollution include limiting outdoor activities (especially for O_3) and treatment of exacerbation of asthma and COPD. The latter can include bronchodilators, inhaled or systemic corticosteroids, and oxygen.

Empirical antibiotics, glucocorticosteroids, and bronchodilators are generally prescribed for patients with COPD exacerbations. The possible specific efficacy against air pollution-provoked health effects of chemopreventive and therapeutic efficacy of drugs like nonsteroidal anti-inflammatory agents (which blunt O_3 -induced decrease in inspiratory capacity), leukotriene antagonists, and omalizumab, or enhancement of antioxidant metabolism, has not yet been sufficiently evaluated. In addition to individuals with asthma or COPD, patients with diabetes and cardiovascular disease are likely to benefit by following recommendations included in the Environmental Protection Agency AIRNOW air quality index (Fig. 24-1). Attempts at reduction to exposure to PM might include the following:

- Avoidance of residence in areas that frequently exceed the NAAQS
- Reduction of physical activities requiring exertion on days that pollution exceeds the NAAQS for PM or O_3

- Avoidance of exposure to environmental tobacco smoke
- Deferral of activities entailing exposure in environments affected by wildfires (e.g., Western United States)
- Avoidance of wood-burning stoves, fireplaces, and kerosene heaters
- Avoidance of specific household activities involving particle exposure (e.g., use of household cleansers and mulching)
- Consulting the AIRNOW internet site before travel to areas within the United States
- Avoidance of travel to international locations with high ambient air pollution levels

Future Directions

Control of air pollution by air quality monitoring, delineation of air quality standards, and imposition of controls on emissions from stationary and mobile sources has been the principal approach by which federal and state agencies have attempted to prevent adverse health effects. Individ-

ual avoidance of exposure to polluted ambient air is recommended. Future efforts will include identification of susceptible individuals (including determinants of genetic susceptibility). Chemoprophylaxis for such persons, including enhancement of antioxidant defenses, may follow.

Hypertension

Introduction

Hypertension is a major risk factor for cardiovascular disease (Fig. 25-1). Numerous large-scale prospective observational studies have demonstrated five major effects of hypertension, all of which contribute to the overall mortality and morbidity associated with hypertension. First, high blood pressure accelerates atherogenesis and increases the risk for cardiovascular events twofold to threefold. Second, the level of systolic and diastolic blood pressure is associated with cardiovascular events in a continuous, graded, and apparently independent fashion. In subjects 50 years and older, an elevated systolic blood pressure is a much more important cardiovascular risk factor than an elevated diastolic blood pressure (Fig. 25-2; see Fig. 25-1). Third, the risk for cardiovascular disease, beginning at 115/75 mm Hg, doubles with each increase of 20/10 mm Hg. Between a diastolic blood pressure of 110 mm Hg and 70 mm Hg, a persistently lower usual diastolic blood pressure of 5 mm Hg is associated with at least a 40% decrease in the incidence of stroke and a 21% decrease in the incidence of coronary heart disease. Fourth, hypertension often occurs in association with, and as a result of, other atherogenic risk factors, including dyslipidemia, glucose intolerance, hyperinsulinemia, and obesity. Fifth, the association of hypertension with other cardiovascular risk factors increases the risk for cardiovascular events in a multiplicative rather than additive fashion.

Pharmacologic treatment of hypertension reduces the incidence of stroke and coronary artery disease, and decreases mortality from cardiovascular causes in middle-aged and older adults (Fig. 25-3). The results of the randomized clinical trials of the treatment of hypertension indicate that the average percentage reductions in the incidence of stroke, myocardial infarction, and heart failure with drug treatment are 35% to 40%, 20% to 25%, and 50%, respectively. If anything, these trials likely underestimate the cardiovascular benefits of blood pressure control because numerous study patients assigned to active therapy stopped their treatment, whereas others assigned to placebo were prescribed medications. In addition, the average duration of treatment was only about 5 years, and most patients enrolled were at low risk for developing cardiovascular disease.

More recent clinical trials have focused on head-to-head comparisons of different antihypertensive drugs or combinations of drugs, to determine whether certain agents offer benefits beyond those attributable to lowering of blood pressure, particularly in older persons with cardiovascular risk factors. Meta-analyses of these trials have indicated that, with few exceptions, the most important factor in decreasing cardiovascular morbidity and mortality in hypertensive subjects is the magnitude of the blood pressure reduction rather than the drug or drugs used to achieve the reduction of the blood pressure. However, as indicated later, there are some compelling indications for the use of specific drug classes in appropriate patients. There is also evidence that β -adrenergic blockers may not be as effective as other medications in preventing cardiovascular complications in older people with hypertension.

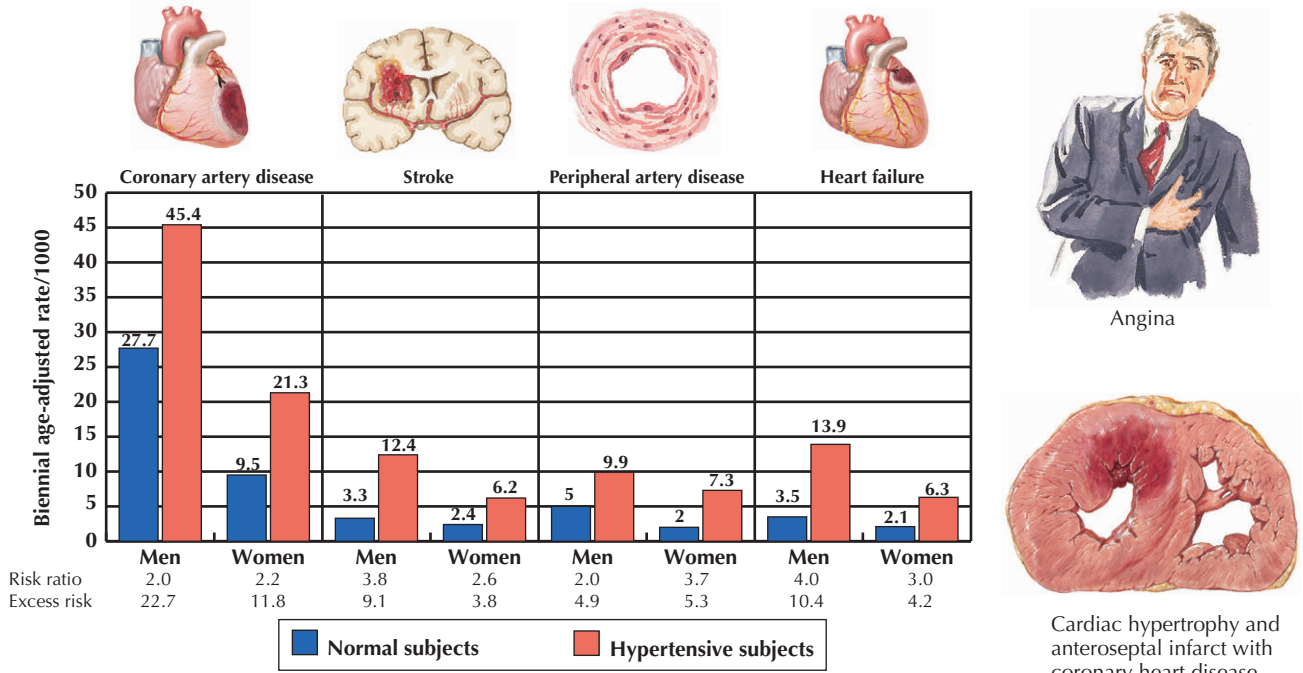

Definition of Hypertension

Blood pressure is a continuous variable, and any level of blood pressure chosen to define hypertension will be arbitrary. Nevertheless, an operational definition of hypertension has long been advocated by clinicians as a guideline

for treatment. Such a definition should theoretically be based on the estimated level of blood pressure above which the benefit of pharmacologic therapy in reducing cardiovascular risk exceeds the risk and inconvenience of therapy. The report of the Seventh Joint National Committee on the Prevention, Detection, Evaluation, and Treatment of

B

High Blood Pressure (JNC VII) recommended the classification of blood pressure for adults shown in Table 25-1. As compared with the previous classification recommended by JNC VI, subjects with a blood pressure of 120/80 to 139/89 mm Hg are now designated as having prehypertension because they are at high risk for developing hypertension. Patients and clinicians need to be aware of this condition to ensure follow-up and institution of lifestyle modifications. Several observational studies have shown that subjects with prehypertension have increased cardio-

vascular morbidity, but it has yet to be demonstrated that antihypertensive drug therapy or even lifestyle modifications decrease morbidity in such subjects.

Similar, but subtly different, recommendations have been proposed by other organizations. The British Hypertension Society and the European Society of Hypertension classify as high-normal systolic blood pressures of 130 to 139 mm Hg and diastolic blood pressures of 80 to 89 mm Hg. However, both societies recommend lifestyle modifications for subjects having high-normal blood

pressure. The U.S. guidelines suggest that achieving a blood pressure of less than 130/80 mm Hg with pharmacologic therapy is beneficial in patients with diabetes and kidney disease. The European guidelines also recommend that such levels of blood pressure be achieved in subjects with heart disease.

Epidemiology

Hypertension is a major health problem throughout the world. The prevalence of hypertension worldwide may be as high as 1 billion persons, and deaths attributed to hypertension now total about 7 million per year. The prevalence of hypertension is higher in developed countries, but it is increasing rapidly in developing countries as a consequence of longer life span, obesity, and changing dietary habits. In the United States, even those who are normotensive at 55 years have a 90% lifetime risk for hypertension. According to the World Health Organization, suboptimal blood pressure is the number one attributable cause of death throughout the world. Hypertension is the most common cause of preventable death in developed countries.

The U.S. National Health and Nutrition Examination Surveys (NHANES) have defined the characteristics of

hypertension in subjects 18 to 76 years of age between 1976 and 2004. The overall prevalence of hypertension in the United States in 2004, based on measurement of blood pressure or reported use of prescribed antihypertensive medication, was 29.3%. About 30 million men and 35 million women had hypertension in that survey (Fig. 25-4). The trend in awareness, treatment, and control of high blood pressure during those years is shown in Table 25-2. During the year 2003 to 2004, 76% of patients with hypertension were aware of their condition, 65% were receiving treatment, and 37% had controlled hypertension, defined as a blood pressure of less than 140/90 mm Hg. There has been a gradual improvement of these parameters over the years in both genders, in all age groups, and in various ethnic groups, but only 57% of treated subjects had controlled hypertension. The percentage of patients with controlled hypertension is lower in some Western countries such as Canada and England, and is less than 10% in developing countries—a disappointing figure given the medications available to treat hypertension and efforts made to educate the public and physicians about the risks of high blood pressure. Hypertension is therefore a major worldwide public health problem and a highly prevalent major cardiovascular risk factor, the prevention and treatment of which should be prioritized.

Table 25-2 Trends in the Awareness, Treatment, and Control of High Blood Pressure in U.S. Adults

	<i>National Health and Nutrition Examination Survey (%)</i>				
	1976-1980	1988-1991	1991-1994	1999-2000	2003-2004
Awareness	51	73	68	70	76
Treatment	31	55	54	59	65
Control	10	29	27	34	37

Data are for adults 18 to 74 years of age with a systolic blood pressure equal to or greater than 140 mm Hg or a diastolic blood pressure equal to or greater than 90 mm Hg. Control is defined as a systolic blood pressure <140 mm Hg and a diastolic blood pressure <90 mm Hg.

Etiology and Pathogenesis

Hypertension is a disorder of blood pressure regulation that most often results from an increase in total peripheral vascular resistance. Although increased cardiac output plays an etiologic role in the development of hypertension, most individuals with essential hypertension have normal cardiac output. This apparent paradox is explained by the phenomenon of autoregulation, whereby an increase in cardiac output causes a persistently elevated peripheral vascular resistance, with a resulting return of cardiac output to normal. Figure 25-5 shows the numerous mechanisms that can lead to hypertension.

Inappropriate activation of the renin-angiotensin system, decreased renal sodium excretion, and an increase in sympathetic nervous system activity, individually or in combination, are most likely involved in the pathogenesis of all types of hypertension. Hypertension has both genetic and environmental causes, including excess sodium intake, obesity, and stress. The inability of the kidneys to optimally excrete sodium, and thus regulate the plasma volume, leads to a persistent increase in blood pressure regardless of the specific underlying etiology.

Many elderly patients with elevated blood pressure have isolated systolic hypertension—a systolic pressure that exceeds 140 mm Hg with a normal diastolic pressure.

Figure 25-6 Wave Reflection and Isolated Systolic Hypertension.

JOHN A. CRAIG AD

Amplitude of reflected wave greatest in periphery, accounting for higher systolic pressures in extremities than in aorta. Diastolic return of reflected wave to heart increases coronary perfusion and decreases afterload

Stiffening of arterial wall increases pulse wave velocity and results in systolic return of reflected wave with increase in systolic pressure (isolated systolic hypertension), decreased diastolic pressure, increased afterload, and left ventricular hypertrophy

Isolated systolic hypertension correlates with stiffening of large arteries, an increase in systolic pulse wave velocity causing an increase in systolic blood pressure, and increased myocardial work with decreased coronary perfusion (Fig. 25-6).

Clinical Presentation

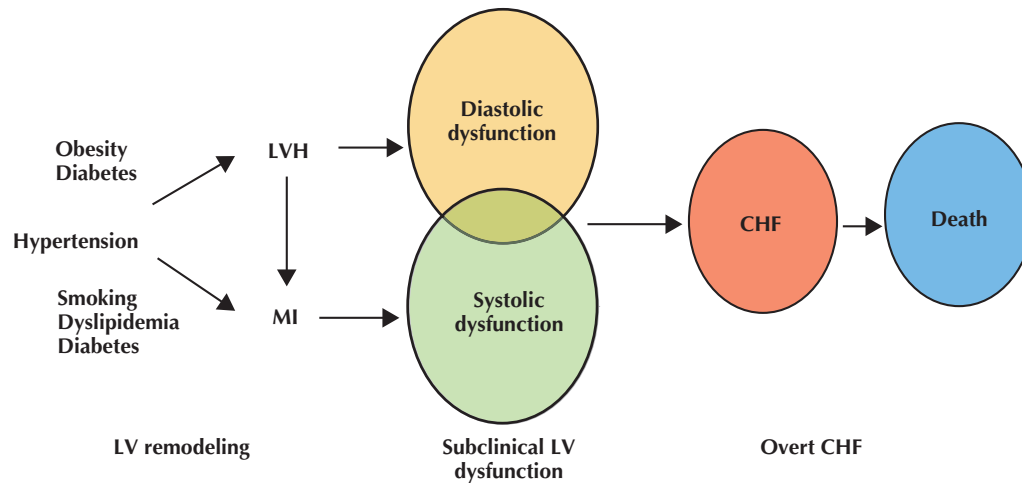

Most patients with early hypertension have no symptoms attributable to high blood pressure. It is essential to detect and treat hypertension at this asymptomatic stage because

by the time symptoms occur in individuals with long-term blood pressure elevation, hypertensive heart disease, atherosclerosis of the aorta and peripheral vessels, cerebrovascular disease, or renal insufficiency may be present.

The cardiac manifestations of hypertension result from both the hypertrophic effects of increased afterload and the acceleration of coronary atherosclerosis seen in hypertensive patients. Left ventricular hypertrophy is a powerful and independent risk factor for cardiovascular morbidity and mortality. Most hypertensive patients with left ventricular hypertrophy have concentric hypertrophy—an

Figure 25-7 Development of Congestive Heart Failure in Patients with Hypertension.

CHF, congestive heart failure; LV, left ventricular; LVH, left ventricular hypertrophy; MI, myocardial infarction. Adapted from Vasan RS, Levy D: *The role of hypertension in the pathogenesis of heart failure. A clinical mechanistic overview. Arch Intern Med 156:1789-1796, 1996.*

increase in wall thickness relative to chamber dimensions. In addition, myocardial fibrosis, stimulated in part by increased angiotensin II and aldosterone levels, causes decreased ventricular compliance and diastolic dysfunction and may result in congestive heart failure despite normal left ventricular systolic function. Sustained blood pressure elevations may ultimately lead to left ventricular decompensation and diminished cardiac output. Hypertension is an independent risk factor for coronary artery disease. The incidence of coronary events increases proportionally with increases in systolic or diastolic blood pressure. These two effects, left ventricular hypertrophy and accelerated atherosclerosis, combine to greatly enhance the risk for congestive heart failure and cardiovascular death in patients with hypertension (Fig. 25-7).

As many as half of patients with high blood pressure and heart failure have a normal left ventricular ejection fraction. Typically, these patients have long-standing hypertension and left ventricular hypertrophy, and their symptoms result from diastolic dysfunction. Compared with patients with heart failure and a decreased ejection fraction, patients with diastolic heart failure tend to be older and are more likely to be female and hypertensive. Although diastolic heart failure confers a lower risk for mortality, it is an important cause of morbidity and hospitalization.

Occasionally, asymptomatic hypertension may enter a phase called *malignant* or *accelerated* hypertension. This syndrome is characterized by greatly elevated systolic and diastolic blood pressures, severe neuroretinitis, proteinuria, microscopic hematuria, impairment of renal function, and a variety of symptoms caused by proliferative endarteritis and fibrinoid necrosis of small arteries and arterioles.

Differential Diagnosis

About 95% of patients with elevated arterial pressure have essential hypertension. In many such patients, obesity is a contributing factor. Obstructive sleep apnea is frequently associated with obesity and hypertension, but it has yet to be definitively proved that appropriate treatment of this condition consistently lowers blood pressure. The remaining 5% of patients with high blood pressure have secondary hypertension (Fig. 25-8). The prevalence of secondary hypertension is higher in the very old and in the very young. Although patients with secondary hypertension are few in number, it is important to identify such patients because their hypertension can often be cured or significantly improved by an interventional procedure, a specific drug therapy, or stopping a culprit drug.

Evidence of identifiable causes of hypertension should be sought in the initial history, physical examination, and laboratory studies. Further diagnostic evaluation for causes of secondary hypertension should be pursued when the presentation is atypical for essential hypertension, or when the initial evaluation suggests an identifiable cause (Box 25-1). Diagnostic methods used in evaluating specific causes of secondary hypertension are discussed in Chapters 26 and 27.

Diagnostic Approach

The initial evaluation of the hypertensive patient should include the following steps:

- Confirmation of the presence of hypertension
- Determination of the presence and extent of target organ disease

Figure 25-8 Causes of Hypertension.

Combined systolic and diastolic hypertension	Essential hypertension		Unknown etiology		
	Renal disorders		Parenchymal renal disease	Glomerulonephritis Chronic pyelonephritis Diabetic nephropathy Interstitial nephritis Polycystic kidney Connective tissue disease Hydronephrosis	Hypernephroma JG cell tumor Wilms' tumor Solitary renal cyst Perinephritis Renal hematoma Fibrous constriction (Ask-Upmark kidney)

Box 25-1 Indications for Considering Testing for Identifiable Causes of Hypertension

- Age of onset of hypertension <20 years or >50 years
- Target organ damage at presentation
 - Serum creatinine concentration >1.5 mg/dL
 - Left ventricular hypertrophy by electrocardiography
- Presence of features indicative of secondary causes:
 - Hypokalemia
 - Abdominal bruit
 - Labile pressures with tachycardia, sweating, and tremor
 - Family history of renal disease
- Poor response to generally effective therapy

- Identification of cardiovascular risk factors and coexisting conditions that influence prognosis and therapy
- Exclusion or detection of identifiable causes of elevated blood pressure

These goals can usually be achieved with a comprehensive history, a thorough physical examination, and selected laboratory studies.

A comprehensive history is essential, and should include the following:

- The duration and severity of elevated blood pressure, and the results of prior medication trials
- The presence of diabetes, hypercholesterolemia, tobacco use, and other cardiovascular risk factors
- A history or symptoms of target organ disease, including coronary heart disease and heart failure, cerebrovascular disease, peripheral vascular disease, and renal disease
- Symptoms suggesting identifiable causes of hypertension
- The use of drugs or substances that may raise blood pressure
- Lifestyle factors, such as diet, leisure time physical activity, and weight gain, that may influence blood pressure control
- Psychosocial and environmental factors, such as family support, income, and educational level, including factors that could influence the efficacy of antihypertensive therapy
- Any family history of hypertension or cardiovascular disease

The physical examination should focus on determining the level of blood pressure and searching for evidence of target organ disease or identifiable causes of hypertension. Important facets of the examination include the following:

- Careful measurement of blood pressure
- Measurement of height and weight
- Funduscopic examination for hypertensive retinopathy
- Examination of the neck for carotid bruits, elevated jugular venous pressure, and thyromegaly

- Examination of the heart for abnormalities of the apical impulse or the presence of extra heart sounds or murmurs
- Examination of the abdomen for bruits, enlarged kidneys, and other masses
- Examination of the extremities for diminished arterial pulsations or peripheral edema

Laboratory studies are recommended to determine the presence of target organ damage and other cardiovascular risk factors and to exclude identifiable causes of hypertension. These include the following:

- Complete blood count
- Serum concentrations of potassium, creatinine, thyroid-stimulating hormone, fasting glucose, and high-density lipoprotein and total cholesterol
- Urinalysis for blood, protein, glucose, and microscopic examination
- An electrocardiogram

Detection and diagnosis of hypertension begins with the accurate measurement of blood pressure. Measurements should be acquired at each health care encounter, with follow-up determinations at intervals based on the initial blood pressure level. Accurate equipment and utilization of a standardized technique are critical. In many patients, home blood pressure monitoring may help in establishing baseline blood pressure levels or evaluating the response to therapy. Home blood pressures, when acquired with a reliable device in a systematic fashion and recorded accurately, correlate more closely with cardiovascular event rates than do office blood pressure measurements. Patients with white-coat hypertension, who may not require additional therapy, as well as those who remain at increased risk because of masked hypertension, can be identified with this technique. Twenty-four-hour ambulatory blood pressure monitoring may be useful in cases of unusual variability between visits, suspected white-coat hypertension, symptoms suggesting hypotensive episodes, or hypertension resistant to medication, or when there are large discrepancies between home and office measurements.

Management and Therapy

Optimum Treatment

The principal goal in treatment of hypertension is to reduce the risk for cardiovascular morbidity and mortality. The approach to therapy in an individual should be determined in part by the absolute risk for a cardiovascular event, based on the presence of major cardiovascular risk factors or target organ damage. Patients with diabetes mellitus, chronic kidney disease, or clinical cardiovascular disease are at particularly high risk for cardiovascular events. Pharmacologic therapy should be considered for these individuals when blood pressure is mildly elevated or in the prehypertensive range, with a treatment goal of

Table 25-3 Classification and Management of Blood Pressure for Adults

Classification	Systolic* (mm Hg)	Diastolic* (mm Hg)	Lifestyle Modification	Initial Drug Therapy	
				Without Compelling Indication	With Compelling Indication
Normal	<120	and <80	Encourage		
Prehypertension	120-139	or 80-89	Yes	No antihypertensive drug indicated	Drug(s) for compelling indications [†]
Stage 1 hypertension	140-159	or 90-99	Yes	Thiazide-type diuretics for most; may consider ACE-1, ARB, BB, CCB, or combination	Drug(s) for the compelling indications [†]
Stage 2 hypertension	≥160	or ≥100	Yes	Two-drug combination for most [‡] (usually thiazide-type diuretic and ACE-1, ARB, BB, or CCB)	Other antihypertensive drugs (diuretics, ACE-1, ARB, BB, CCB) as needed

*Treatment determined by highest blood pressure category.

[†]Initial combined therapy should be used cautiously in those at risk for orthostatic hypotension.

[‡]Treat patients with chronic kidney disease or diabetes to blood pressure goal of <130/80 mm Hg.

ACE-1, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker; BB, β blocker, CCB, calcium channel blocker.

Data from the National High Blood Pressure Education Program; National Heart, Lung and Blood Institute; National Institutes of Health and the Department of Health and Human Services.

normalizing the pressure (i.e., <130/80 mm Hg). Lower-risk patients may benefit from a period of observation and lifestyle modification, using medical therapy if the average systolic pressure exceeds 140 mm Hg or diastolic pressure exceeds 90 mm Hg over months of monitoring. The management strategy recommended in the JNC VII report is outlined in Table 25-3.

Lifestyle modifications are an important component of the therapy for high blood pressure. All patients with hypertension, prehypertension, or a strong family history of hypertension should be encouraged to lose weight if overweight, participate in regular aerobic exercise, limit alcohol intake, and adopt a healthy diet. The Dietary Approaches to Stop Hypertension (DASH) eating plan, a diet rich in fruits, vegetables, and low-fat dairy products with reduced saturated fats, is as effective as single-drug therapy in many hypertensive individuals. Additional benefit can be realized by limiting dietary sodium intake. These lifestyle changes not only lower blood pressure but also enhance the effectiveness of antihypertensive drugs and favorably influence other cardiovascular risk factors. Smoking cessation further reduces cardiovascular risk and should be strongly encouraged.

Drug therapy is indicated if lifestyle modifications do not bring the blood pressure into the desired range. The optimal agent for initial therapy of uncomplicated patients with hypertension remains a subject of considerable controversy. Thiazide diuretics, β -adrenergic receptor blockers, angiotensin-converting enzyme (ACE) inhibitors, angiotensin-receptor blockers (ARBs), and calcium antagonists have all been viewed as appropriate first-line agents for the treatment of hypertension. Thiazide diuretics are inexpensive and generally well-tolerated, and

ALLHAT* and other comparative trials suggest that they are as effective as newer drugs in preventing stroke and myocardial infarction. Compared with ACE inhibitors, ARBs, and calcium antagonists, however, diuretics increase the risk for developing diabetes. The results of the ASCOT** study reinforce data from several previous trials suggesting that β -blockers are less effective than alternative therapies in preventing cardiovascular events, especially stroke, in elderly patients. Ultimately, however, most patients will require more than one antihypertensive drug, and achieving optimal blood pressure control is more important than the choice of the initial agent. In many patients, the appropriate antihypertensive drug is dictated by comorbid conditions. Table 25-4 lists agents that are preferred or relatively contraindicated in specific circumstances.

In general, medical therapy should be initiated at low doses in an effort to minimize side effects. Based on the patient's response, the dose of the initial agent can be titrated upward, or a small dose of a second agent can be added. Many experts favor using lower doses of two or even three antihypertensive drugs with a goal of minimizing dose-dependent side effects. Other experts favor up-titration of monotherapy, arguing that patient adherence to therapy will be better with less complicated regimens. It should be noted that with the advent of many once-daily antihypertensive medications, most patients can be treated with once-a-day therapies, even if this involves more than one antihypertensive agent.

*Antihypertensive and Lipid-Lowering Treatment of Prevent Heart Attack Trial.

**Anglo-Scandinavian Cardiac Outcomes Trial.

Table 25-4 Choice of Antihypertensive Agent Based on Coexistent Illnesses

Indications for Specific Drugs	
Diabetes mellitus	ACE inhibitor or ARB
Congestive heart failure	ACE inhibitor or ARB, β -blocker, diuretic, aldosterone antagonist
Myocardial infarction	ACE inhibitor or ARB, β -blocker, aldosterone antagonist
Chronic coronary disease	ACE inhibitor, β -blocker
Renal insufficiency	ACE inhibitor or ARB
Contraindications to Specific Drugs	
Pregnancy	ACE inhibitor, ARB
Renal insufficiency*	Potassium-sparing agent
Peripheral vascular disease	β -blocker
Gout*	Diuretic
Depression*	β -blocker, central α agonist
Reactive airway disease	β -blocker
Second- or third-degree heart block	β -blocker, nondihydropyridine calcium antagonist
Hepatic insufficiency	Labetalol, methyldopa

*Relative contraindications.

ACE, angiotensin-converting enzyme inhibitor; ARB, angiotensin receptor blocker.

Patients with stage 2 hypertension can be started on two drugs initially. Effective drug combinations utilize medications from different classes and result in additive blood pressure lowering effects, while minimizing dose-dependent adverse effects. Diuretics potentiate the effect of β -blockers, ACE inhibitors, and ARBs; other useful combinations include dihydropyridine calcium antagonists and β -blockers, or calcium antagonists and ACE inhibitors or ARBs. Long-acting formulations with 24-hour efficacy are preferred over shorter-acting agents because of greater patient adherence, as discussed previously, as well as because more consistent blood pressure control during the course of the day can be obtained with long-acting medications.

Lowering blood pressure is but one mechanism by which cardiovascular risk can be lowered in hypertensive patients. Irrespective of baseline cholesterol levels, statin therapy is effective in reducing the incidence of myocardial infarction and stroke in hypertensive patients, and most patients with high blood pressure benefit from treatment with a lipid-lowering agent. Low-dose aspirin also reduces the risk for cardiovascular events.

The goal of preventing cardiovascular morbidity and mortality is usually achieved with a gradual reduction of blood pressure, maintained over many years. Occasionally, a hypertensive crisis may occur, and blood pressure must be reduced urgently. A hypertensive crisis is defined as acute organ dysfunction of the cardiovascular or nervous system accompanied either by a marked absolute elevation of blood pressure or an abrupt increase in blood pressure in a previously normotensive individual. The initial therapy for hypertensive crisis may involve use of intravenous medications in an intensive care unit setting (Box 25-2).

Avoiding Treatment Errors

- Distinguish between severe, grade 2 hypertension and a hypertensive crisis. The latter mandates a decrease in

Box 25-2 Agents Used for Intravenous Drug Therapy of Hypertensive Emergencies

- Nitroprusside: preferred agent in most instances except acute coronary syndromes or pregnancy. Should be combined with β -blocker in some instances
- Nitroglycerine: use in acute coronary syndromes alone or combined with metoprolol or labetalol
- Labetalol: use as adjunctive therapy with nitroprusside or nitroglycerine. Use alone in less intensely monitored situations or treatment of postoperative hypertension
- Enalaprilat: use for scleroderma crisis or as adjunctive therapy in some high renin states
- Hydralazine: may use for treatment of preeclampsia, eclampsia
- Fenoldopam: same indication as for nitroprusside. Useful in postoperative or postprocedure hypertension in closely monitored situations
- Esmolol: use in case of need for immediate, very short-acting β -blocker effect. Use for supraventricular tachycardia

blood pressure and achievement of a certain blood pressure goal within minutes or hours. In grade 2 hypertension, blood pressure can be lowered within days and titration to the desired level may sometimes take weeks.

- Use thiazide diuretics as first-line therapy in certain salt-sensitive hypertensive patients such as African Americans and in patients requiring a combination of antihypertensive drugs, unless there is a clear contraindication to the use of such drugs.
- Institute lifestyle modifications as the first step in the treatment of hypertension, and continue these measures if drug therapy is ultimately required.
- Monitor patients for the metabolic effects of antihypertensive medications at initiation of therapy and periodically as needed.

- Look for an orthostatic fall in blood pressure in older patients and in those suspected of having autonomic dysfunction, such as subjects with long-standing diabetes mellitus. Titrate antihypertensive medication to avoid an excessive fall in blood pressure in the standing position.
- Treat isolated systolic hypertension with slow titration of antihypertensive medications, starting at a low dose of the drug: “Go low and slow.”
- Avoid continuing to try to lower an elevated systolic blood pressure if the diastolic blood pressure is persistently lower than 65 mm Hg because of the risk for cardiac ischemia, particularly in patients with preexisting coronary artery disease.
- Avoid sudden withdrawal of certain antihypertensive medications such as β -blockers and clonidine to prevent acute coronary syndromes or rebound hypertension.
- Select antihypertensive drugs according to the individual clinical conditions of the patients and the associated comorbidities. Use specific antihypertensive medication for certain conditions unless contraindicated. For example, use ACE inhibitors and angiotensin II receptor blockers in patients with kidney disease, diabetes, or heart failure; use β -blockers for secondary prevention of myocardial infarction and in patients with heart failure due to left ventricular systolic dysfunction; use a combination of a thiazide diuretic and an inhibitor of the renin-angiotensin system for the secondary prevention of stroke.
- Avoid ACE inhibitors and angiotensin II receptor blockers in pregnant women.
- Avoid overtreatment of subjects with white-coat hypertension and undertreatment of patients with masked hypertension.

Future Directions

The past half-century has witnessed remarkable advances in the understanding of the pathophysiology, epidemiology, and natural history of hypertension, as well as dramatic advances in therapy. Nevertheless, many patients with hypertension are undiagnosed or inadequately treated, and high blood pressure remains an important contributor to coronary events, congestive heart failure, stroke, and end-stage kidney disease.

Future research and public health initiatives should be directed at achieving the following objectives:

- Ascertain the most effective antihypertensive agents in reducing cardiovascular end points in patients with uncomplicated hypertension.
- More accurately define treatment thresholds and optimal target blood pressures in patients with diabetes mellitus or with target organ damage.
- Determine the treatment threshold and optimal target blood pressure in elderly patients with isolated systolic hypertension.

- Develop more effective drugs for treating elderly patients with isolated systolic hypertension.
- Develop better strategies to improve patient compliance.
- Decrease the content of sodium and fat in American diets.
- Improve screening techniques and care delivery systems.
- Further define the roles of home and ambulatory blood pressure monitoring.

British Hypertension Society. Available at: <http://www.bhsoc.org>. Accessed October 11, 2007.

Through this website, the British Hypertension Society provides a medical and scientific research forum to enable sharing of clinical information for the management of hypertension. Included in the website is information regarding cutting-edge research in the field, ongoing clinical trials, and important recent publications. The website also reviews recent guidelines, such as the partial update of the UK National Institute of Clinical Excellence and British Hypertension Society's Guidelines for Management of Hypertension in Adults published in June 2006. This document reviews the most recent clinical trials on the treatment hypertension in a brief but comprehensive manner.

Kaplan NM: Kaplan's Clinical Hypertension. 9th ed. Philadelphia, Lippincott Williams & Wilkins, 2006.

This thorough, detailed, yet succinct, eminently readable textbook on clinical hypertension was authored by Dr. Norman Kaplan. It reflects the vast clinical experience and wisdom of the author and offers up-to-date references on all topics.

Pickering TG, Hall JE, Appel LJ, et al: Recommendations for blood pressure measurement in humans and experimental animals. Part 1: Blood pressure measurement in humans. *Hypertension* 45:142-161, 2005.

This is a scientific statement by the American Heart Association with a major focus on the recommended techniques of blood pressure measurement in different clinical settings and circumstances. There is valuable and useful information in this statement for all who treat patients with hypertension and for those in charge of selecting and maintaining the equipment used to measure blood pressure in clinical facilities.

U.S. Department of Health and Human Services, National Heart, Lung, and Blood Institute. National High Blood Pressure Education Program. Available at: <http://www.nhlbi.nih.gov/about/nhbpep/index.htm>. Accessed October 11, 2007.

The National High Blood Pressure Education Program provides valuable educational information on hypertension for health care providers and the general public. All of the reports, guidelines, and publications sponsored by the Program are available, and educational materials such as slides, tables, and graphs can be downloaded. Some of the materials are available in Spanish.

EVIDENCE

1. ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group: Major outcomes in high-risk hypertensive patients randomized to angiotensin-converting enzyme inhibitor or calcium channel blocker vs diuretic: The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT). *JAMA* 288:2981-2997, 2002.

This is the largest double-blind trial undertaken in hypertensive patients, and strongly influenced the recommendations of JNC VII. The trial compared treatment with amlodipine or lisinopril with a reference drug, chlorthalidone, and found no advantage of newer drugs over a thiazide-type diuretic in preventing fatal coronary heart disease or nonfatal myocardial infarction.

2. Appel LJ, Brands MW, Daniels SR, et al: Dietary approaches to prevent and treat hypertension: A scientific statement from the American Heart Association. *Hypertension* 47:296-308, 2006.
This scientific statement provides a concise review of dietary interventions to both prevent and treat hypertension. The DASH diet, reduced salt intake, weight loss, and moderation of alcohol consumption are promoted as dietary modifications that have an established role in blood pressure reduction.
3. Blood Pressure Lowering Treatment Trialists' Collaboration: Effects of different blood-pressure-lowering regimens on major cardiovascular events: Results of prospectively-designed overviews of randomized trials. *Lancet* 362:1527-1535, 2003.
This set of prospectively designed overviews with data from 29 randomized trials examines the comparative effects of different blood pressure-lowering regimens and the benefits of targeting lower blood pressure goals on the risk of major cardiovascular events and death. The overall conclusion is that treatment with any commonly used regimen reduces the risk for major cardiovascular events and that larger reductions in blood pressure produce larger reductions in risk.
4. Chobanian AV, Bakris GL, Black HR, et al: National High Blood Pressure Education Program Coordinating Committee: Seventh report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: JNC 7—Complete Version. *Hypertension* 42:1206-1252, 2003.
This report from the National High Blood Pressure Education Program provides a comprehensive guideline for hypertension prevention and management, and is a "must read" for all physicians who treat patients with high blood pressure. Differences from previous reports include an emphasis on systolic blood pressure as a cardiovascular disease risk factor, and introduction of the classification "prehypertension." Thiazide-type diuretics are recommended for most patients with uncomplicated hypertension, either alone or combined with drugs from other classes.
5. Chobanian AV, Bakris GL, Black HR, et al: The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: The JNC 7 Report. *JAMA* 289:2560-2572, 2003.
This condensed version of the JNC VII report highlights the major points of the National High Blood Pressure Education Program recommendations.
6. Dahlof B, Sever PS, Poulter NR, et al: The ASCOT Investigators. Prevention of cardiovascular events with an antihypertensive regimen of amlodipine adding perindopril as required versus atenolol adding bendroflumethiazide as required, in the Anglo-Scandinavian Cardiac Outcomes Trial-Blood Pressure Lowering Arm (ASCOT-BPLA): A multicentre randomised controlled trial. *Lancet* 366:895-906, 2005.
This large European study found an advantage of newer drugs (amlodipine ± perindopril, as required) over conventional blood pressure lowering therapy (atenolol ± bendroflumethiazide, as required) in reducing cardiovascular mortality. These results reinforced data from previous studies suggesting that β-blocker-based therapy is less effective than other first-line drugs in reducing cardiovascular events in older patients.
7. Fields LE, Burt VL, Cutler JA, et al: The burden of adult hypertension in the United States 1999 to 2000. A rising tide. *Hypertension* 44:498-504, 2004.
The purpose of this study was to estimate the absolute number of persons with hypertension in the year 2000 using data from the National Health and Nutrition Examination Survey of U.S. resident adults. The authors found that at least 65 million adults had hypertension in 1999 to 2000. A more recent survey has shown that the prevalence of hypertension in this population remains constant at about 29%. Because the adult population is now greater than in the year 2000, the burden of hypertension continues to rise in the United States.
8. Guidelines Committee: 2003 European Society of Hypertension—European Society of Cardiology guidelines for the management of arterial hypertension. *J Hypertens* 21:1011-1053, 2003.
Like the BHS report, this set of guidelines also recommends initiation of medical therapy based on a comprehensive assessment of other risk factors, target organ disease, diabetes, and associated clinical conditions.
9. Ong KL, Cheung BM, Man YB, et al: Prevalence, awareness, treatment, and control of hypertension among United States adults 1999-2004. *Hypertension* 49:69-75, 2007.
This latest report from the National Health and Nutrition Examination Survey (NHANES) 1999-2004 examines changes in the prevalence, awareness, treatment, and control of hypertension in the United States. Although encouraging trends are noted, the overall prevalence of hypertension remains high (>29%), and the blood pressure control rate is only 37%.
10. Sever PS, Dahlof B, Poulter NR, et al: The ASCOT Investigators. Prevention of coronary and stroke events with atorvastatin in hypertensive patients who have average or lower-than-average cholesterol concentrations, in the Anglo-Scandinavian Cardiac Outcomes Trial-Lipid Lowering Arm (ASCOT-LLA): A multicentre randomised controlled trial. *Lancet* 361:1149-1158, 2003.
This study demonstrated the value of a statin in reducing the risk for coronary heart disease and stroke in patients with hypertension.
11. Williams B, Poulter NR, Brown MJ, et al: Guidelines for management of hypertension: Report of the Fourth Working Party of the British Hypertension Society, 2004—BHS IV: British Hypertension Society Guidelines. *J Hum Hypertens* 18:139-185, 2004.
This comprehensive guideline differs from the JNC VII report in several important respects: it recommends a more individualized threshold blood pressure for treatment with medications, based on the presence of target organ damage, cardiovascular complications, diabetes, and estimated 10-year risk of cardiovascular disease. The report recommends basing the choice of an initial blood pressure-lowering drug on the age and ethnicity of the patient. ACE inhibitors, angiotensin receptor blockers, or perhaps β blockers are recommended for young, nonblack patients without compelling indications, whereas calcium antagonists or thiazide-like diuretics are recommended as first-line therapy for older or black patients. The report recommends statin therapy for all people with high blood pressure complicated by cardiovascular disease or with a 10-year risk for cardiovascular disease of more than 20%, irrespective of blood lipid levels.

Hypertension Secondary to Renovascular Diseases

Introduction

Up to 20% of middle-aged men and women in the United States have high blood pressure. In 90% to 95% of these patients, the cause of the hypertension is unknown. This is termed *essential* or *primary hypertension*. The remaining 5% to 10% of the general population who have hypertension have an identifiable cause for the elevated blood pressure, with a defined pathophysiology and, in some instances, unique clinical or laboratory findings. This condition is called *secondary hypertension*. There is a strong incentive for diagnosing secondary forms of hypertension because, in many instances, the cause of the hypertension can be eliminated or treated with a specific drug, procedure, or surgical intervention. Furthermore, early diagnosis of these conditions is of paramount importance because most studies have shown that the longer secondary hypertension remains untreated, the less likely the hypertension can be cured. Secondary hypertension is more common in older people because of the higher incidence and prevalence of two frequent forms of secondary hypertension: renal parenchymal disease and atherosclerotic renal artery stenosis (RAS).

There are several primary diseases of the renal artery that cause RAS; the most common are atherosclerosis and fibromuscular dysplasia (FMD). Atherosclerotic RAS accounts for about 80% to 90% of cases, whereas FMD accounts for 10% to 20% of such cases. Atherosclerotic RAS is associated with atherosclerosis of the abdominal aorta and other arteries. The atheroma usually narrows the lumen of the proximal third of one or both renal arteries; the ostium is involved in about 75% of cases. FMD is characterized by fibrous changes in the wall of the distal two thirds of one or both renal arteries and their branches. This condition affects the media of the arteries in most subjects, although in some individuals, the disease involves only the intima or the adventitia of the vessel wall.

Etiology and Pathogenesis

Atherosclerotic RAS is caused by the same factors that cause generalized atherosclerosis obliterans: smoking, dyslipidemia, hypertension, glucose intolerance, genetic predisposition, and other factors. The etiology of the fibrous changes that occur in young patients with FMD is unknown. Possible causes include diseases of the vasa vasorum, genetic predisposition, and hormonal factors. There is evidence that smoking can worsen this condition. Hypertension secondary to atherosclerotic RAS or FMD is caused by a decrease in renal perfusion pressure and is termed *renovascular hypertension* (RVH). Renovascular hypertension occurs in the presence of one or more high-

grade stenoses, defined as a 60% or greater reduction of the lumen of the main renal artery or its branches, and accounts for about 3% of cases of hypertension. High-grade RAS does not always cause hypertension, and even when hypertension and high-grade RAS coexist, the RAS may be incidental, and the subject may have essential or another type of secondary hypertension. RAS is more common than renovascular hypertension. Figure 26-1 depicts the events leading to hypertension in the presence of high-grade unilateral RAS. Bilateral atherosclerotic RAS, or atherosclerotic RAS in a solitary kidney, can cause a decrease in excretory function of the kidney with the development of chronic renal failure. This is called *ischemic nephropathy*.

Figure 26-1 Pathophysiology of Renovascular Hypertension in Unilateral Renal Artery Stenosis.

Causes of renovascular hypertension

Atherosclerotic renal artery stenosis (RAS)
 Severe concentric atherosclerosis of renal artery with lipid deposition, calcification, and thrombosis

Fibromuscular dysplasia
 Longitudinal section fibromuscular dysplasia demonstrating variations in mural thickness

F. Netter M.D.
JOHN A. CRAIG MD
 with E. Hatton

Atherosclerosis is most common cause of renal artery stenosis

Aortorenogram. Atherosclerotic narrowing and poststenotic dilation of both renal arteries

Renal arteriogram. Characteristic beaded appearance caused by alternating stenoses and aneurysmal dilations

Renal arteriogram is gold standard in diagnosis and assessment of severity of renal artery stenosis

Clinical Presentation

Atherosclerotic RAS may be silent or may cause renovascular hypertension, ischemic nephropathy, or both. Ischemic nephropathy can occasionally occur in the absence of hypertension. *Flash pulmonary edema*, acute pulmonary edema that develops abruptly, is a syndrome related to renovascular hypertension and ischemic nephropathy.

Atherosclerotic RAS occurs in older patients. About 90% of patients are or have been heavy smokers. Most

have evidence of atherosclerosis in other vascular beds. There may be abrupt onset of hypertension, worsening of existing hypertension, or development of malignant hypertension after the age of 50 years. Physical examination may show advanced retinopathy, an abdominal or flank bruit, and pulse deficits or bruits over major arteries. Laboratory studies may show hypokalemia caused by elevated plasma renin activity (secondary aldosteronism) and elevation of serum creatinine concentration caused by ischemic nephropathy or other associated

Table 26-1 Screening Tests for Renal Artery Stenosis

Test	Type of Assessment	Features
Captopril renogram	Functional: ACE inhibitor–induced reduction of GFR	High sensitivity and specificity if kidneys of equal size, SCr <2 mg/dL. Prognostic value for improvement of HTN
MRA of the renal arteries	Anatomic: proximal renal arteries	No nephrotoxicity. Cannot use after stent placement
Doppler ultrasound of renal arteries	Anatomic, functional: proximal renal arteries	Highly variable results; technically difficult; operator dependent
Spiral CT angiography	Anatomic: proximal renal arteries	Large volume of contrast dye

ACE, angiotensin-converting enzyme; CT, computed tomography; GFR, glomerular filtration rate; HTN, hypertension; MRA, magnetic resonance angiography; SCr, serum creatinine concentration.

kidney diseases. There may be a large discrepancy in kidney size.

RAS caused by FMD presents as renovascular hypertension starting at a young age. The disease is more common in women younger than 50 years, and also occurs in children. An abdominal bruit may be present, but peripheral pulses are normal. Laboratory studies may show hypokalemia. A large discrepancy in kidney size is unusual. Fibromuscular dysplasia does not cause ischemic nephropathy or flash pulmonary edema.

Differential Diagnosis

The main differential diagnosis of renovascular hypertension caused by atherosclerotic RAS is essential hypertension and other types of secondary hypertension, particularly renal parenchymal disease. In older people with peripheral vascular disease or abdominal aortic disease, the prevalence of atherosclerotic RAS is as high as 38% to 55%. The prevalence of essential hypertension in this population is about 60%. Therefore, it is often difficult to establish whether atherosclerotic RAS in this setting is causing the hypertension or is an incidental occurrence, perhaps related to long-standing hypertension with consequent atherosclerosis. Correction of the stenosis in the latter situation would not lead to cure or improvement of hypertension. Renal failure caused by atherosclerotic RAS must be distinguished from renal failure resulting from renal parenchymal disease such as small vessel disease (nephrosclerosis or atheroembolic disease) or other diseases such as diabetic nephropathy. Characteristics of ischemic nephropathy include minimal proteinuria, scant urine sediment, and frequently a large discrepancy in kidney size with involvement of both renal arteries.

The differential diagnosis of renovascular hypertension caused by FMD includes other causes of hypertension in children or young women: essential hypertension, subtle renal disease, obesity-related hypertension, endocrine hypertension, and coarctation of the aorta.

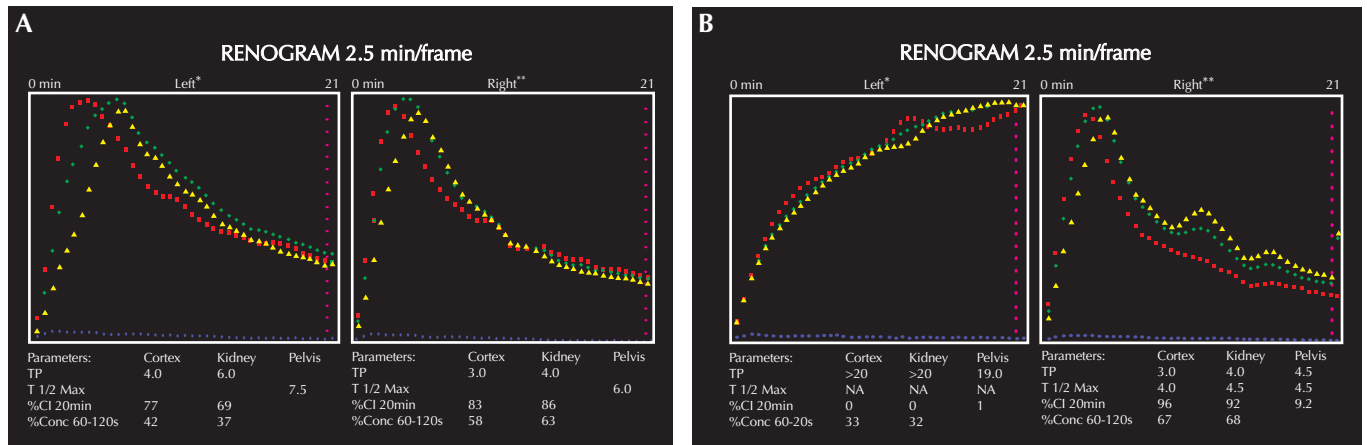

Diagnostic Approach

The gold standard for the diagnosis of RAS is a renal arteriogram, which permits an assessment of the degree of stenosis and shows the characteristic atherosclerotic involvement of the proximal third of the renal artery in atherosclerotic RAS. The most common form of FMD, medial fibroplasia (75%), has characteristic areas of stenoses alternating with aneurysmal dilations (“string of pearls” image) in the distal renal artery, sometimes extending to the branches of the main renal artery. A renal arteriogram is an expensive and invasive test with associated discomforts and risks, and generally provides no information about the functional significance of the lesion. In view of these limitations, several screening tests for the detection of RAS or assessment of its functional significance have been developed (Table 26-1). The sensitivity and specificity of these tests vary from institution to institution according to the local expertise in performing the various studies. For example, Doppler ultrasound of the renal arteries is the preferred screening test in some institutions, yet others find this test to be cumbersome, unreliable, and operator dependent.

None of the anatomic screening tests is adequate to evaluate the distal renal artery; therefore, there is no adequate screening test for FMD, although a captopril renogram may suggest the presence of functionally significant RAS (Fig. 26-2).

Figure 26-3 shows the diagnostic scheme we use to evaluate subjects suspected of having RAS at our institution. The first step in the evaluation is to look for unsuspected renal parenchymal disease with renal sonography and urinalysis. We recommend measuring the resistive indexes over the kidney using Doppler studies at the same time as the kidney ultrasound is performed. This study is easier to perform and more reliable in our institution than Doppler ultrasound of the renal arteries. The resistive indexes appear to have some prognostic value in terms of the response to revascularization. Screening evaluation is

Figure 26-2 Captopril Renogram.

Uptake and excretion of Tc-99m mertiatide, given intravenously, by the left and right kidney before (A), and after (B), oral administration of 50 mg of captopril. Panel B shows slow uptake and no excretion of the radiopharmaceutical, suggesting functionally significant stenosis of the left renal artery. The aortogram (C) shows a high-grade atherosclerotic RAS of the left renal artery with poststenotic dilation in the same patient. The right renal artery is normal. Note the atherosclerotic changes of the abdominal aorta.

* Left kidney
** Right kidney

Figure 26-3 Evaluation for Renal Artery Stenosis in Subjects with Compatible Clinical Picture and Predicted Benefit of Revascularization.

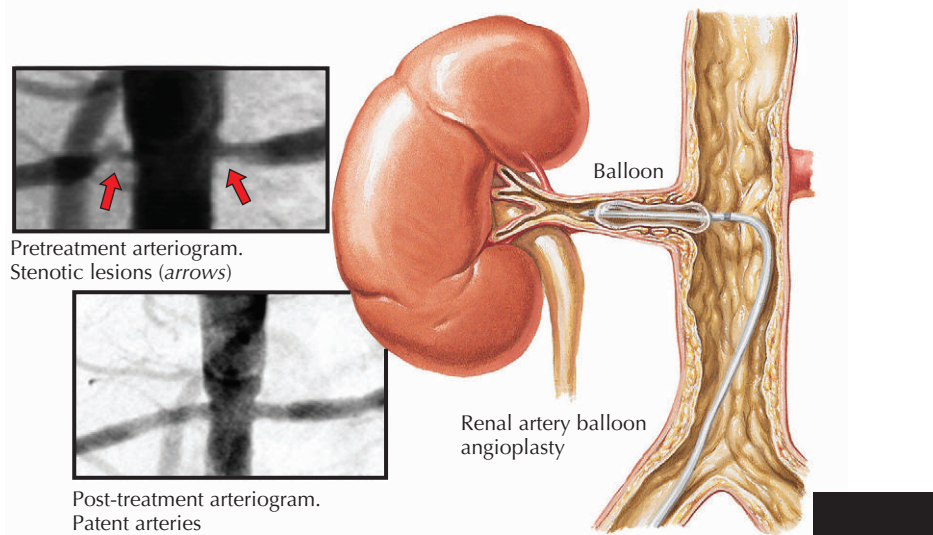

Figure 26-4 Balloon Angioplasty of Stenotic Renal Arteries.

Patients with hypertension and atherosclerotic renal artery stenosis most likely to respond to balloon angioplasty are those with onset of hypertension within the past 5 years, those without primary renal disease, and middle-aged men with atherosclerotic renal artery stenosis and malignant hypertension not caused by primary renal disease. A positive captopril renogram predicts cure or improvement of hypertension after revascularization

limited to patients who have a compatible clinical picture and who are likely to benefit from revascularization of the renal arteries. There is no functional test that predicts improvement of renal function after revascularization.

Management and Therapy

Optimum Treatment

The treatment of RAS can be divided into medical treatment and surgical or endovascular revascularization. Endovascular revascularization consists of balloon angioplasty with or without placement of a vascular stent (Fig. 26-4). Medical treatment for atherosclerotic RAS consists of antihypertensive therapy, smoking cessation, aspirin and other antiplatelet agents, and lipid-lowering drugs. The treatment of choice for young people with FMD is balloon angioplasty. If the balloon can reach the lesion, dilation is usually successful, and hypertension is cured or greatly improved in about 90% of patients. Randomized clinical trials of older patients with atherosclerotic RAS and hypertension have suggested that medical therapy is as effective as angioplasty and stent placement for treating hypertension. The patients with atherosclerotic RAS most likely to respond to balloon angioplasty with cure or marked improvement are those who have had onset of hypertension within the past 5 years and do not have primary renal disease, and middle-aged men with atherosclerotic RAS and malignant hypertension not caused by primary renal disease. We do not advocate revascularization for treatment of hypertension in patients with atherosclerotic RAS

unless the foregoing conditions are met or the patient does not respond to an optimal antihypertensive three- to four-drug regimen. A positive captopril scan is a good predictor of cure or improvement of hypertension after revascularization.

Revascularization for Treatment of Ischemic Nephropathy

Atherosclerotic RAS may be a cause of end-stage renal disease. Several studies have suggested that 11% to 22% of older people reaching end-stage renal disease have high-grade atherosclerotic RAS in at least one renal artery. No major clinical trials have compared medical treatment to balloon angioplasty of the renal artery for preserving or improving renal function. Only a minority of patients with atherosclerotic RAS and renal failure appear to derive long-term benefit from relief of the stenosis with angioplasty. Therefore, it is important to identify those subjects who are not likely to benefit from the procedure or who may be harmed by it. Factors that predict lack of improvement, or worsening of renal function with correction of high-grade atherosclerotic RAS are (1) low-grade stenosis with reduction in luminal diameter of less than 50% in at least one renal artery; (2) unilateral RAS unless the artery supplies a solitary kidney; (3) kidney length less than 8 cm; (4) presence of diabetic nephropathy or other known kidney diseases, or severe proteinuria accompanied by an active urine sediment suggestive of a primary renal disease; and (5) a high resistive index as determined with Doppler ultrasonography.

The National Heart, Lung, and Blood Institute of the National Institutes of Health is sponsoring an ongoing prospective, randomized, multicenter clinical trial called Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL). This study, involving 1080 subjects, will compare optimal medical therapy alone with angioplasty and stenting plus optimal medical therapy in patients with hemodynamically significant atherosclerotic renal artery stenosis and systolic hypertension.

Avoiding Treatment Errors

The main error to avoid in treating atherosclerotic RAS is performing angioplasty and stent placement in an artery with stenosis when there is limited functional or historical data to suggest that endovascular revascularization will be better than optimal medical therapy for the control of hypertension or improvement of kidney function. Under these conditions, the risk of the procedure may exceed the benefits. Before deciding to proceed with revascularization, one should review the history, response to medical therapy, laboratory findings, and anatomic information.

Future Directions

We believe that continued progress in the diagnosis and treatment of atherosclerotic RAS in the coming years will require the following:

- Continued technical improvement of balloon angioplasty and vascular stents
- Development of noninvasive imaging techniques for assessment of the distal renal artery and its branches
- Development of better functional tests to predict the effects of renal artery revascularization on blood pressure and renal function
- Development of markers to detect diseases of the small arteries and arterioles of the kidney
- Randomized clinical trials, such as the CORAL study, to compare the effect of revascularization of the renal arteries with intensive medical therapy on hypertension, cardiovascular disease, and the progression of chronic renal failure
- Development of new drugs to treat atherosclerosis and continued promotion of public health measures to decrease risk factors for atherosclerosis

Additional Resource

Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL). Available at: <http://www.coralclinicaltrial.org>. Accessed October 11, 2007.

This is the website of the CORAL study, the only ongoing, prospective, randomized study in the United States that is comparing angioplasty plus stent placement of atherosclerotic RAS and optimal medical therapy with optimal medical therapy alone. Information about the progress of the trial, enrollment, and participating centers can be obtained through this website.

EVIDENCE

1. Cooper CJ, Murphy TP, Matsumoto A, et al: Stent revascularization for the prevention of cardiovascular and renal events among patients with renal artery stenosis and systolic hypertension: Rationale and design of the CORAL trial. *Am Heart J* 152(1):59-66, 2006.

The National Institutes of Health, after hearing from many experts on atherosclerotic renal artery stenosis, concluded that it is not known whether angioplasty and stent placement combined with optimal medical therapy is superior to optimal medical therapy alone for the prevention of cardiovascular morbidity and progressive kidney disease in patients with high-grade atherosclerotic RAS. Given this situation of " equipoise " regarding the best treatment for the condition, the NIH is sponsoring the study described in this publication.

2. Pedersen EB: New tools in diagnosing renal artery stenosis. *Kidney Int* 57(6):2657-2677, 2000.

Many recent publications have dealt with the several tests available to screen for renal artery stenosis. This article by Pedersen is one of the most detailed and balanced reviews on this topic. Although some of the tests, such as magnetic resonance angiography, have been refined in the past few years, the recommendations and guidelines regarding diagnosis of RAS presented in this paper are still valid. The techniques, advantages, disadvantages, and predictive values of the several tests are described in detail.

3. Radermacher J, Chavan A, Bleck J, et al: Use of Doppler ultrasonography to predict the outcome of therapy for renal-artery stenosis. *N Engl J Med* 344(6):410-417, 2001.

The authors relate their experience in treating RAS with renal artery angioplasty in a large cohort of patients with hypertension, kidney failure, or both. They found that a resistive index above 80 reliably identifies patients with RAS in whom angioplasty or surgery will not improve kidney function, blood pressure, or kidney survival.

4. Safian RD, Textor SC: Renal-artery stenosis. *N Engl J Med* 344(6):431-442, 2001.

The authors provide a comprehensive review of the pathophysiology, clinical manifestations, diagnostic approaches and treatment of renovascular hypertension and ischemic nephropathy.

5. Textor SC: Ischemic nephropathy: Where are we now? *J Am Soc Nephrol* 15(8):1974-1982, 2004.

An excellent review of ischemic nephropathy, defined as kidney failure directly caused by high-grade atherosclerotic renal artery stenosis of both renal arteries or of the artery to a solitary kidney, which describes the epidemiology, clinical manifestations, and presumed pathophysiology of the condition.

Hypertension Secondary to Diseases of the Adrenal Gland

Introduction

Diseases of the adrenal gland are clinically important causes of secondary hypertension. In this chapter, we review their clinical presentation, evaluation, and therapy. Renovascular hypertension, another cause of secondary hypertension, is reviewed in Chapter 26.

The adrenal cortex can cause hypertension through overproduction of aldosterone, deoxycorticosterone (DOC), and cortisol. The first two are mineralocorticoid hormones that cause increased salt and water retention by the kidney. Cortisol is a glucocorticoid. When hypersecretion is marked, it can stimulate mineralocorticoid receptors and can be associated with release of DOC and vasoconstrictors. Pheochromocytoma is a tumor of the adrenal medulla that produces excessive quantities of catecholamines.

Identifying causes of adrenal hypertension is important for the following reasons:

- Many of these disorders are curable or responsive to specific therapy.
- These conditions, particularly pheochromocytoma, are associated with the risk for severe hypertension and major cardiovascular complications, including sudden death; the consequences of aldosterone, aside from blood pressure elevation, on cardiovascular outcomes have become increasingly recognized.
- The prevalence of primary aldosteronism among individuals with hypertension is higher than the 1% or less previously estimated.
- New syndromes of mineralocorticoid hypertension have been described or defined in the past few years.
- Diagnostic tests for primary aldosteronism have been simplified.

PRIMARY ALDOSTERONISM AND MINERALOCORTICOID HYPERTENSION

Etiology and Pathogenesis

Table 27-1 shows the causes of mineralocorticoid hypertension and its associated syndromes, the most common of which is primary aldosteronism. The normal physiologic control of aldosterone secretion is by the renin-angiotensin system. Adrenocorticotropic hormone (ACTH) and serum potassium concentration are less important. Hyperaldosteronism is caused by autonomous secretion of

the hormone, totally or largely independent of the control of the renin-angiotensin system.

Hypertension caused by aldosterone results from increased stimulation of mineralocorticoid receptors in the cortical collecting ducts of the kidney. This causes opening of sodium channels leading to increased tubular reabsorption of sodium, and secondary reabsorption of water. There is also increased secretion and urinary excretion of potassium and hydrogen ions. Salt and water retention causes an increase in plasma volume and an increase in cardiac output, resulting in increased blood pressure and suppressed renin production. Total exchangeable sodium

Table 27-1 Differential Diagnosis of Mineralocorticoid Hypertension

Cause	Pathophysiology
Primary aldosteronism* DOC-secreting tumors† Congenital adrenal hyperplasia‡	Increased aldosterone secretion Increased DOC secretion Congenital deficiency of enzymes needed for cortisol synthesis. Increased ACTH secretion: increased DOC
Liddle's syndrome†	Congenital up-regulation of sodium channels in collecting ducts. Increased sodium reabsorption by kidney
11β-Hydroxysteroid dehydrogenase deficiency and inhibition†	Congenital deficiency (syndrome of AME) or inhibition (licorice) of the enzyme that converts cortisol to cortisone. Increased cortisol levels stimulate mineralocorticoid receptors
S81OL mutation in MR‡	MR constitutively activated by steroids lacking 21 (OH) groups to progesterone
Ectopic ACTH syndrome‡	1. ↑ Secretion of DOC 2. ↑ Cortisol: cannot all be degraded to cortisone 3. ↑ Vasoconstrictors, vasodilators

*Causes of primary aldosteronism are discussed in the text.

† Aldosterone secretion inhibited, plasma renin activity suppressed.

‡ Aldosterone secretion inhibited, plasma renin activity variable.

↑, increased; ↓, decreased; ACTH, corticotrophin; AME, apparent mineralocorticoid excess; ectopic ACTH syndrome, production of corticotrophin by a tumor outside the pituitary gland; DOC, deoxycorticosterone; MR, mineralocorticoid receptor.

is increased, but the process is limited by a subsequent decrease in sodium reabsorption from the proximal tubule and the terminal part of the nephron under the influence of atrial natriuretic peptide and other natriuretic factors, an effect known as *aldosterone escape*. The escape explains the lack of edema in primary aldosteronism and related syndromes. Other factors that may contribute to mineralocorticoid hypertension include central nervous system effects of aldosterone, increased sympathetic nerve activity, and release of vasoconstrictive agents such as anti-diuretic hormone (Fig. 27-1).

About 30% of patients with primary aldosteronism have a surgically curable aldosterone-producing adenoma (APA), whereas two thirds have bilateral adrenal gland hyperplasia, a condition termed *idiopathic hyperaldosteronism*. Very rarely, the hyperplasia can be unilateral, a condition called *primary adrenal hyperplasia*. In glucocorticoid-remediable aldosteronism (GRA), ACTH controls secretion of aldosterone. This is an autosomal dominant disorder caused by a mutation in chromosome 8, so that aldosterone secretion is no longer under the control of angiotensin II but under the control of normal concentrations of ACTH. If ACTH secretion is inhibited with the glucocorticoid dexamethasone, aldosterone secretion decreases. Primary aldosteronism can also be caused by aldosterone-producing adrenal or ovarian carcinomas.

Clinical Presentation

The typical clinical features of primary aldosteronism are hypertension, hypokalemia, excessive urinary excretion of potassium, suppressed plasma renin activity (PRA), mild hypnatremia, and metabolic alkalosis. The symptoms of

hypokalemia may include polyuria, polydipsia, muscle cramps, muscle weakness, and glucose intolerance. The hypokalemia is more severe in patients with APA than in those with idiopathic hyperaldosteronism. The hypertension may be severe and resistant to treatment.

The disease usually presents in middle age (generally, patients are 30 to 50 years old) and may be more common among women. The presence of the above symptoms in younger patients, or in those with a family history of hyperaldosteronism, suggests a congenital type of mineralocorticoid hypertension such as GRA or Liddle's syndrome. In most series, 10% to 20% of patients with primary aldosteronism may present with normokalemia. Patients with GRA frequently have a normal serum potassium concentration.

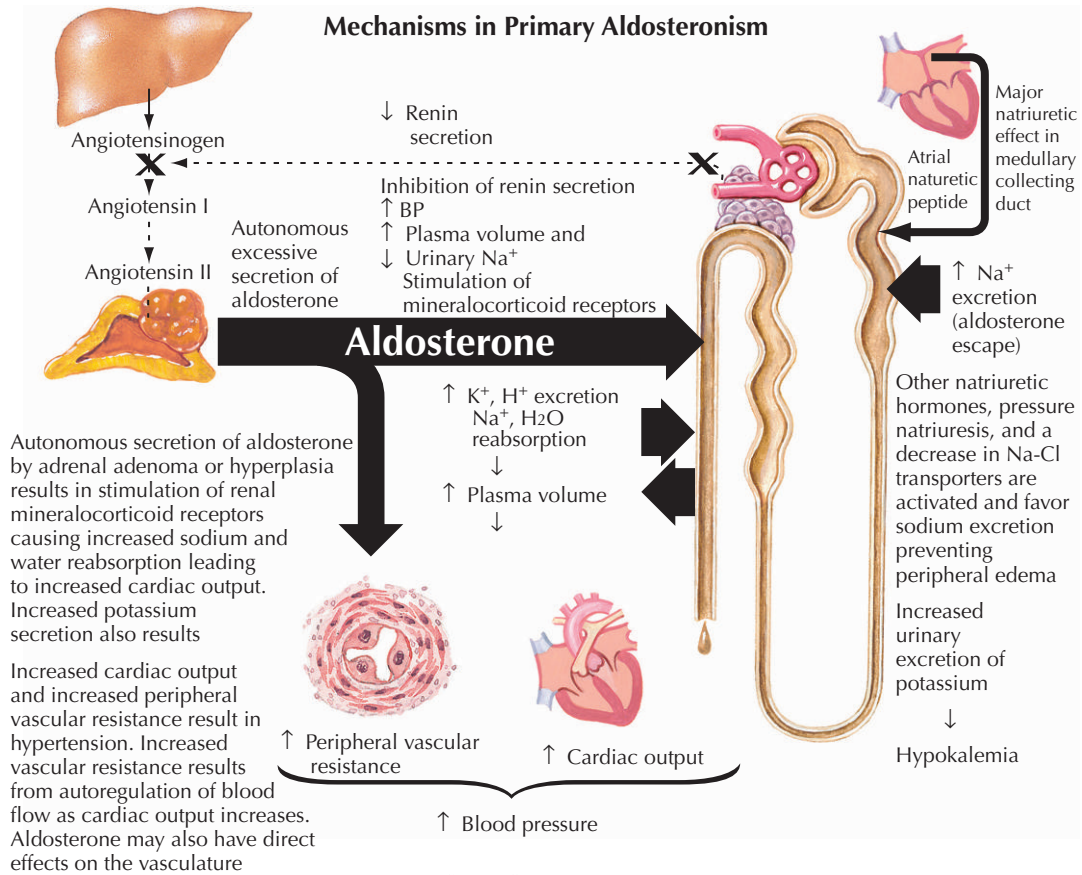

Differential Diagnosis

Primary aldosteronism should be suspected in the following circumstances:

- Hypertension with spontaneous (unprovoked) hypokalemia
- Hypertension with severe and refractory diuretic-induced hypokalemia (serum potassium concentration <3 mEq/L)
- Family history of hyperaldosteronism
- Unexplained hypertension, refractory to treatment
- Unexplained hypertension in children and young adults
- Incidentally discovered adrenal tumor

Patients with hypokalemia and hypertension should have measurement of PRA. A PRA greater than 3 ng/mL/hr

Figure 27-1 Primary Hyperaldosteronism and Mineralocorticoid Hypertension.

Clinical Features

Primary aldosteronism

Plasma aldosterone concentration (PAC) >20 ng/dL

+

PAC/PRA ≥30 (aldosterone-to-renin ratio)

Purpose of serum screen is to distinguish between primary aldosteronism and low renin essential hypertension

CT scan of the abdomen showing the adrenal glands to help select between surgically remediable APA and idiopathic hyperaldosteronism. Note adenoma in the left adrenal gland

suggests secondary hyperaldosteronism as seen with malignant hypertension, renal artery stenosis, primary renal disease, reninoma, and estrogen use. A value of less than 1 ng/mL/hr suggests low-renin essential hypertension or mineralocorticoid hypertension. Under these circumstances, screening and confirmatory tests for the presence of primary aldosteronism should be performed.

Diagnostic Approach

Figure 27-2 shows a diagnostic approach for subjects with hypertension and unprovoked or severe diuretic-induced hypokalemia. The same approach can be used in evaluating difficult-to-treat hypertension of unknown etiology with normal serum potassium concentration.

The first step of the evaluation is to distinguish primary aldosteronism from low-renin essential hypertension. The measurement of plasma aldosterone concentration (PAC) and PRA in peripheral venous blood has become the most useful screening test for primary aldosteronism. A PAC greater than 20 ng/dL combined with an aldosterone-to-renin ratio (ARR) greater than 30 has a sensitivity and specificity of more than 95% for primary aldosteronism in subjects with normal renal function. A very high ARR but normal PAC can be seen in some patients with low-renin essential hypertension or in rare forms of mineralocorticoid hypertension (see Table 27-1). Therefore, the test can only be considered indicative of primary aldosteronism if a high ARR coexists with a PAC greater than 20 ng/dL. False-positive results with high PAC are seen in patients with chronic renal failure and in patients taking large doses of spironolactone. Severe hypokalemia can cause a false-negative result by decreasing PAC. Diuretics and inhibitors of the renin-angiotensin system may theoretically produce false-negative results because of an increase in PRA, and β -blockers may produce false-negative results. Ideally, the test should be done off all antihypertensive medications, but this is neither practical nor generally safe for most patients. Several authors have reported that the test is robust even if patients are taking antihypertensive drugs, with the exception of aldosterone antagonists. Some centers recommend that PAC and PRA be measured in the early morning and in the seated position.

The diagnosis of primary aldosteronism can be confirmed by demonstrating that secretion of aldosterone is not suppressed after an infusion of a solution of isotonic sodium chloride or ingestion of a very-high-salt diet with or without administration of the mineralocorticoid fludrocortisone for several days. However, this confirmatory test is somewhat cumbersome and involves discomfort and risk for the patient. Many authors consider a positive screening test enough evidence of primary aldosteronism to proceed with a computed tomography (CT) scan or magnetic resonance imaging of the adrenal glands to distinguish between surgically curable APA and idiopathic hyperaldosteronism. In cases in which proof of nonsuppressibility is considered

important, infusion of 2 liters of normal saline over 3 to 4 hours with measurement of PAC before and after is a reasonable approach. If the plasma aldosterone is not suppressed to less than 10 ng/dL, nonsuppressibility is confirmed.

Patients with APA have a high serum concentration of the aldosterone precursor 18-hydroxycorticosterone (18-[OH]-B). Thus, in addition to CT or MRI, we obtain a blood sample for measurement of 18-(OH)-B. The presence of a hypodense adrenal adenoma, larger than 1 cm in diameter, on CT or MRI and a serum concentration of 18-(OH)-B greater than 65 ng/dL is diagnostic of APA and is an indication for adrenalectomy. Ambiguous findings in the adrenal glands or low serum levels of 18-(OH)-B require measurement of ACTH-stimulated aldosterone concentration from each adrenal vein to look for increased unilateral production of aldosterone indicative of surgically curable primary aldosteronism. If GRA is suspected, genetic testing should be done. Some patients with long-standing hypertension who have ambiguous findings on the imaging studies can be treated with aldosterone antagonists without having adrenal vein sampling because even if an adenoma were present, adrenalectomy would not be expected to cure the hypertension, and the hypokalemia usually can be controlled pharmacologically.

Management and Therapy

The treatment of primary aldosteronism depends on the etiology of the condition as ascertained by diagnostic studies.

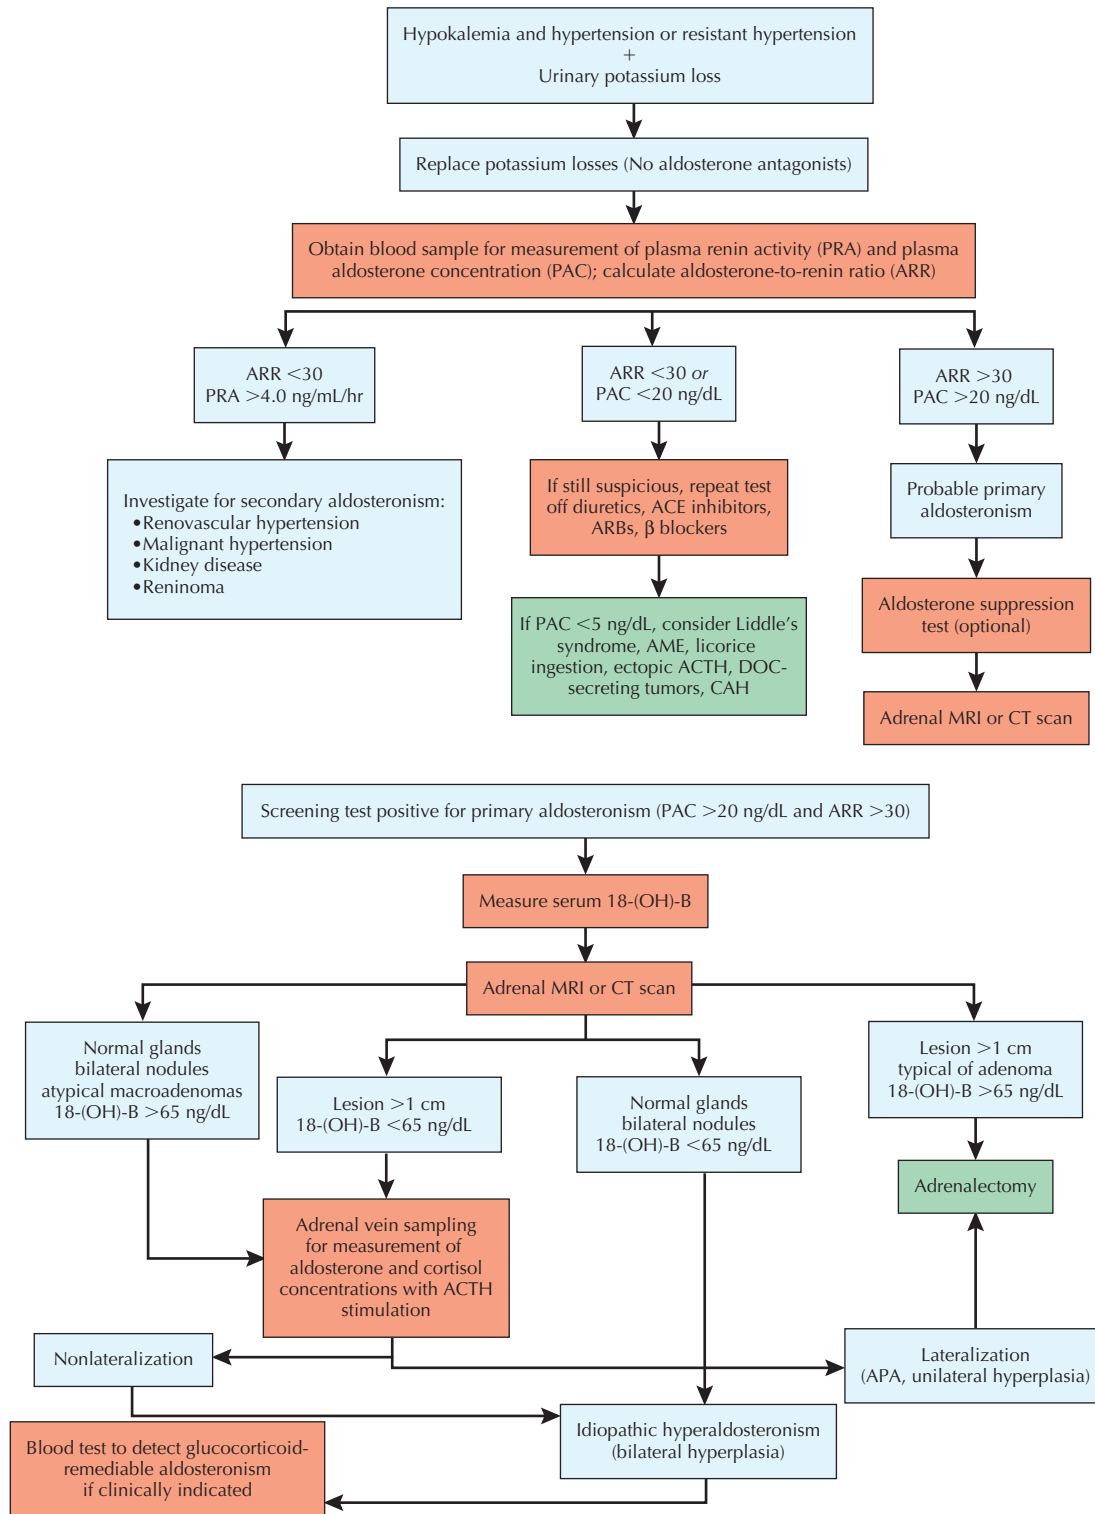

Optimum Surgical Treatment

Most patients with APA should undergo adrenalectomy, which can usually be performed by a laparoscopic approach. Patients should be treated with spironolactone, 100 to 200 mg/daily for 6 to 8 weeks before surgery, permitting correction of the hypokalemia and improvement of the hypertension. This therapy also decreases extracellular fluid volume and restores the responsiveness of the renin-angiotensin system. A decrease in blood pressure predicts a good response to surgery. About 65% to 70% of patients with an APA are cured of their hypertension; the remainder show improvement. The main postoperative complication is transient hypoaldosteronism with inability to conserve sodium, hypotension, and mild hyperkalemia. This can be prevented by prior treatment with spironolactone and can usually be treated with an increase in salt intake. Persistent hypertension suggests superimposed primary hypertension or nephrosclerosis caused by long-standing hypertension.

Optimum Medical Treatment

Medical treatment of bilateral adrenal hyperplasia is initiated with spironolactone, 50 to 200 mg/daily, with a

Figure 27-2 Diagnostic Approach to Patients with Suspected Primary Aldosteronism.

AME, syndrome of apparent mineralocorticoid excess; serum 18-(OH)-B, serum concentration of 18-hydroxycorticosterone; APA, aldosterone-producing adenoma; ARR, aldosterone-to-renin ratio; CAH, congenital adrenal hyperplasia; CT, computed tomography; ectopic ACTH, production of corticotropin by a tumor outside the pituitary gland; PAC, plasma aldosterone concentration; PRA, plasma renin activity. Definition; lateralization=aldosterone: cortisol concentration ratio in an adrenal vein 4 times greater than that in the other adrenal vein, and/or an aldosterone: cortisol concentration ratio from the vein of the unaffected adrenal that is less than the ratio in the vena cava. Urinary loss of potassium can be documented by measuring potassium excretion in a 24-hour collection of urine; excretion of more than 30 mEq per day in the presence of hypokalemia indicates potassium wasting. An alternative and simpler approach is to obtain a random sample of urine to calculate fractional excretion of potassium. A fractional excretion greater than 10% when hypokalemia is present indicates potassium wasting.

maximum dose of 400 mg. However, painful gynecomastia and erectile dysfunction in men and menstrual irregularities in women are common at high doses. Therefore, the goal should be to reduce the dose of spironolactone to 50 mg/daily, with the addition of amiloride, 5 to 15 mg/daily, or triamterene, 75 to 150 mg/daily, if needed. Eplerenone, a specific inhibitor of aldosterone receptors, has been approved in the United States for treatment of hypertension and heart failure but not specifically for treatment of primary aldosteronism. A dose of 50 mg once or twice daily may be used as an alternative to spironolactone in those experiencing antiandrogenic adverse effects with spironolactone.

Many patients will require additional antihypertensive therapy. Drugs of choice are thiazide diuretics, calcium channel blockers, and angiotensin-converting enzyme inhibitors. The diet should be low in sodium and rich in potassium. Patients with GRA or apparent mineralocorticoid excess can be treated with 1 to 2 mg/daily of dexamethasone to suppress ACTH secretion; however, there may be corticosteroid-related adverse effects, and hypertension may not be adequately controlled. Patients with Liddle's syndrome do not respond to spironolactone and should be treated with amiloride or triamterene and other antihypertensive drugs combined with salt restriction and potassium supplementation, as needed.

Avoiding Treatment Errors

Postoperative hyperkalemia can be avoided by preoperative treatment with spironolactone or eplerenone.

PHEOCHROMOCYTOMA

Etiology and Pathogenesis

Pheochromocytoma is a tumor arising from adrenomedullary chromaffin cells that produces excess secretion of catecholamines causing intermittent or sustained hypertension (Fig. 27-3). These tumors account for less than 0.5% of causes of hypertension. Although rare, pheochromocytomas are important because of their potential lethality.

Clinical Presentation

Hypertension is the most common presenting feature, occurring in greater than 90% of patients. The hypertension may be severe and is usually sustained, but it may be paroxysmal and associated with spells or may present as a hypertensive emergency. The paroxysms may cause the classic symptom triad of headache, sweating, and palpitation. Other common symptoms are pallor, nausea, tremor, weakness, anxiety, epigastric pain, chest pain, flushing, and dizziness. The paroxysms may be fleeting or last for hours and may occur spontaneously or be precipitated by activities such as lifting, straining, or stretching. The hyperten-

sion is sometimes resistant to pharmacologic treatment but usually responds to α -adrenergic blocking agents.

Pheochromocytomas may occur at any age. Ninety-eight percent of pheochromocytomas are in the abdomen or pelvis, and 90% are in the adrenal gland; 5% to 10% are multiple, less than 10% are malignant, and 10% are familial. Bilateral tumors are more likely to be familial. When extra-adrenal, the tumors are associated with chromaffin cells in paraganglia and are called paragangliomas (see Fig. 27-3). Pheochromocytomas may be inherited as part of the multiple endocrine neoplasia (MEN) syndromes. In MEN IIA, the pheochromocytoma is associated with medullary carcinoma of the thyroid gland and with parathyroid adenoma or hyperplasia. In MEN IIB, pheochromocytomas are also associated with neuromas of the lip and tongue, corneal nerve thickening, and marfanoid body features.

Pheochromocytomas may range in size from microscopic to kilograms in weight. The tumors are usually encapsulated. Only 10% of adrenal pheochromocytomas invade local structures or metastasize, whereas about 40% of extra-adrenal pheochromocytomas invade or metastasize.

Pheochromocytomas most often secrete norepinephrine and epinephrine, but rarely only one of these catecholamines. The finding of excess dopamine secretion suggests the presence of malignancy.

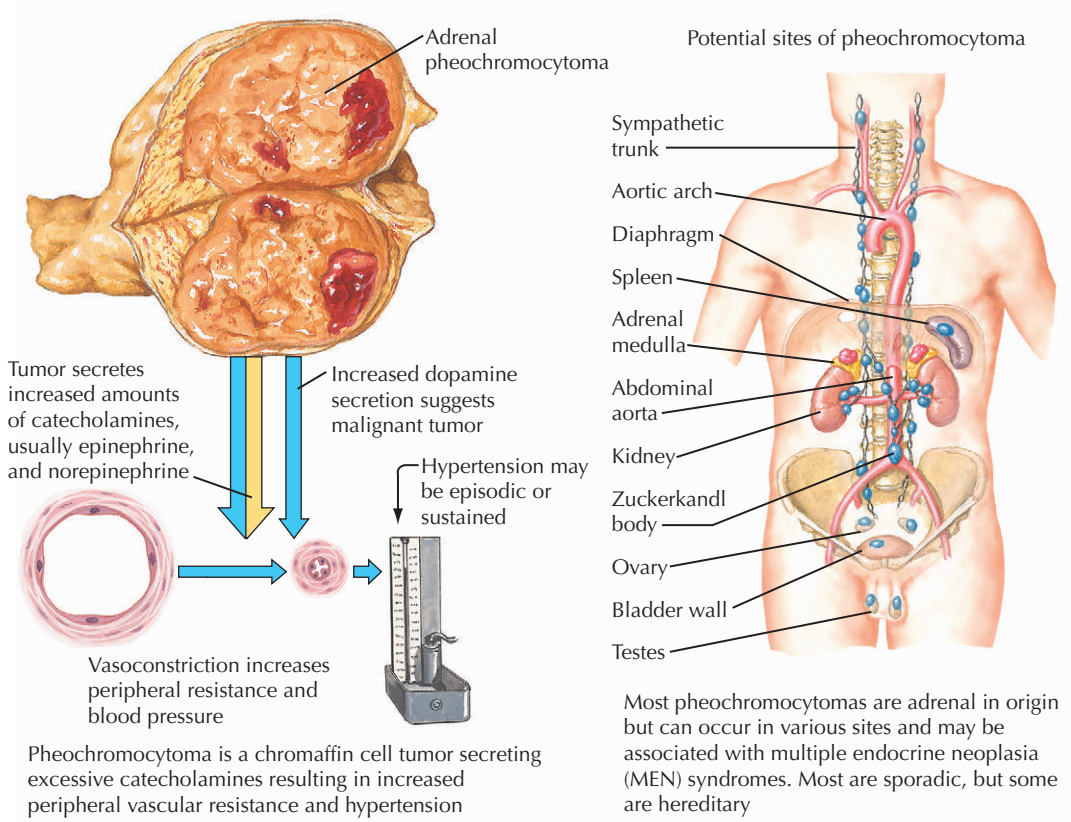

Differential Diagnosis

Pheochromocytoma should be considered in patients with primary hypertension and hyperadrenergic symptoms such as tachycardia, palpitations, sweating, anxiety, and panic attacks. Other syndromes with increased sympathetic nervous system activity and hypertensive crises include use of monoamine oxidase inhibitor antidepressants, clonidine or β -blocker withdrawal, use of drugs with sympathomimetic effects such as cocaine, increased intracranial pressure, thyrotoxicosis, and angina pectoris.

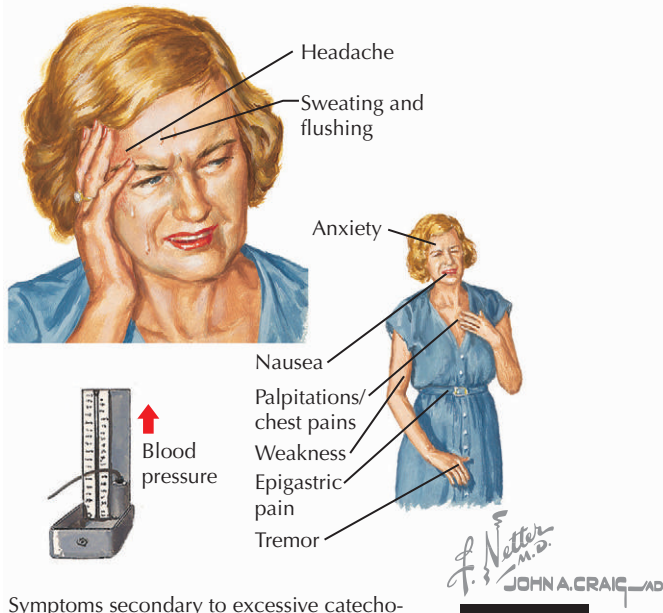

Diagnostic Approach

The key to diagnosis is a high index of suspicion. Most patients who have a pheochromocytoma with a typical clinical presentation will have a positive biochemical test result. However, one third of pheochromocytomas are found incidentally. The approach to screening tests depends on the level of clinical suspicion. If there is any suspicion and screening test results are equivocal, a different screening test should be considered. Measurement of free metanephrines (metanephrine and normetanephrine) in plasma has become the most convenient and accurate screening test, with a sensitivity of 99% and specificity of 89%. Measurement of 24-hour urinary metanephrines and free catecholamines has a diagnostic sensitivity of about 75% to 99% and specificity of about 70% to 93%. The

Figure 27-4 Clinical Suspicion of Pheochromocytoma.

MIBG, iodine-131 metaiodobenzylguanidine.

adequacy of the urine collection should be ascertained by measuring creatinine excretion. Plasma catecholamines are highly specific but inconvenient to perform and somewhat less sensitive than urinary measurements. The lower sensitivity may be related to episodic secretion in most patients. However, a value of more than 2000 pg/mL is rarely seen in the absence of a pheochromocytoma. Values between 1000 and 2000 pg/mL require further investigation. Figure 27-4 shows a diagnostic approach to the patient with suspected pheochromocytoma.

Once a pheochromocytoma is suspected clinically and biochemically, a radiographic approach to localization is initiated. CT or MRI depicts most pheochromocytomas; MRI is preferred because of higher specificity on T2-weighted images (see Fig. 27-3). Nuclear scanning with iodine-131 metaiodobenzylguanidine (MIBG) or total-body MRI may be used when CT or abdominopelvic MRI results are negative in the presence of suggestive biochemical results.

Management and Therapy

Optimum Treatment

Surgical removal is the definitive treatment for pheochromocytoma. During anesthesia and surgery, blood pressure may fluctuate widely. Blockade of α -adrenergic receptors blocks the effects of the high circulating catecholamine levels. Before elective surgery, oral phenoxybenzamine is prescribed and is switched to parenteral phentolamine the day of surgery and titrated to maintain blood pressure stability. Metyrosine has recently been approved for the short-term management of pheochromocytoma before

surgery, for long-term management when surgery is contraindicated, and for treatment of chronic malignant pheochromocytoma. The drug blocks the conversion of tyrosine to dihydroxyphenylalanine, the rate-limiting step in the catecholamine biosynthetic pathway.

Once blood pressure control is attained, β -adrenergic blocking drugs are administered to control heart rate and prevent arrhythmias, but they should not be used as the only therapy because this would allow unopposed α -adrenergic stimulation. Patients with pheochromocytoma tend to be volume depleted because of pressure natriuresis. Therefore, volume repletion is important before and during surgery.

Avoiding Treatment Errors

Proper preoperative management reduces the risk for perioperative morbidity and mortality.

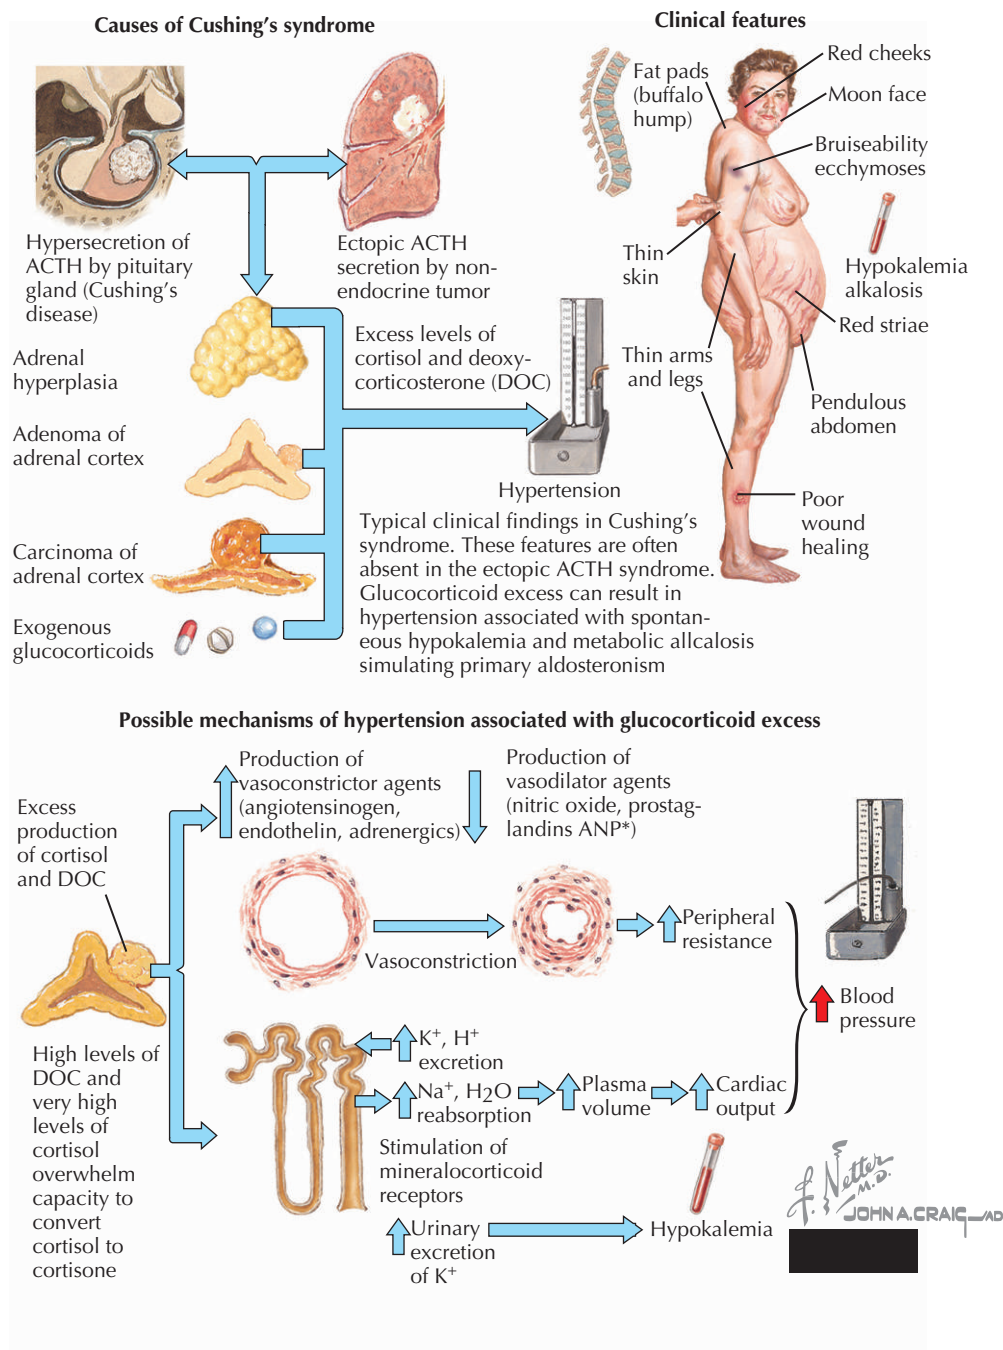

CUSHING'S SYNDROME

Clinical Presentation

Hypertension is present in 80% of patients with Cushing's syndrome (Fig. 27-5). The hypertension may be severe, and target organ damage is common. Most cases of Cushing's syndrome are caused by the administration of exogenous glucocorticoids, but hypertension is more common with the endogenous causes of hypercortisolism: primary hypersecretion of ACTH by the pituitary gland (Cushing's disease); adrenal adenoma, carcinoma, or hyperplasia; and ectopic secretion of ACTH by a nonen-

Figure 27-5 Cushing's Syndrome and Mineralocorticoid Hypertension.

*ANP, atrial natriuretic peptide.

doctrine tumor. ACTH secretion in this situation is greater than that with pituitary hypersecretion. Severe hypertension with hypokalemia and metabolic alkalosis is common with ectopic ACTH secretion.

The possible mechanisms of hypertension associated with glucocorticoid excess include stimulation of mineralocorticoid receptors with plasma volume expansion, increased cardiac output, and sodium shifts from the intra-

cellular to the extracellular space. There is also an increase in peripheral vascular resistance caused by decreased production of vasodilator substances (nitric oxide, prostaglandins, atrial natriuretic peptide), and increased production of vasoconstrictor factors (angiotensinogen, adrenergic agents, endothelin). Increased levels of DOC and very high levels of cortisol are seen, particularly with ectopic ACTH secretion (see Fig. 27-5).

Differential Diagnosis

Patients presenting with hypertension, hypokalemia, and typical clinical features should be considered for evaluation. Patients with ectopic ACTH syndrome do not usually display the physical features associated with glucocorticoid excess. The main differentiation is from other causes of mineralocorticoid-associated hypertension. The approach to the diagnosis of Cushing's syndrome is presented in Chapter 44.

Management and Therapy

Optimum Treatment

Medical management of the hypertension associated with glucocorticoid excess is the same as that for low-renin essential hypertension, pending possible surgical approaches. Diuretics, including potassium-sparing diuretics, are first-line therapy. Additions or substitutions are based on the blood pressure response and individual patient characteristics. The management of Cushing's syndrome is discussed in Chapter 44.

FUTURE DIRECTIONS

The next few years will see rapid advances in the diagnosis, localization, management, and genetics of adrenal hypertension. The following are key areas of interest:

- Developing imaging studies to distinguish functional from nonfunctional masses of the adrenal cortex
- Determining the prevalence of normokalemic hyperaldosteronism
- Continuing the study of genetic types of primary hyperaldosteronism and pheochromocytoma
- Optimizing cost-effectiveness of diagnostic imaging for pheochromocytoma and determining the role of new techniques such as positron emission tomography in the diagnostic evaluation

In these comprehensive recommendations for the approach to the incidentally discovered adrenal mass with emphasis on proof of function and suppressibility, the author indicates that subjects need not discontinue antihypertensive medications, except aldosterone antagonists, to screen for primary aldosteronism. The author favors measurement of urinary catecholamines and metanephrines to exclude pheochromocytoma.

Angina Pectoris

Introduction

Angina is the sensation caused by the myocardial ischemia that results when cardiac metabolic demand exceeds supply. It is generally defined as “pressure,” “discomfort,” or a “choking sensation” in the left chest that is precipitated by exertion, excitement, or cold weather, and relieved by rest or nitroglycerin. In some patients, the discomfort radiates into the left arm, into the jaw, or, more rarely, into the right arm (Fig. 28-1). When severe, it can be accompanied by dyspnea, diaphoresis, or nausea. Not all patients experience these classic symptoms, and in some individuals, myocardial ischemia may cause atypical symptoms, such as jaw pain, fatigue, arm discomfort, or upper abdominal pain. Myocardial ischemia can also be “silent” (not associated with symptoms), especially in diabetic patients.

Etiology and Pathogenesis

The most common cause of angina is obstruction of coronary arteries by atherosclerosis (Figs. 28-2 and 28-3). Atherosclerosis, the leading cause of death in the developed world, develops over a period of decades. Risk factors include hypertension, tobacco use, diabetes mellitus type 1, insulin-resistant states (such as diabetes mellitus type 2 and obesity), hypercholesterolemia, and family history of premature vascular disease.

Angina can also result from other less common conditions in which cardiac metabolic demand exceeds supply. These include coronary artery anomalies, coronary artery spasm (Prinzmetal’s syndrome), aortic stenosis, anemia, hyperthyroidism, cocaine use, carbon monoxide poisoning, and hypertrophic cardiomyopathy.

Clinical Presentation

Coronary artery disease (CAD) generally manifests as chronic stable angina, unstable angina, acute myocardial infarction, unrecognized myocardial infarction, or sudden cardiac death. Patients with acute myocardial infarction can be further subdivided into those with ST elevation on electrocardiogram (ECG) and those without (commonly called non-ST elevation myocardial infarction).

Chronic Stable Angina

Fixed, stable, obstructive CAD causes a syndrome termed *chronic stable angina* that occurs when myocardial metabolic

demand exceeds a fixed threshold of supply. Angina is commonly precipitated by exertion, emotional excitement, mental stress, or exposure to cold, and resolves after the precipitating event has ceased. Angina generally occurs at the same level of exertion but may vary depending on time of day, recent meals, and ambient temperature.

The most commonly used classification for grading angina severity is the Canadian Cardiovascular Society scale. Patients in Class I experience angina with strenuous or protracted physical activity, whereas those in Class II occasionally have angina with normal daily activities such as climbing stairs or walking up a hill. Patients in Class III have marked limitation and commonly experience angina during activities of everyday living (e.g., walking across a room). Class IV symptoms occur at rest.

Unstable Angina or Non-ST Elevation Myocardial Infarction

Unstable angina, or non-ST elevation myocardial infarction, is generally due to formation of a nonocclusive thrombus at the site of rupture or erosion of the surface of an atherosclerotic plaque (see Fig. 28-3). This event exposes the blood to the highly thrombotic materials within the plaque, leading to thrombus formation. The thrombus can progress until it occludes the blood vessel or, alternatively, may embolize and occlude smaller, more distal vessels. Sudden onset of chest discomfort that is unrelated to a precipitating event is a hallmark of this

Figure 28-1 Angina Pectoris.

Common precipitating factors in angina pectoris: heavy meal, exertion, cold, smoking

Characteristic distribution of pain in angina pectoris

F. Netter M.D.

syndrome. Other patients initially have symptoms that occur with exertion, but over a period of days to weeks, the discomfort occurs with less and less exertion.

Acute Myocardial Infarction with ST Segment Elevation

Acute myocardial infarction with ST segment elevation is characterized by the abrupt onset of unremitting chest discomfort and is generally associated with dyspnea, diaphoresis, and a “sense of doom.” It is typically caused by abrupt occlusion of a coronary artery by thrombus at the site of a ruptured atherosclerotic plaque. The ECG shows ST elevation in two or more leads corresponding to the territory of a coronary artery. Patients who are not treated

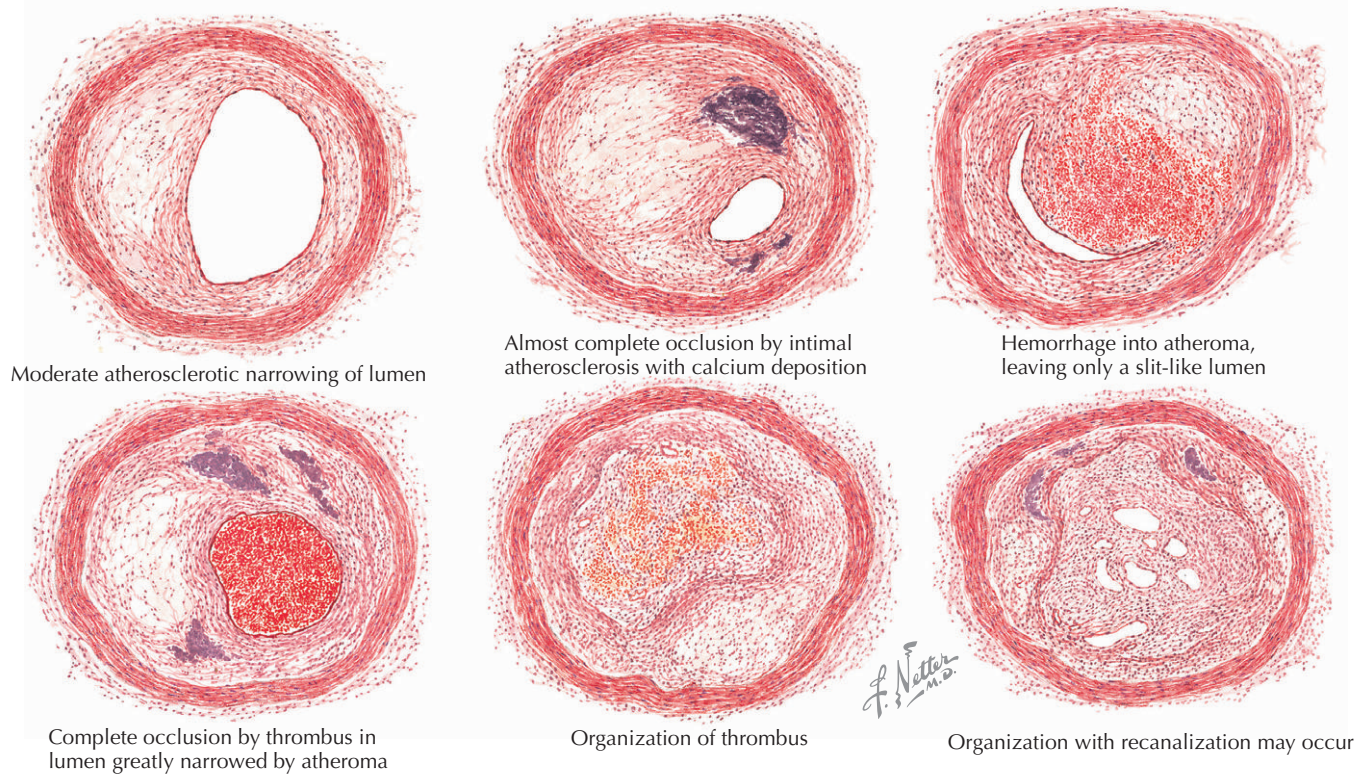

within 6 to 12 hours generally suffer significant myocardial damage.

Variant (Prinzmetal’s) Angina

In Prinzmetal’s angina, an uncommon disorder, coronary spasm develops, usually at the site of an atherosclerotic lesion. The hallmark is transient chest pain with ST elevation on ECG, often occurring at rest.

Syndrome X

Syndrome X includes patients with angina, evidence of exercise-induced ischemia, and normal epicardial coronary arteries. These patients are often female (about 70%), with

Figure 28-2 Types and Degrees of Coronary Atherosclerotic Narrowing or Occlusion.

an average age of 50 years. The pathophysiology of this syndrome is incompletely understood; various proposed etiologies include microvascular dysfunction, incipient cardiomyopathy, and altered pain perception.

Differential Diagnosis

A number of disease states can cause chest discomfort. In some cases, the symptoms can closely mimic angina, although a careful history can help distinguish between the various conditions. Exertional symptoms are common in diastolic dysfunction, exertional hypertension, asthma, and pulmonary hypertension. Response to nitroglycerin can be observed in esophageal spasm and diastolic dysfunction. Other diagnoses mimicking angina or myocardial infarction include esophageal spasm, peptic ulcer, asthma, aortic dissection, mitral valve prolapse, pulmonary embolism, exertional hypertension, cholecystitis, musculoskeletal syndromes, anxiety (panic attack), pericarditis or pleuritis, congestive heart failure, diastolic dysfunction, and costochondritis. A diagnostic algorithm is outlined in Figure 28-4.

Diagnostic Approach

Chronic Stable Angina

In chronic stable angina, typical history and presence of risk factors are the most important information for diag-

nosis. The physical examination is usually not helpful but may provide evidence of left ventricular systolic or diastolic dysfunction (S_3 or S_4 , respectively). During an attack of angina, patients tend to be still and may appear pale. The ECG is normal in more than half of patients with coronary atherosclerosis, but there may be evidence of prior myocardial infarction or ischemia (e.g., ST depression). The three most important determinants of prognosis in patients with chronic stable angina are age, number of diseased coronary arteries, and left ventricular function.

An exercise treadmill test can diagnose CAD by the development of ECG changes with exercise. In addition, symptoms during exercise, blood pressure response, and duration of exercise are all important in determining the post-test probability of CAD and whether the patient needs further evaluation. The treadmill test can be enhanced by assessing left ventricular wall motion (with echocardiography) or myocardial perfusion (with nuclear imaging). Pharmacologic stress testing can be used in patients who are unable to exercise.

The recent advent of 64-slice computed tomography (CT) scanners has enabled noninvasive coronary angiography. Patients are given an intravenous bolus of contrast dye, and then the coronary arteries are imaged. The usefulness of this test remains to be determined, but there are promising data, especially in excluding CAD in low-risk patients. CT angiography has several limitations, including significant radiation exposure, exposure to contrast

Figure 28-3 Atherogenesis: Unstable Plaque Formation.

dye, the need to be in sinus rhythm, and an ability to tolerate relative bradycardia.

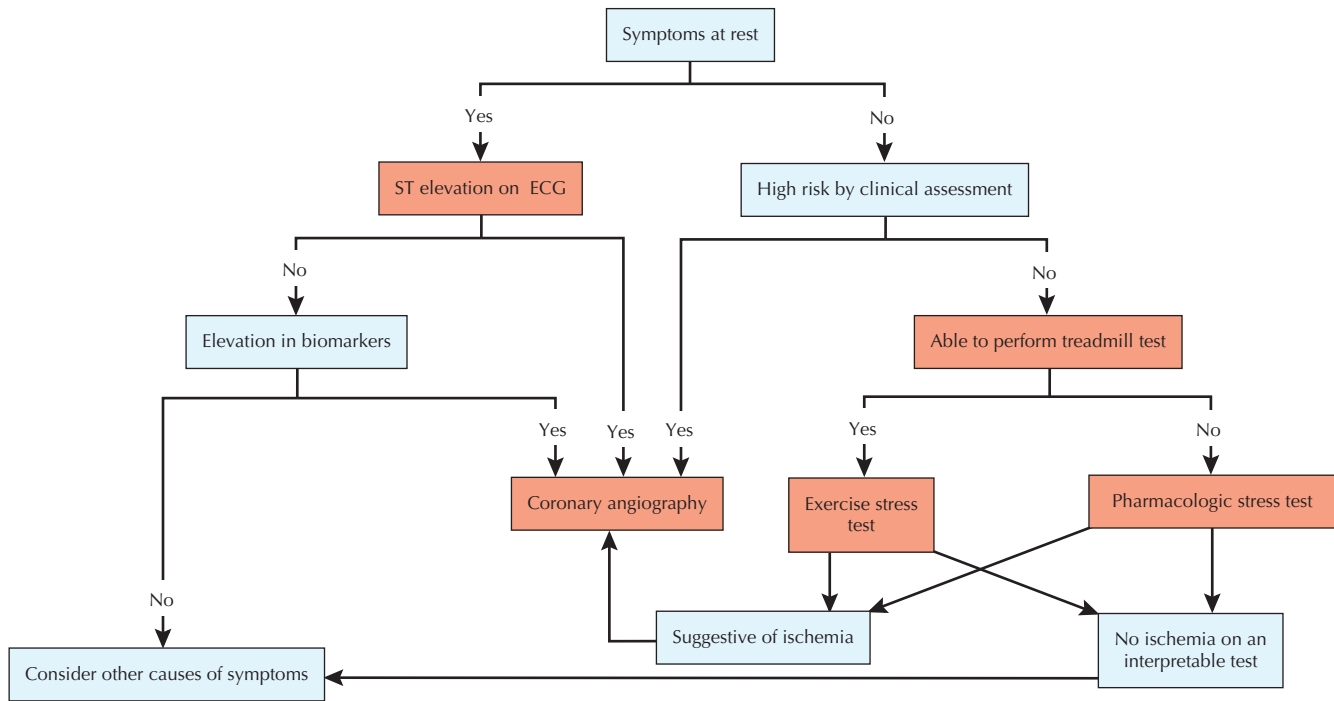

Direct coronary angiography remains the gold standard for diagnosing CAD. This test, which involves direct injection of contrast dye into the coronary arteries, delineates the location and severity of obstructive coronary disease. As such, angiography is a necessary prerequisite for coronary revascularization through either percutaneous intervention or coronary artery bypass surgery. Left ventriculography, generally performed immediately before or

after coronary angiography, provides important information regarding intracardiac pressures and left ventricular function.

Clinically assessing the functional importance of intermediate lesions (lesions that appear to obstruct 40% to 60% of the coronary lumen) may be difficult using coronary angiography alone. This limitation can be partially overcome by using intracoronary ultrasound or by measuring coronary flow velocity or intracoronary pressure changes during maximal hyperemia.

Figure 28-4 Assumptions for Diagnostic Algorithm.

This algorithm is highly simplified. Symptoms worrisome for myocardial ischemia will vary depending on the patient. The decision to perform angiography must be individualized and take into account the patient's wishes, renal status, age, etc. ECG, electrocardiogram. *Pretest probability of coronary artery disease can be estimated using information in Diamond GA, Forrester JS: Analysis of probability as an aid in the clinical diagnosis of coronary-artery disease. N Engl J Med 300(24):1350-1358, 1979.*

**Acute Coronary Syndromes**

Patients with unstable angina, non–ST elevation myocardial infarction, or ST elevation myocardial infarction are considered to have an acute coronary syndrome. The diagnosis is generally based on the constellation of typical symptoms (described earlier), ECG changes, and elevated levels of cardiac enzymes (in the case of myocardial infarction).

The ECG is essential in differentiating unstable angina or non–ST elevation myocardial infarction from ST elevation myocardial infarctions. In unstable angina, the ECG may be normal or may demonstrate T-wave inversion or ST depression. ST depression often indicates multivessel CAD and is associated with a worse prognosis in patients with unstable angina. In patients with ST elevation myocardial infarction, the ECG shows contiguous ST elevation involving the anterior (V1 to V4), lateral (V5, V6, I, AVL), or inferior (II, III, AVF) walls.

Myocardial Infarction

Highly sensitive blood tests for myocardial proteins have greatly enhanced our ability to diagnose myocardial infarction. Troponins and creatine kinase-MB (CK-MB) are intracellular cardiac proteins released into the bloodstream upon the death of myocytes. Plasma levels of these proteins

are useful both in detecting myocardial infarction and establishing prognosis. Troponins and CK-MB do not appear in plasma in significant levels until 8 or more hours after the onset of symptoms, limiting their diagnostic value in the very early stages of an acute coronary syndrome.

Management and Therapy**Optimum Treatment***Nonpharmacologic Interventions*

Controlling risk factors for atherosclerosis is crucial. In particular, patients should be advised on the need to lower the intake of cholesterol and saturated fat in their diets, the importance of weight loss if obese, and the need to avoid tobacco. A regular exercise program should be prescribed for all patients in whom it is feasible. An exercise stress test can be used to determine safe levels of activity.

Transmyocardial revascularization, enhanced external counterpulsation, spinal cord stimulation, and sympathectomy are occasionally used in patients who have refractory angina despite optimal medical treatment.

Pharmacologic Interventions

Pharmacologic therapy for angina was traditionally directed at relieving symptoms. More recently, medications have been classified based on their effect on survival (Table

Table 28-1 Summary of Pharmacologic Treatment of Patients with Chronic Stable Angina

Medication	Dosage	Which Patients?	Effect on Cardiovascular Clinical Endpoints
Aspirin	80-325 mg every day	All patients with vascular disease	Decreases the risk for death, MI, and stroke
Statin drugs	Varies depending on particular drug	All patients with vascular disease	Decreases the risk for death in patients who have had a prior MI
Angiotensin-converting enzyme inhibitors	Varies depending on particular drug; initial dosage will depend on blood pressure	All patients with vascular disease (in particular, any patient with vascular disease and hypertension or diabetes)	In the HOPE trial, ramipril, 10 mg every day, reduced the rate of death, MI, and stroke in patients with vascular disease
β-Blockers	Begin at low dose (e.g., metoprolol, 12.5 mg twice a day) and titrate depending on heart rate and blood pressure	Patients with prior MI or with cardiomyopathy (caution is needed when initiating β-blockers in patients with congestive heart failure)	Decreases the risk for death in patients who have had a prior MI and improves outcomes in patients with dilated cardiomyopathy
Nitrates	Sublingual or buccal spray can be used as needed; longer-acting oral and transdermal formulations are available	Patients with anginal symptoms	None
Calcium channel blockers	Varies depending on particular drug; initial dosage will depend on blood pressure and heart rate	Patients with anginal symptoms	No beneficial effect on survival; nifedipine worsens survival in acute coronary syndromes; diltiazem worsens survival in left ventricular dysfunction
Warfarin	Varies depending on response; needs continual monitoring	Useful in selected patients with vascular disease	A meta-analysis demonstrates reduction in the risk for death, MI, or stroke if INR >2 and used with concurrent ASA; bleeding increased by 1.9-fold

ASA, aspirin; HOPE, Heart Outcomes and Prevention Evaluation; INR, international normalized ratio; MI, myocardial infarction.

28-1). Medications that improve survival and decrease cardiovascular events in patients with CAD include aspirin, hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (“statins”), and angiotensin-converting enzyme inhibitors. In patients with prior myocardial infarction or left ventricular dysfunction, β-blockers also reduce mortality. Medications that treat symptoms without improving survival include nitrates and calcium channel blockers. The use of calcium channel blockers, with the exception of amlodipine and felodipine, should be avoided in patients with left ventricular dysfunction.

Low-density lipoprotein (LDL) cholesterol levels should be aggressively lowered, even in patients with ostensibly normal LDL levels, through the use of diet and statins. Recent guidelines suggest that LDL cholesterol should be less than 70 mg/dL in patients with CAD. Blood pressure should be closely monitored, with optimum levels

below 140/90 mm Hg. In diabetic patients, optimum levels are even lower, with the goal of diastolic blood pressures at 80 mm Hg or less. Patients must be strongly encouraged to quit smoking and offered pharmacologic aids (e.g., nicotine patches, bupropion, varenicline) or support group help as needed. Antioxidant vitamins have not been shown to be beneficial.

Therapies that interrupt thrombus formation have an important role in acute coronary syndromes. In unstable angina or non-ST elevation myocardial infarction, aspirin and heparin reduce the rate of death and myocardial reinfarction. Glycoprotein IIb/IIIa inhibitors are useful in patients with high-risk features (e.g., elevated troponins or ST depression) who are undergoing percutaneous coronary intervention.

In ST elevation myocardial infarction, the goal of therapy is rapid restoration of blood flow using either

thrombolytic therapy or a percutaneous coronary intervention such as balloon angioplasty. In hospitals with 24-hour availability of an experienced interventional cardiologist and staff, percutaneous intervention is the preferred treatment. In other hospitals, prompt administration of thrombolytic therapy, especially within 6 hours of the onset of symptoms, improves patient survival. Streptokinase and tissue plasminogen activator (tPA) have been extensively studied, but newer thrombolytic drugs derived from tPA, including reteplase and tenecteplase, have similar efficacy and are easier to administer (1 or 2 bolus injections).

Revascularization

Revascularization re-establishes unobstructed blood flow either through percutaneous intervention, in which the atherosclerotic blockage is relieved by angioplasty balloon inflation or stent placement, or by coronary artery bypass grafting, in which blood flow is diverted around atherosclerotic obstructions using an arterial (e.g., left internal mammary artery) or venous conduit. Revascularization prolongs survival in patients with significant left main CAD and multivessel CAD with impaired left ventricular function. The most common indication for revascularization, however, is relief of symptoms.

Avoiding Treatment Errors

One of the most common, major, preventable treatment errors is the misdiagnosis of acute myocardial infarction. It has been estimated that approximately 4% of patients with myocardial infarction presenting to emergency rooms are discharged home inappropriately. The mortality rate associated with a missed diagnosis of myocardial infarction is twice as high as that of patients who are admitted to the hospital. Misdiagnosis of myocardial infarction is a major medical malpractice issue and accounts for up to 20% of emergency department litigation expenses in the United States.

Another major problem to avoid is the undertreatment of ST elevation myocardial infarction. It has been estimated in various studies that 20% to 30% of patients with ST elevation myocardial infarction who would benefit from reperfusion therapy (either thrombolytic therapy or primary angioplasty) do not receive it. In these cases, the diagnosis is correct; however, appropriate therapy is withheld. Common misperceptions that lead to withholding of therapy include overestimation of the bleeding risk (especially intracerebral bleeding), comorbid conditions, and time to presentation.

Future Directions

Plasma levels of C-reactive protein, a marker of inflammation, are useful in determining the prognosis of patients with unstable angina or non-ST elevation myocardial infarction. Large population-based studies have also shown

a correlation between C-reactive protein levels and CAD. Electron-beam CT and three-dimensional echocardiography may enhance the ability of noninvasive testing to detect CAD. In preliminary studies, inroads are being made into the identity of genetic polymorphisms that contribute to CAD. Further progress in this area may identify high-risk individuals who will benefit from specific, risk factor-modifying therapy initiated early in life.

Several new pharmaceuticals are being evaluated for use in patients with angina, including potassium channel blockers and agents that enhance nitric oxide production. Large-scale clinical studies are also testing the use of antibiotics and anti-inflammatory medications as means to slow the progression of atherosclerosis. Finally, the stimulation of myocardial angiogenesis through intracoronary injection of growth factors (e.g., vascular endothelial growth factor) or genes encoding angiogenic factors is an exciting area now entering clinical trials.

Myocardial Infarction

Introduction

Each year, about 32 million myocardial infarctions (MIs) occur worldwide, resulting in 12.5 million deaths. MI reflects myocyte necrosis and is clinically defined as a typical rise and fall in biochemical markers of myocardial necrosis (preferentially troponin) accompanied by ischemic symptoms and/or electrocardiogram (ECG) changes. The terms MI and acute coronary syndrome (ACS) are often mentioned in the same context. ACS encompasses the spectrum of myocardial ischemia, which includes myocardial infarction with ST-segment elevation (STEMI), myocardial infarction without ST elevation (NSTEMI), and unstable angina (UA). MI refers to the first two components of ACS wherein sufficient myocardial damage has occurred to release detectable quantities of troponin into the bloodstream.

Etiology and Pathogenesis

MI occurs as a result of an imbalance between myocardial oxygen supply and demand. Most MIs arise from the pathologic substrate of coronary artery atherosclerosis (Fig. 29-1). Localized vascular endothelial injury and inflammation, uptake and oxidation of low-density lipoprotein (LDL), and smooth muscle cell proliferation contribute to development of the atherosclerotic plaque that is sequestered from circulating blood by a collagenous fibrous cap. Disruption of the fibrous cap exposes this inflammatory mixture, leading to platelet activation, thrombin generation, and thrombus formation. Patients with STEMI typically have complete thrombus occlusion of the infarct artery on angiography, whereas NSTEMI/UA patients have partial stenoses of varying severity. Decreased epicardial coronary blood flow results in myocardial ischemia and necrosis that start in the more vulnerable endocardium and spread outward. This process is modulated by the extent of collateral flow and by determinants of myocardial oxygen demand. Subsequent anaerobic metabolism results in myocardial dysfunction with impairment of myocardial contractility and ventricular compliance, and electrical instability with conduction disturbances. Mechanical problems such as mitral regurgitation, free wall or ventricular septal rupture, and ventricular aneurysm can also occur as a result of myocardial structural disruption.

Other causes of MI include microembolization, dynamic obstruction (focal coronary artery spasm or abnormal constriction of intramural vessels), increased myocardial

oxygen requirement (fever, tachycardia, thyrotoxicosis), and decreased myocardial oxygen delivery (hypotension, anemia, hypoxemia).

Clinical Presentation

The clinical presentation of MI can range from typical chest discomfort to nonspecific symptoms with varying degrees of severity. The most typical presentation is of chest pain that is described as an intense, substernal pressure, often radiating to either arm, the neck, the jaw, or the epigastrium. Accompanying symptoms include dyspnea, diaphoresis, nausea or vomiting, palpitations, weakness, and lightheadedness. Occasionally, these associated symptoms, rather than chest discomfort, may predominate. Atypical symptoms are common in elderly patients (particularly among women) and in diabetic patients. These individuals have a higher risk for adverse outcomes, so MI should be considered even in the presence of minor or atypical symptoms. More than 40% of patients have sudden cardiac death as their first symptom of MI.

Physical Examination

The physical examination should focus on identifying potentially correctable causes of myocardial ischemia, complications of ischemia, and signs pointing to an alternative diagnosis. Vital signs, including blood pressure measurements in both arms, are critical. Treatment of

Figure 29-1 Atherogenesis: Unstable Plaque Formation.

uncontrolled hypertension, tachyarrhythmias, fever, or evident thyrotoxicosis reduces myocardial oxygen demand. Similarly, correction of bradycardia, hypotension, or hypoxemia improves oxygen supply. Bradycardia commonly occurs in inferior MIs as a result of atrioventricular node ischemia. Cardiopulmonary examination often reveals an S_4 gallop due to an ischemia-induced decrease in left ventricular compliance. Signs of congestive heart failure, including pulmonary rales, jugular venous distention, S_3 gallop, and hepatosplenomegaly, can be harbingers of cardiogenic shock, which is manifested by hypotension,

tachycardia, and cool extremities. A new systolic murmur may indicate mechanical complications such as mitral valvular incompetence or a ventricular septal defect.

The physical examination includes an assessment of cardiac risk. Findings of obesity, xanthelasma (indicative of hypercholesterolemia), nicotine stains on fingers (suggestive of smoking history), ophthalmologic evidence of hypertension, limb weakness, facial asymmetry or slurred speech (indicative of previous stroke), or differential pulses and bruits (suggestive of peripheral vascular disease) identify patients at higher risk for coronary artery disease.

Differential Diagnosis

Several conditions can mimic MI and may be life threatening if not diagnosed accurately.

Aortic dissection typically presents with a stabbing or ripping chest discomfort radiating to the back. Differential blood pressures between the right and left arm or a new diastolic murmur (aortic regurgitation) suggests aortic dissection, and the diagnostic suspicion is increased when a wide mediastinum is seen on chest radiography. Confirmation requires computed tomography (CT) or transesophageal echocardiographic imaging. An acute MI can occur concurrently with aortic dissection if the dissection involves a coronary ostium (more commonly that of the right coronary artery), resulting in its exclusion from the true aortic lumen. Excluding aortic dissection is important before administering thrombolytics or antithrombotic medications for acute MI. When the chief complaint is dyspnea associated with pleuritic chest discomfort, hemoptysis, and low oxygen saturation, pulmonary embolism should be suspected. This diagnosis is confirmed by ventilation-perfusion scanning or CT of the chest with contrast. Differential breath sounds suggest pneumothorax. Pericarditis pain is usually sharp, pleuritic, and positional and is better when sitting up or leaning forward. A friction rub or pulsus paradoxus suggests pericarditis.

Other conditions, including esophageal spasm, gastroesophageal reflux, peptic ulcer disease, acute cholecystitis, and costochondral pain, often present with similar symptoms and should be ruled out by a careful history and physical examination.

Diagnostic Approach

Electrocardiography

The ECG drives therapeutic decision making for the patient with MI and should be performed within 10 minutes of arrival. Evidence of a new left bundle branch block or new ST-segment elevation greater than 0.1 mV in two or more contiguous leads identifies patients who should be considered for acute reperfusion therapy (Fig. 29-2).

Patients without ST elevation do not benefit from acute reperfusion therapy, except for those with acute posterior MI with ST depression in leads V_1 to V_3 , which is equivalent to ST elevation seen in posterior chest leads. Patients with NSTEMI or UA can have ST-segment depression and T-wave inversion. Acute symmetrical precordial T-wave inversion (≥ 0.2 mV) suggests acute ischemia from a critical stenosis of the left anterior descending coronary artery. A completely normal ECG in the setting of chest pain does not exclude the possibility of MI. The presence of bundle branch block, left ventricular hypertrophy, or ST-segment deviation on ECG predicts poor prognosis independently of clinical findings and cardiac biomarker elevation.

Findings such as a known left bundle branch block, a paced rhythm, left ventricular hypertrophy with strain, wide complex tachycardia, or Wolff-Parkinson-White syndrome can obscure the diagnosis of MI; comparison to a prior ECG if available can occasionally enhance diagnostic accuracy.

Biomarker Testing

Myocyte necrosis with subsequent loss of cell membrane integrity releases cardiac-specific biomarkers that are detectable in the peripheral circulation. Before the advent of troponin, creatine kinase-MB (CK-MB) was the principal biomarker available; however its use was hampered by low sensitivity and specificity. CK-MB becomes elevated 3 to 4 hours after onset of MI, peaks between 12 and 24 hours, and remains elevated for 36 to 48 hours. Troponin assays have demonstrated superior sensitivity and tissue specificity, such that current guidelines have declared troponins the preferred biomarker for diagnosing MI, and their use has been incorporated into the definition of MI. Troponin I and T measurements provide similar diagnostic and prognostic information. Troponin levels begin to rise 3 to 6 hours after symptom onset and remain elevated 7 to 14 days after infarction. Troponin elevation independently predicts higher mortality even among patients with normal CK-MB levels, and NSTEMI patients with troponin elevation may benefit from more aggressive therapies such as low-molecular-weight heparin, glycoprotein IIb/IIIa inhibitors, or an early invasive cardiac catheterization strategy.

Serial biomarker testing for up to 18 hours should be performed for all patients with suspected MI. However, for patients with STEMI, the decision for acute reperfusion therapy should not be delayed while awaiting results of biomarker testing. To permit earlier diagnosis before myocardial damage occurs, recent efforts have focused on markers of cardiac ischemia and plaque instability, including ischemia-modified albumin, malondialdehyde, and pregnancy-associated plasma protein A. These assays are not yet widely available and require large clinical trial validation.

Other Diagnostic Tools

Although the ECG and cardiac biomarkers are the most important tests for suspected MI, diagnostic imaging such as two-dimensional echocardiography, nuclear scintigraphy, or cardiac magnetic resonance imaging can provide complementary diagnostic and prognostic information. Bedside echocardiography is useful in detecting infarction in electrocardiographically silent areas such as the circumflex artery distribution; new wall motion abnormalities are diagnostic of ischemia. Echocardiography can provide further information regarding left ventricular function, size and location of infarction, valvular pathology, and

Figure 29-2 Localization of Myocardial Infarcts.

F. Netter M.D.

mechanical complications such as mitral regurgitation or ventricular septal rupture. Radionuclide imaging, particularly during ongoing chest discomfort, can be useful but is limited by lack of 24-hour personnel or isotope availability. Recent enthusiasm about cardiac magnetic resonance imaging reflects its dual advantages of providing superior structural information as well as detecting ischemic, viable, or scarred vascular territories.

Management and Therapy

Optimum Treatment

Every patient presenting with symptoms and signs suggestive of MI should be triaged per a standardized protocol to expedite evaluation and therapy. All patients should receive an intravenous line, oxygen administered through nasal prongs, and continuous cardiac telemetry monitoring for arrhythmias. After targeted history and physical examination are performed, 160 to 325 mg of aspirin should be given. Aspirin is associated with a 24% reduction in early mortality. Patients with ongoing chest discomfort should receive 0.4 mg of sublingual nitroglycerin at 5-minute intervals unless they are hypotensive, are bradycardic, or have evidence of right ventricular infarction. Nitrates reduce preload and afterload and promote coronary vasodilation. β -Blockers reduce myocardial oxygen demand and, in the absence of hypotension, bradycardia, congestive heart failure, or a history of bronchospasm, should be given orally and titrated upward in dosing as clinical condition allows. Further treatment is stratified by the presence or absence of ST elevation on ECG.

ST Elevation Myocardial Infarction

All patients with ST elevation or new left bundle branch block should be considered for immediate reperfusion therapy. Restoration of coronary flow can be achieved pharmacologically with thrombolytic medications or mechanically with percutaneous coronary intervention (PCI).

Commonly used thrombolytic agents include intravenous streptokinase and recombinant tissue plasminogen activators such as tPA (alteplase), rPA (reteplase), and TNK (tenecteplase). Streptokinase is less costly and more commonly used worldwide. Recombinant agents are more efficacious and, in the cases of rPA and TNK, are more easily administered. All have been associated with significant reductions in 30-day and long-term mortality. Contraindications to thrombolysis include recent bleeding, stroke, intracranial hemorrhage, major surgery, or chronic warfarin anticoagulation. Adjunctive therapies include heparin and clopidogrel. Low-molecular-weight heparin has been shown to be superior to unfractionated heparin when combined with TNK. Clopidogrel use has been shown to significantly reduce mortality as well as recurrent infarction and stroke.

Primary PCI of the infarct-related artery is superior to thrombolysis in terms of both efficacy (reduced mortality) and safety (reduced bleeding complications). However, its use is limited by timely availability of qualified catheterization facilities and staff. Adjunctive glycoprotein IIb/IIIa inhibition has been found to enhance the outcome of primary PCI with lower rates of death, reinfarction, and need for urgent repeat revascularization. Clopidogrel use after stent implantation is routine. Recent evidence shows that delayed opening of an occluded infarct-related artery (>3 days from symptom onset) is not beneficial, emphasizing the need for timely reperfusion therapy.

Time to artery patency is a key determinant of both short- and long-term prognosis; hence, rapid triage and decision making are critical. A door-to-needle time of 30 minutes and a door-to-balloon time of 90 minutes are the longest acceptable time delays, and in the absence of contraindications, the selection of reperfusion strategy should be based on which method allows the most rapid means of restoring coronary flow. Primary PCI is the preferred reperfusion strategy in patients with cardiogenic shock.

Non-ST Elevation Myocardial Infarction

Although there is less urgency in managing patients with NSTEMI compared with those with ST elevation, early cardiac catheterization with appropriate revascularization (either PCI or surgical bypass grafting) has been shown to reduce mortality and morbidity, particularly in higher risk patients with recurrent ischemia, elevated troponin, heart failure symptoms, and new ST-segment changes on ECG. In general, antiplatelet and antithrombotic medications remain the cornerstone of NSTEMI therapy. Combination antiplatelet therapy with aspirin and clopidogrel is superior to aspirin alone. Low-molecular-weight heparin reduces mortality and major adverse cardiac events compared with unfractionated heparin in troponin-positive patients. Furthermore, in high-risk patients, use of glycoprotein IIb/IIIa inhibitors further reduces mortality and adverse outcomes, particularly among patients undergoing PCI. Patients with troponin-positive NSTEMI derive additional benefit from glycoprotein IIb/IIIa inhibition even after receiving aspirin, heparin, and clopidogrel. Although individual glycoprotein IIb/IIIa inhibitors are mostly interchangeable, in patients not proceeding to early revascularization, use of abciximab provides no significant benefit and is discouraged. In patients treated with an early invasive cardiac catheterization strategy, recent evidence shows that bivalirudin, used as an alternative to heparin plus glycoprotein IIb/IIIa inhibition, provides similar anti-ischemic benefits with a reduced rate of bleeding complications. Fondaparinux has also demonstrated comparable reductions in death, MI, and refractory ischemia, accompanied by a significantly lower bleeding rate when compared with low-molecular-weight heparin in patients with non-ST elevation ACS. However, concerns regarding an

Figure 29-3 Nondrug Therapy.

increased risk for catheter-related thrombosis have limited its use to patients who are managed with a conservative invasive strategy.

Coronary Revascularization

Recent advances, including use of drug-eluting stents and adjunctive antiplatelet therapies (clopidogrel, glycoprotein IIb/IIIa inhibitors), have increased the utilization and success rates of percutaneous coronary revascularization. Although indications for catheter-based therapies are continuing to expand, currently, coronary artery bypass graft-

ing provides more long-term survival benefit for high-risk patients with significant left main or multivessel coronary artery disease, particularly for those with abnormal left ventricular function or diabetes.

Secondary Prevention

Aggressive blood pressure and glycemic control, smoking cessation, dietary modification, and cardiac rehabilitation are key components of secondary prevention (Fig. 29-3). Aspirin therapy provides a 25% reduction in recurrent ischemic events. β-Blockers provide benefit in patients

across all age groups treated with or without reperfusion. Angiotensin-converting enzyme (ACE) inhibitors improve survival in post-MI patients with or without left ventricular dysfunction. In the absence of hypotension, β -blockers and ACE inhibitors should be started during the hospitalization and are routine components of post-MI care. Patients with MI complicated by left ventricular dysfunction and heart failure who are already optimized on the aforementioned therapies receive further morbidity and mortality reduction with aldosterone blockade.

A fasting lipid profile should be obtained in the first 24 hours after admission. Recent studies have shown that intensive early post-MI lipid lowering with statins provides greater protection against death and other major cardiac events. This evidence has led to a revision of the National Cholesterol Education Program—Adult Treatment Panel III guidelines, which now recommend initiation of statin therapy in all post-MI patients irrespective of baseline LDL level. Statin therapy should be initiated before hospital discharge (to enhance compliance) and target an LDL goal of less than 70 mg/dL.

Postinfarction patients are at higher risk for sudden cardiac death due to ventricular arrhythmias. Antiarrhythmic drugs such as amiodarone have limited efficacy in preventing sudden death after MI. Recent randomized clinical trials have suggested that prophylactic implantation of implantable cardioverter defibrillators (ICDs) improves survival in patients with left ventricular dysfunction irrespective of the presence or absence of spontaneous or “provokable” ventricular arrhythmias. ICD implantation should be considered for patients with an ejection fraction of 30% or less who have been on optimal medical therapy for at least 6 weeks after the MI.

Avoiding Treatment Errors

A chest pain protocol should be in place to triage symptomatic patients, such that the appropriate diagnostic and therapeutic measures can be delivered in an expeditious manner. Keeping in mind that not all patients present with typical chest pain, a 12-lead ECG, in particular, is critical for rapid risk stratification. The phrase “time is muscle” is frequently used to describe the urgency of revascularization once coronary artery occlusion is suspected. Therapies for MI involve the use of antithrombotic medications, which carry the risk for bleeding. This bleeding risk can be minimized by proper dosing of medications (e.g., heparin, glycoprotein IIb/IIIa inhibitors), with careful attention to weight and creatinine clearance.

Future Directions

Current treatment paradigms for MI are founded on anticoagulating medications and invasive therapies that increase the risk for bleeding. Early trials of novel pharmacologic therapies such as fondaparinux and bivalirudin

show reduction in both mortality and bleeding risk compared with standard therapies. Their long-term benefit and risk remain to be studied. New anti-ischemic agents, such as fatty acid oxidation inhibitors (ranolazine) and adenosine diphosphate receptor antagonists (prasugrel), are being studied for both acute and chronic treatment of coronary disease. Novel single-strand nucleic acid aptamers, providing the advantages of both high specificity to the target molecule (e.g., factor IXa) and availability of an antidote that allows controlled, rapidly reversible anticoagulation, are also being studied in patients with coronary disease. Studies evaluating newer-generation drug-eluting stents and coronary debulking devices are also ongoing in the hope of minimizing the need for open-chest surgical procedures. In this era of genomics, proteomics, and metabolomics, the ultimate goal is to deliver therapies for MI tailored to individual genetic and phenotypic profiles that will allow optimal outcomes without significant complications.

Electrocardiography

Introduction

In 1902, the Dutch physiologist Willem Eintoven recorded the first electrocardiogram (ECG) from humans. Since then, the number of recording leads has increased from 3 to 12, and the recording instruments have evolved into sophisticated automated digital recorders capable of recording, measuring, and interpreting the electrocardiographic waveform. However, the basic principals underlying the ECG are unchanged. It records, from the body surface, the uncanceled voltage gradients created as myocardial cells sequentially depolarize and repolarize.

The ECG is the most commonly used technique to detect and diagnose heart disease and to monitor therapies that influence the electrical activity of the heart. It is noninvasive, virtually risk free, and relatively inexpensive. Since its introduction, a large database has been assembled correlating the ECG waveform recorded from the body surface to the underlying electrical activity of individual cardiac cells on the one hand, and to the clinical presentation of the patient on the other, thereby providing insight into the electrical behavior of the heart and its modification by physiologic, pharmacologic, and pathologic events.

Leads

Twelve leads are routinely used to record the body surface ECG. Three bipolar limb leads, leads 1, 2 and 3; three augmented limb leads, leads aVR, aVL, and aVF; and six unipolar chest leads, leads V₁ through V₆ (Fig. 30-1). In the bipolar limb leads, the negative pole for each of the leads is different, whereas in the unipolar chest leads, the negative pole is constant and created by the three limb leads. The positive chest lead is, in effect, an exploring lead that can be placed anywhere provided that the ECG reader knows its position. For instance, in children, the routine ECG often includes placing leads on the right side of the chest wall in positions referred to as V_{3R} and V_{4R}. Similar right-sided chest leads are often used in adults to diagnose right ventricular infarction, and one or more leads positioned on the back are sometimes used to diagnose posterior wall infarction.

The chest leads are relatively close to the heart and are influenced by the electrical activity directly under the recording electrode. This is in contrast to the limb leads in which the electrodes are placed outside of the body torso. Changes in the position of an individual chest lead or the relationship between the chest leads and the heart may cause significant changes in the ECG pattern. For

instance, if the patient is in a sitting rather than a supine position, the relationship of the various chest leads to the heart and the ECG waveform will be affected. Similarly, if the lead is placed an interspace too high or too low, the ECG waveform recorded by that lead will change. For this reason, in assessing a patient with serial ECGs, it is very important that lead placement be consistent and reproducible. In contrast to the situation with chest leads, limb leads may be placed anywhere on the various limbs with little significant alteration of the ECG waveform.

Electrocardiographic Waveform

The ECG waveform consists of a P wave, a PR interval, the QRS complex, an ST segment, and T and U waves. The relationship of these waveform components to the underlying action potentials of the various cardiac tissues is shown in Figure 30-2. The P wave reflects depolarization of the atria, the QRS complex reflects depolarization of the ventricles, and the ST segment and T wave reflect repolarization of the ventricles. The U wave, which occurs after the T wave, is thought to be an electrical event coupled to contraction.

Depolarization of the sinus node occurs before the onset of the P wave, but the voltage gradients created are

Figure 30-1 Electrocardiographic Leads and Reference Lines.

When current flows toward red arrowheads, upward deflection occurs in ECG
 When current flows away from red arrowheads, downward deflection occurs in ECG
 When current flows perpendicular to red arrows, no deflection or biphasic deflection occurs

too small to be recorded on the body surface by clinically used electrocardiographic machines. Therefore, the event is electrocardiographically silent. Similarly, the electrical activity of the atrioventricular (AV) junction and the His-Purkinje system, which occur during the PR interval, is electrocardiographically silent. Figure 30-3 is an example of the normal ECG.

P Wave

The P wave is caused by the voltage gradients created as the atrial cells sequentially depolarize. The shape and duration of the P wave are determined by the sequence of atrial depolarization and the time required to depolarize the cells of both atria. The sinus node is located at the

Figure 30-2 Relation of Action Potential from the Various Cardiac Regions to the Body Surface ECG.**Figure 30-3 Normal ECG.**

Example of a normal ECG recorded from a 24-year-old woman. Note that the P wave is upright in leads I and II and inverted in aVR. The QRS complex gradually changes from negative to V₁ to positive V₆. Note that the polarity of the T wave is similar to that of the QRS complex.

junction of the superior vena cava and the right atrium, and the direction of atrial depolarization is from right to left, from superior to inferior, and from anterior to posterior. This results in a P wave that is characteristically upright or positive in leads I, 2, V₅, and V₆ and inverted or negative in lead aVR. In lead V₁, the P wave may be upright, biphasic, or inverted (see Fig. 30-3). The amplitude and duration of the normal sinus P wave may be affected by atrial hypertrophy and dilation and by slowing of interatrial and intra-atrial conduction by atrial fibrosis.

Impulses arising from an ectopic atrial focus are associated with P waves whose shape depends on the location of the focus. If the abnormal focus is in close proximity to the sinus node, the sequence of atrial activation will be normal or nearly normal, and the P wave will resemble the normal sinus P wave described earlier. The further the abnormal ectopic focus is from the sinus node, the more abnormal will be the sequence of atrial activation and the P-wave configuration. For instance, impulses originating in the inferior portion of the atrium or within the AV node will

Figure 30-4 Ectopic Atrial Rhythm.

Electrocardiogram showing an ectopic atrial rhythm. It was recorded from a 59-year-old man. The polarity of the P wave is abnormal. It is inverted in leads II, III, and aVF and upright in lead aVR.

depolarize the atria in a retrograde, superiorly oriented direction and will be associated with the P waves that are inverted in leads 2, 3, and aVF and upright in aVR (Fig. 30-4).

PR Interval

The PR interval includes the P wave and the PR segment, that is, the segment from the end of the P wave to the onset of the QRS complex. Although appearing flat or isoelectric on the body surface ECG, the PR segment consists of atrial repolarization and depolarization of the AV node and His-Purkinje system. The PR interval is prolonged by factors that slow AV nodal conduction, such as a decrease in sympathetic tone or an increase in vagal tone, by drugs that have these effects such as digitalis and the β -adrenergic blocking agents, and by a variety of inflammatory, infiltrative, and degenerative diseases that affect the AV junction. The PR interval is shortened when impulses reach the ventricles through an AV nodal bypass tract to cause ventricular preexcitation (as in the Wolff-Parkinson-White syndrome).

QRS Complex

The QRS complex reflects ventricular depolarization. The interventricular septum is the first portion of the ventricle to be depolarized. Thereafter, the ventricles depolarize simultaneously, with the impulse spreading from endocardium to epicardium and from apex to base. Because the left ventricle is 3 times the size of the right, its depolarization overshadows and largely obscures right ventricular depolarization. The QRS complex reflects this left ventricular dominance, and for this reason, the QRS complex is usually upright or positive in leads 1, V₅, and V₆, the

left-sided and more posterior leads, and negative or inverted in aVR and V₁, the right-sided and more anterior leads. It is only in situations such as right bundle branch block and significant right ventricular hypertrophy that the electrical activity associated with right ventricular depolarization is identified on the ECG.

The QRS complex is altered in both shape and duration by abnormalities in the sequence of ventricular activation. These include the bundle branch blocks (Fig. 30-5), the fascicular blocks, ventricular preexcitation (Fig. 30-6), and nonspecific intraventricular conduction disturbances. The increase in QRS duration may range from a few milliseconds, as in the case of the fascicular blocks, to more than 80 milliseconds, as in the bundle branch blocks. The fascicular blocks reflect conduction slowing in one fascicle of the left bundle and are characterized by a shift in electrical axis. The bundle branch blocks are caused by conduction slowing or block in the right or left bundle branch, usually caused by fibrosis, calcification, or congenital abnormalities involving the conducting system. They are associated with more pronounced abnormalities in the sequence of ventricular activation and thus with more significant changes in the QRS configuration than are associated with the fascicular blocks. Nonspecific conduction abnormalities may occur without a change in QRS configuration and reflect slow conduction throughout the ventricles without a change in the sequence of activation. Such slowing may be caused by cardioactive drugs, an increase in extracellular potassium concentration, and diffuse intraventricular slowing of conduction due to fibrosis or scarring as frequently occurs in patients with severe cardiomyopathies.

The electrocardiographic criteria for the diagnosis of intraventricular conduction disturbances have been published. Important features include the following:

Figure 30-5 Bundle Branch Block.

Electrocardiogram showing left bundle branch block. It was recorded from a 73-year-old man. Note that the QRS complex is diffusely widened and is notched in leads V_3 , V_4 , V_5 , and V_6 . Note also that the T wave is directed opposite to the QRS complex. This is an example of a secondary T-wave change.

Figure 30-6 Ventricular Preexcitation.

ECG showing ventricular preexcitation. It is recorded from a 28-year-old woman. Note the short PR interval (0.9 sec) and the widened QRS complex (0.134 sec). The initial portion of the QRS complex appears slurred. This is referred to as a *delta wave*. This combination of short PR interval and widened QRS complex with a delta wave is characteristic of ventricular preexcitation. Note also that the T wave is abnormal, another example of a secondary T-wave change.

1. The fascicular blocks not only alter the electrical axis in the frontal plane but also influence the initial portion of the QRS complex. As a result, they may obscure the diagnosis of a prior myocardial infarction while causing other changes that simulate an infarction.
2. Right bundle branch block does not affect the initial portion of the QRS complex because activation of the interventricular septum and the left ventricle are unaffected. Thus the electrocardiographic changes of a prior myocardial infarction or left ventricular hypertrophy can still be appreciated in an individual with a right bundle branch block.
3. Left bundle branch block and ventricular preexcitation do affect the initial portion of the QRS complex. Thus, the ECG changes associated with a prior myocardial infarction and hypertrophy are often obscured and cannot be diagnosed.
4. Abnormalities in the sequence of depolarization are always associated with abnormalities in the sequence of repolarization. This results in changes in the ST segment and T wave that are referred to as *secondary changes*. This is particularly prominent in the setting of left bundle branch block and ventricular preexcitation (see Figs. 30-5 and 30-6).

Figure 30-7 ECG Changes of LV Hypertrophy.

Example of the ECG changes of LV hypertrophy. It is recorded from an 83-year-old woman with aortic stenosis and insufficiency. Note the increase in QRS amplitude, the slight increase in QRS duration to 100 ms, and the ST-segment and T-wave changes.

5. Changes in intraventricular conduction may be rate dependent and present only when the rate is above a critical level or after an early atrial premature beat. In this situation, it is referred to as *rate-dependent aberrant ventricular conduction*.

The amplitude of the QRS complex is subject to a variety of factors: the thickness of the left ventricular and right ventricular walls, the presence of pleural or pericardial fluid, or an increased tissue mass. QRS amplitude is also affected by age, sex, and race. For instance, younger individuals have greater QRS voltages than older individuals, and men have greater QRS voltages than women. In left ventricular hypertrophy, the R wave in the left-sided leads (V_5 and V_6) and the S wave in the right-sided chest leads (V_1 and V_2) are increased. QRS duration may increase, reflecting the increased thickness of the left ventricle. There may also be changes in repolarization that cause changes in the ST segment and T wave (Fig. 30-7). Right ventricular hypertrophy is more difficult to diagnose electrocardiographically. Initially it causes cancellation of left ventricular forces, resulting in a decrease in S-wave amplitude in the right-sided leads V_1 and V_2 and a decrease in R-wave amplitude in the left-sided lead V_5 and V_6 . With more advanced right ventricular hypertrophy, an increased R wave occurs in the right-sided leads and a deeper S wave is seen in the left-sided leads. Pericardial and pleural effusions decrease QRS voltage in all leads, as may infiltrative diseases such as amyloidosis.

ST Segment and T Wave

The ST segment and T wave reflect ventricular repolarization. During the ST segment, the ventricular action potentials are at their plateau voltage, and only minimal voltage gradients are generated. Therefore, the ST segment is at

the same level on the ECG as the TP and PR segments, during which time there are also no voltage gradients created because the action potentials are all at their resting levels. The T wave occurs as a result of the sequential repolarization of the ventricular cells. If the sequence of repolarization were the same as the sequence of depolarization, the T wave would be opposite in direction to the QRS complex. However, the sequence of repolarization is reversed relative to the sequence of depolarization, and as a result, the normal T wave is generally upright or positive in leads with an upright or positive QRS complex (leads 1, V_5 , and V_6) and inverted or negative in leads with an inverted QRS complex (aVR and V_1) (see Fig. 30-3).

Abnormalities in repolarization are manifest by elevation or depression of the ST segment and changes in polarity of the T wave. As mentioned, such changes may occur as the result of an intraventricular conduction disturbance, in which case they are referred to as secondary. They may also occur as a result of electrolyte abnormalities or cardioactive drugs or as the manifestation of diseases such as hypertrophy, ischemia, or myocarditis, in which case they are considered to be primary.

Changes in T-wave polarity occurring in the absence of QRS and ST-segment changes are the most difficult ECG abnormalities to interpret because they are nonspecific and may be caused by a variety of nonpathologic as well as pathologic causes. The following guidelines have served as an approach to interpreting T-wave abnormalities:

1. In general, T-wave amplitudes should be equal to or greater than 10% of the QRS amplitude.
2. Inverted T waves in lead I are always abnormal and usually indicative of underlying cardiac pathology.
3. Minor T-wave changes such as T-wave flattening or slightly inverted T waves, particularly when they occur in the absence of known cardiac abnormalities or in

Figure 30-8 Changes Associated with Hypokalemia.

Example of the changes associated with hypokalemia. It is recorded from a 44-year-old man who was receiving long-term thiazide therapy. The QT interval is prolonged due to the presence of a U wave, which interrupts the descending limb of the T wave and is of equal amplitude to the T wave. In this patient, the serum potassium concentration was 2.7 mM.

populations at low risk for cardiac disease, are more likely to be nonspecific and nonpathologic than more marked T-wave changes or T-wave changes occurring in the presence of cardiac disease.

4. Flat or inverted T waves often occur in association with rapid ventricular rates and in the absence of other ECG changes. These changes are nonspecific and not indicative of underlying cardiac disease.

Elevation or depression of the ST segment indicates the creation of voltage gradients during the plateau phase of the ventricular action potentials and, unlike the T-wave changes referred to above, are most often a manifestation of cardiac disease. The most common causes of ST-segment elevation include acute transmural ischemia and pericarditis. High serum potassium and acute myocarditis may also occasionally cause ST-segment elevation and simulate ischemia, although this is quite rare. A normal variant referred to as *early repolarization* is not an uncommon cause of ST elevation, particularly in young males. These changes characteristically occur in the V leads, involve elevation of the junction of the ST segment with the end of the QRS complex, and may simulate acute ischemia or pericarditis.

Left ventricular hypertrophy, cardioactive drugs, low serum potassium, and acute nontransmural or subendocardial ischemia are the most common causes of ST-segment depression.

U Wave

When present, the U wave follows the T wave or may arise within the terminal portion of the T wave and be difficult to distinguish from a notched T wave. The precise etiology of the U wave is not clear, although most believe it is an

electrical manifestation of mechanical events. An increase in the magnitude of the U wave or a change in its polarity may occur in several clinical entities. An increase in U-wave amplitude is frequently associated with hypokalemia (Fig. 30-8) and with some direct-acting cardiac drugs. Notching of the T wave resembling an increase in the U-wave amplitude and lengthening of the QT-U interval also often occurs in patients with congenital long QT syndromes (Fig. 30-9).

QT Abnormalities

The interval from the onset of the Q wave to the end of the T wave is referred to as the QT interval and includes the QRS complex, the ST segment, and the T wave. Changes in the duration of any of these components will alter the QT interval. The QT interval is rate dependent, becoming shorter at the more rapid rate and longer at slower heart rates. This reflects the rate-dependent changes in action potential duration. To accommodate this rate dependency, several correction factors have been applied to the measured QT interval and used to generate the term referred to as QTc on automated recording systems. In addition to changes in heart rate, the QT interval is influenced by the following:

1. Temperature
2. Drugs
3. Electrolyte abnormalities
4. Genetic factors
5. Neurogenic factors
6. Ischemia

There is an extensive and ever-increasing list of drugs that lengthen the QT interval by prolonging the ST segment or the T wave. For this reason, it is often

Figure 30-9 Congenital Long QT Syndrome.

Recorded from a 16-year-old girl with syncopal episodes that were documented to be due to rapid ventricular tachycardia. It is an example of long QT syndrome. The T wave is notched and prolonged in much the same way as was shown in the patient with hypokalemia. However, in this patient, the serum potassium concentration was normal.

necessary to monitor the ECG when drugs recognized as having potential for lengthening the QT interval are initiated. The lengthening of the QT interval following administration of these drugs is clinically important because it may be a harbinger of a specific type of ventricular tachycardia, torsades de pointes, which may progress to ventricular fibrillation and cause sudden cardiac death.

Low serum potassium and low serum calcium are both associated with prolongation of the QT interval. However, their electrocardiographic patterns are different and distinctive. Low potassium causes ST-segment depression, T-wave changes, a prominent U wave, and prolongation of the QT-U interval (see Fig. 30-8), whereas low calcium lengthens the ST segment without causing significant T-wave changes (Fig. 30-10). An increase in serum potassium and serum calcium shortens the QT interval by shortening the ST segment. In addition, high potassium shortens the duration of the T wave and makes it more symmetrical, giving it the appearance of a tented or peaked T wave (Fig. 30-11).

Abnormalities in one or more of the several genes that regulate the repolarizing currents are responsible for causing the congenital long QT syndromes and are a significant cause of sudden cardiac death in younger individuals due to ventricular arrhythmias. The ECG patterns associated with congenital long QT intervals are often difficult to distinguish from electrolyte abnormalities (see Fig. 30-9).

Marked QT prolongation and a deeply inverted T wave occur frequently within the first several days following an acute myocardial infarction, particularly when the infarction is due to occlusion of the left anterior descending coronary artery. This QT prolongation usually resolves, although the T-wave inversion may persist for long periods of time. Similar T-wave and QT-interval changes may

occur in the chest leads following an acute ischemic event but in the absence of an infarction (Fig. 30-12). This particular ECG pattern usually indicates a severely but not totally obstructed proximal portion of the left anterior descending coronary artery.

Some neurologic events, particularly intracranial hemorrhage and an increase in intracranial pressure, may cause T-wave inversion and dramatic lengthening of the QT intervals, very similar to that shown in Figure 30-12. When it occurs in this clinical setting, it is referred to as the *cerebrovascular accident pattern* and is thought to represent an imbalance of sympathetic stimulation. It is self-limited, and the ECG generally returns to normal within a few days.

Acute Ischemia and Infarction

Acute myocardial ischemia and infarction cause characteristic changes in the ST segment, QRS complex, and T wave, which permit early diagnosis and prompt treatment—either thrombolytic therapy or percutaneous coronary revascularization—that can reverse ischemia and prevent the loss of myocardial cells and subsequent scarring with its attendant effects on morbidity and mortality. For this reason, the ECG is the single most important test currently available for the early detection of acute ischemia and infarction.

The sequence of ECG changes associated with acute ischemia and infarction is as follows:

1. Peaking of the T wave
2. ST-segment elevation or depression
3. Development of abnormal Q waves
4. T-wave inversion

These changes can be understood by recognizing that acute ischemia or infarction is caused by occlusion of a

Figure 30-10 ST-Segment and QT-Interval Changes Associated with Hypocalcemia.

ST-segment and QT-interval changes associated with hypocalcemia. It is recorded from a 53-year-old man with chronic renal disease. The ST segment is prolonged, but the T wave is normal. The QT interval reflects ST-segment lengthening and is prolonged.

Figure 30-11 Changes Associated with Hyperkalemia.

Example of the ECG changes associated with hyperkalemia. It is recorded from a 29-year-old woman with chronic renal disease. The P wave is broad and difficult to identify in some leads. The QRS is diffusely widened (0.188 sec), and the T wave is peaked and symmetrical. These changes are characteristic of severe hyperkalemia, and in this patient, the serum potassium concentration was 8.2 mM.

coronary artery and is localized to the myocardial region supplied by that artery. This produces a gradient of changes between the ischemic and nonischemic regions that are separated by a rather well-defined border zone (Fig. 30-13).

Peaking of the T waves in leads overlying the ischemic region is the earliest ECG manifestation of acute transmural ischemia and is transient. It is only rarely observed because the ECG is usually not recorded early enough to permit its detection unless the patient is in a hospital setting when ischemia first begins. ST elevation and depression are the most frequently observed early changes and occur within minutes of the onset of the acute event. The ST changes are caused by voltage gradients across the ischemic border that result in an electrical current,

referred to as an *injury current*, flowing across the ischemic borders. Whether these injury currents cause ST elevation or depression depends on whether the ischemic zone is transmural, extending from endocardium to epicardium, or is nontransmural and localized to the subendocardial region, and on the relationship of the recording electrodes to the ischemic border. In general, electrodes directly overlying a region of transmural ischemia will record ST elevation, whereas all other electrodes will record ST depression or no change in the ST segment.

Subendocardial ischemia, such as that associated with subtotal coronary occlusion, and that which is often brought on by exercise in patients with flow-limiting coronary artery obstruction, does not extend to the epicardium.

Figure 30-12 T-Wave Changes Induced by a Recent Ischemic Event.

T-wave changes induced by a recent ischemic event, recorded from a 70-year-old man. The QT interval is prolonged, and the T waves are markedly inverted in the precordial leads (V₁ through V₆). These changes gradually evolved over several days, and coronary angiography recorded the day this tracing was taken revealed a subtotal occlusion of the left anterior descending coronary artery.

Figure 30-13 Myocardial Ischemia, Injury, and Infarction.

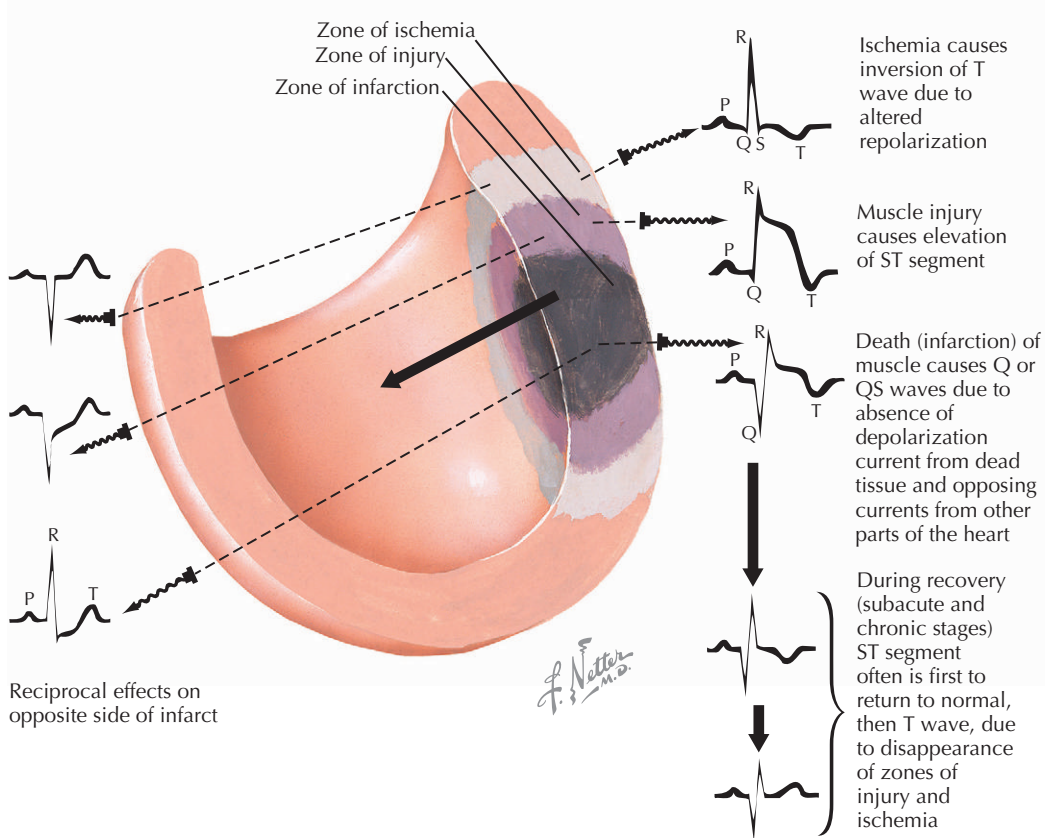

Figure 30-14 Abnormal Cardiac Rhythms.

Thus, none of the body surface leads directly overlie the ischemic region, and ST depression, rather than ST elevation, is recorded.

The development of abnormal Q waves indicates slowed or absent conduction through the ischemic region and implies the presence of severely depressed or infarcted tissue, whereas the T-wave changes that occur after the ischemic event reflect changes in repolarization and may persist for periods ranging from days to years.

These various ECG changes permit the localization of the ischemic or infarcted region and, by inference, the identification of the occluded vessel.

Arrhythmias

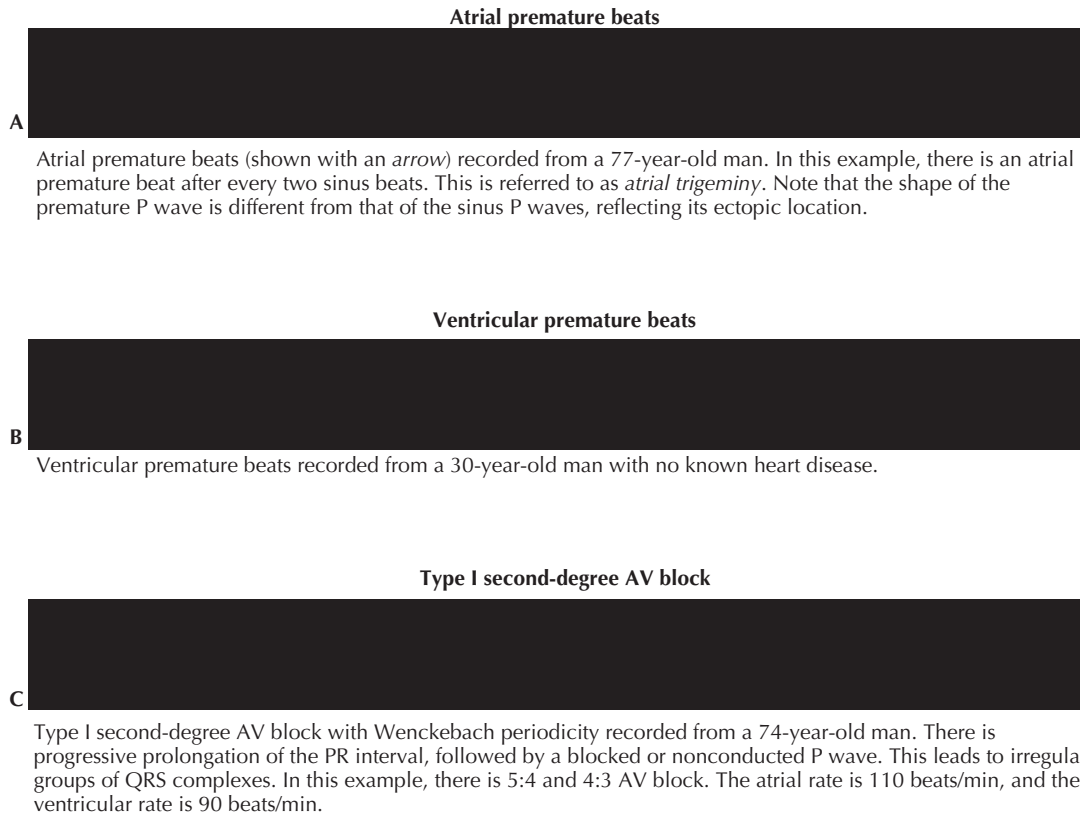

The ECG is indispensable for the diagnosis of bradyarrhythmias and tachyarrhythmias. For instance, a heart rate greater than 100 beats/min may have multiple causes, including sinus tachycardia, atrial and AV junctional tachycardia (Fig. 30-14A), atrial flutter, atrial fibrillation (Fig. 30-14 B), and ventricular tachycardia (Fig. 30-14C). The rate and configuration of the P wave, its relation to the QRS complexes, and the shape and duration of the

QRS complex establish the correct diagnosis. Abnormally slow heart rates may also be caused by several entities, including sinus bradycardia or sinoatrial or AV block (Fig. 30-14D). Again, the diagnosis can be established by noting the rate, regularity, and configuration of the P wave and QRS complexes, the relation of the P wave to the QRS complexes, and the PR interval.

Irregular rhythms may be due to atrial and ventricular premature beats (Fig. 30-15A, B), atrial fibrillation (see Fig. 30-14B), and incomplete (second-degree) sinoatrial or AV block (Fig. 30-15C).

Future Directions

The ECG provides a window into the electrophysiologic properties of the heart and their modification by physiologic, pharmacologic, and pathologic factors. When correctly interpreted, it is of inestimable help in the diagnosis and treatment of a wide variety of cardiac diseases. It is of particular importance in the diagnosis of myocardial ischemia and arrhythmias. The use of the ECG recorded during daily activities and during stress further adds to its capabilities. The value of the ECG is greatly enhanced

Figure 30-15 Irregular Cardiac Rhythms.

when pertinent patient information, such as symptoms, drug usage, and important laboratory findings, is provided to the reader. It is reasonable to anticipate that in the future, additional leads such as V_3R , V_4R , and V_{7-9} may be recorded; that new analytic measurements, particularly those dealing with the QRS complex and the T wave, will be developed; and that the library of diagnostic and prognostic statements will be expanded. However, it is important to stress that the automated interpretations provided by computerized ECG systems now and in the future may be incomplete or inaccurate, particularly when the tracing is abnormal, and require over-reading by qualified personnel.

Peripheral Arterial Disease

Introduction

Peripheral arterial disease (PAD) refers to stenosis or occlusion in the arteries of the lower extremities. Most patients with PAD are asymptomatic. Symptomatic patients can present with mild symptoms, occurring only with extreme exertion to symptoms with moderate exertion, or with severe symptoms occurring at rest with ongoing limb ischemia. In the Framingham Study, and other population studies, PAD is generally a disease of aging. Intermittent claudication, occurring as a result of PAD, increases in prevalence in late middle age. The incidence of PAD is negligible in young adulthood but is present, depending on the definition used, in 10% to 30% of adults older than 50 years. PAD is a marker for the presence of coronary and cerebrovascular disease, and in many patients with PAD, the development and progression of atherosclerosis is a diffuse systemic process (Fig. 31-1). An estimated 60% of patients with PAD have coronary artery disease, cerebrovascular disease, or both. Stroke and myocardial infarction occur in patients with PAD at a rate about 3 times greater than in those without PAD, even among individuals with no vascular symptoms.

Recognizing the link between PAD of the extremities and atherosclerosis elsewhere has led to the integration of therapies that target not only claudication but also cardiovascular death and morbidity.

Etiology and Pathogenesis

Atherogenesis begins with injury to the vascular endothelium and formation of an atherosclerotic plaque. This process is potentiated by a local leukocyte-mediated inflammation and oxidized lipoprotein species, particularly low-density lipoproteins. Although many advances have been made in recent years, the precise molecular mechanisms by which smoking, hypercholesterolemia, diabetes, and hypertension accelerate atherosclerosis remain the focus of ongoing investigation.

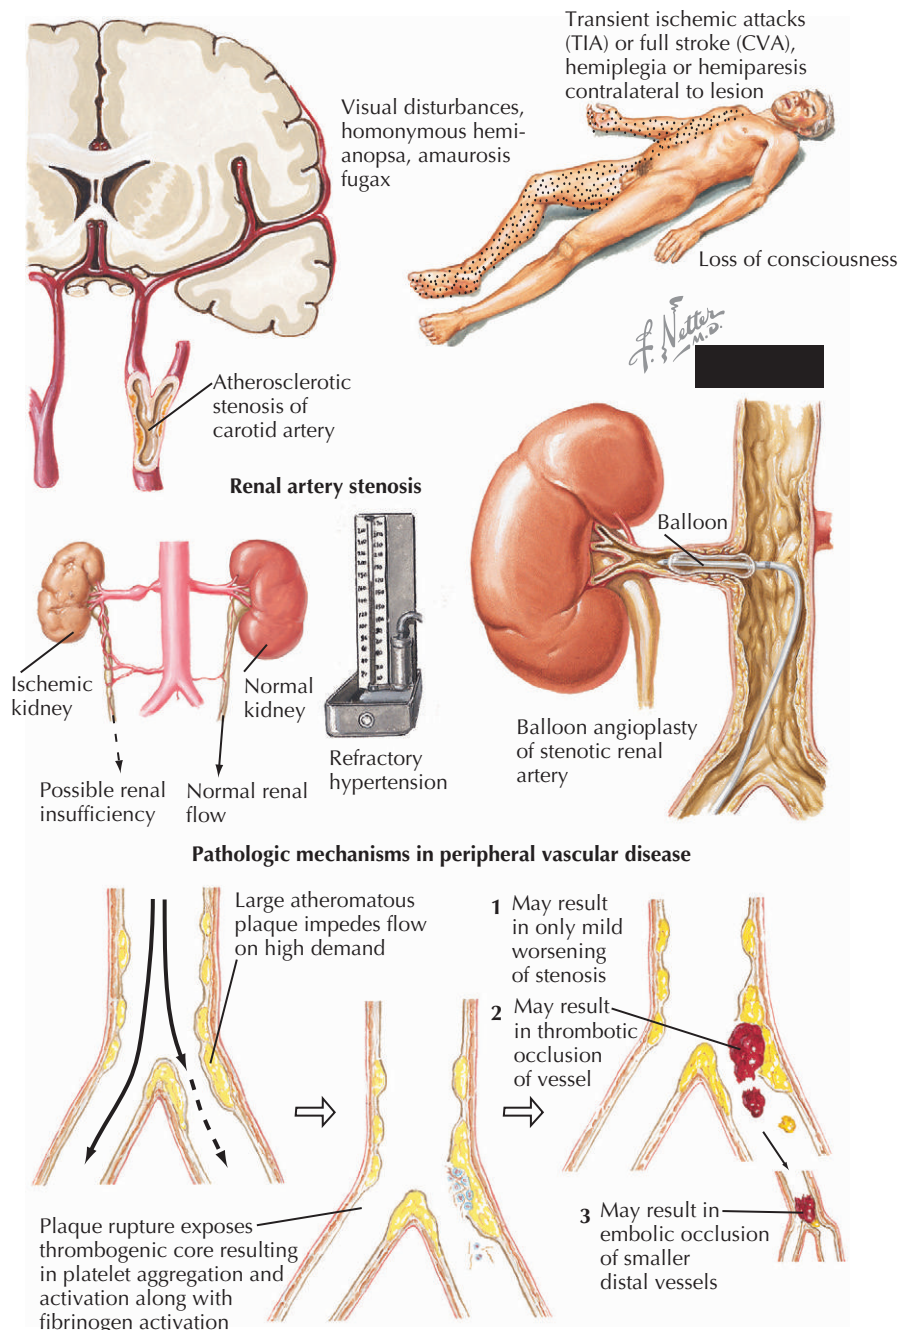

The presence of endothelial dysfunction and fatty streaks (the predecessor of atherosclerotic plaques) is ubiquitous in Western countries, as documented by autopsy studies on young adults dying of other causes. According to current theories, plaques probably expand in increments owing to subclinical episodes of plaque rupture, although plaques likely also undergo gradual enlargement with accretion of cells and noncellular material in the lipid-rich core. Most commonly, the plaque core is surrounded by a complex fibrotic cap composed

of calcium, connective tissue, and smooth muscle cells. Stable symptoms, such as those of claudication, result from an inability to increase blood flow at times of increased demand. Plaque rupture exposes the highly thrombogenic core to circulating blood elements, resulting in platelet activation and aggregation, along with activation of fibrinogen.

As noted, plaque rupture often only worsens an existing lesion without causing arterial occlusion or clinical symptoms. However, more significant episodes of plaque rupture result in worsening limb ischemia with effort, or ischemia at rest. These symptoms result from either thrombotic occlusion of a peripheral artery or embolization of a thrombus with occlusion of small distal arteries. Depending on the location of a thrombotic occlusion, urgent revascularization can be indicated.

The same factors that predispose to coronary atherosclerosis increase the likelihood of PAD. These include male gender, smoking, diabetes, hypertension, and hypercholesterolemia. Of these, the strongest association is between cigarette smoking and PAD.

Figure 31-1 Carotid Artery Stenosis.

Clinical Presentation

PAD produces symptoms of claudication. Derived from the Latin word *claudatiko*, “to limp,” claudication describes pain in the lower extremities produced by inadequate blood flow during exercise. Claudication occurs when there is a reduction in arterial lumen that prevents a sufficient increase in blood flow when tissue oxygen demands increase with exercise. In these cases, exercise-induced local vasodilation is frequently also impaired. This combi-

nation results in local ischemia and production of lactic acid and other metabolites that are responsible for the pain associated with claudication.

Claudication is manifested by cramping pain in the lower extremities or buttocks that is reliably produced by a threshold level of exercise. This pain is relieved by a few minutes of rest. Elevation of the limb can worsen claudication, whereas holding the limb in a dependent position may help. Symptoms may be unilateral or bilateral, depending on the extent and location of atherosclerotic disease.

Calf claudication most commonly occurs because of femoral artery stenoses, whereas foot involvement suggests popliteal or proximal tibioperoneal arterial disease. Thigh and buttock pain are indicative of aortoiliac involvement. As PAD worsens in severity, claudication may occur at night and at rest.

In community cohort studies, ambulatory patients with PAD most commonly reported exertional leg pain atypical for claudication, no symptoms, or intermittent claudication, in that order. Classic claudication occurs in less than one third of patients with PAD. Some patients may experience only mild leg discomfort with exercise and not communicate this to their physician, misinterpreting these symptoms as a normal consequence of aging. Because even asymptomatic patients with PAD still incur a higher relative risk for adverse cardiovascular events, it is important to maintain a high index of suspicion for atypical symptoms of claudication.

Critical limb ischemia is a rare, but potentially fatal, complication of PAD. It is manifested by pain, typically described as a burning pain in the foot that occurs at rest. The pain worsens when the foot is elevated and is relieved when the feet are in a dependent position. In addition to pain, limb ischemia is manifested by nonhealing wounds or tissue necrosis. The development of critical limb ischemia usually requires multiple sites of severe obstruction in the arteries of the lower extremity.

The most useful findings on physical examination in patients with PAD are the presence of arterial bruits and decreased pulses in the lower extremity. In patients with symptoms at rest, additional findings may include cool skin, pallor, dependent rubor, atrophic skin and nails, delayed capillary refill, and ischemic ulcers. Ischemic ulcers tend to be painful and usually occur at the lateral malleolus, tips of the toes, metatarsal heads, or bunion area. In contrast, venous stasis ulcers are usually painless and occur on the medial malleolus. Ulcers, poor wound healing, and frank gangrene can develop with chronic critical ischemia (Fig. 31-2). The absence of any bruits (iliac, femoral, or popliteal) or pulse abnormalities reduces the likelihood of significant PAD.

Loss of femoral and all distal pulses bilaterally, referred to as Leriche's syndrome, is caused by occlusion at the aortoiliac bifurcation.

Differential Diagnosis

Distinguishing true claudication from its mimic, pseudo-claudication (a symptom of spinal stenosis), by clinical symptoms is very important because the diagnostic approach and treatment for the two entities are completely different. In distinction from the symptoms of claudication, pseudo-claudication is characteristically less reproducible based on a specific effort level. Rather than being relieved by cessation of exercise, pseudo-claudication typically is only relieved with sitting or other lumbar flexion

Box 31-1 Differential Diagnosis of Claudication

- Osteoarthritis

- Vasculitis (e.g., thromboangiitis obliterans, Takayasu's disease)
- Lymphangitis
- Phlebotic syndrome after deep venous thrombosis

maneuvers that increase spinal canal volume (spinal stenosis is discussed in more detail in Section XV, "Disorders of the Immune System, Connective Tissue, and Joints"). One useful way to differentiate claudication from pseudo-claudication is to ask the patient what happens when he or she stands still after walking—the discomfort of pseudo-claudication will remain constant (improving only with a change of position such as sitting), whereas the discomfort of claudication will improve.

Alternative diagnoses should be actively sought in patients younger than 50 years and without predisposing risk factors. The extensive differential diagnosis is shown in Box 31-1.

Diagnostic Approach

A careful history and physical exam are essential for the correct diagnosis of PAD and should include a thorough elicitation of symptoms (Fig. 31-3). When PAD is suspected, an ankle-brachial index (ABI) should be measured. This is done by recording the systolic blood pressure by Doppler ultrasound in the brachial artery and comparing it with the pressure in the dorsalis pedis and posterior tibial arteries (Fig. 31-4). The ratio of the highest measurement of the lower extremity divided by arm pressure for each side of the body is calculated. An ABI ≤ 0.90 has a sensitivity of 95% and a specificity near 100% for identifying PAD. An ABI ≤ 0.70 is indicative of moderate PAD, with an ABI ≤ 0.40 consistent with severe PAD. Extremities that are ischemic at rest are generally associated with an ABI ≤ 0.20 .

Sensitivity may be increased by measuring the ABI following exercise treadmill testing. Elderly patients and those with diabetes or renal insufficiency may have significant vessel calcification resulting in an artifactually elevated

ABI > 1.3. These patients are better evaluated with toe-brachial pressure index measurements. Arterial Doppler ultrasound studies and plethysmography are noninvasive modalities that are often useful in diagnosing PAD.

Contrast angiography remains the gold standard for complete assessment and definition of the arterial vasculature (see Fig. 31-4). Angiography is necessary if revascularization is being considered, but not essential for clinical diagnosis. The severity of symptoms or objective evidence of effort-related or rest ischemia and the goal of pursuing revascularization should be considered before proceeding with percutaneous or surgical revascularization. Because of

the risks, however small, of arterial injury and contrast-induced nephrotoxicity, angiography should only be considered if revascularization is a viable option.

Computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) have been touted as alternatives to angiography. A recent meta-analysis showed high accuracy in assessing lower extremity arterial disease, particularly with three-dimensional gadolinium-enhanced images. Although neither CTA nor MRA has supplanted traditional arteriography in the preoperative mapping of vessels, these promising tools merit further study (see Fig. 31-4).

Figure 31-3 Evaluation of Suspected Peripheral Arterial Disease.

Management and Therapy

Exercise programs, smoking reduction, medical therapy, and reduction of cardiovascular risk factors are the cornerstones of treatment of PAD. Revascularization is indicated for rest ischemia or in cases of effort-induced ischemia that are refractory to maximal medical therapy.

Medical Management

Smoking is strongly related to the progression of atherosclerosis and is associated with a higher risk for amputation. Tobacco use is also linked to increased cardiovascular death and events. Smoking cessation programs and, if necessary, treatment with nicotine replacement or other medical approaches should be strongly considered.

Diabetes is a major cardiovascular risk factor and important in patients with PAD because diabetes is associated with a uniformly worse prognosis. Although large prospective trials have not shown a direct effect on PAD with intensive glycemic control in diabetes, given the benefit in reducing microvascular complications, a goal HbA1C (hemoglobin A1C) of less than 7% is warranted. Tight glycemic control may delay the development of peripheral neuropathy, which can complicate the treatment of PAD.

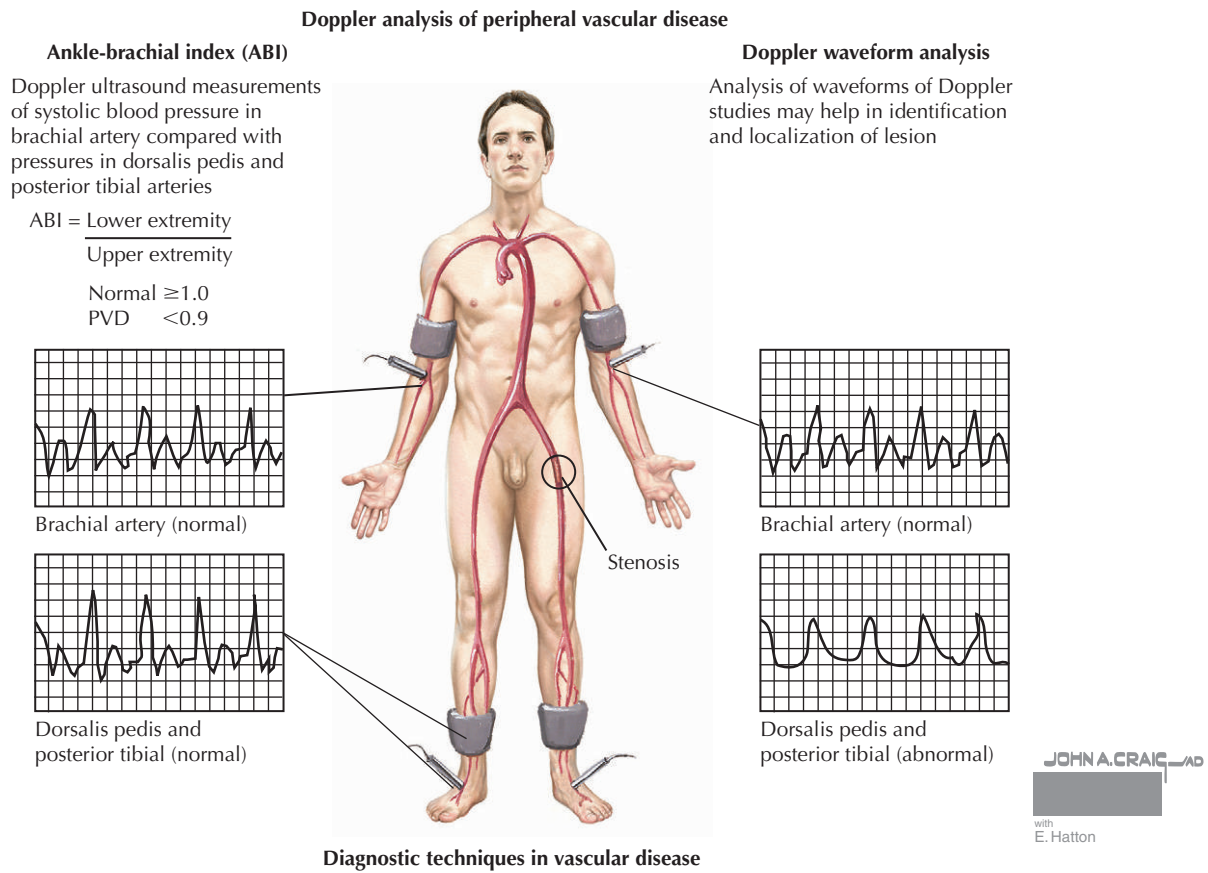

Hypertension is closely linked to development of atherosclerosis. Although lowering of blood pressure has not been clearly shown to reduce claudication, the mortality

benefit in cardiovascular disease is clear. The recommendations of the sixth Joint National Committee on Hypertension outline a goal blood pressure of less than 130/85 mm Hg for most patients with PAD. Angiotensin-converting enzyme inhibitors should be considered first-line agents, along with diuretics and β -blockers. In recent years, the proposed detrimental effect of β -blockers on claudication has been shown to rarely present a problem.

Hypercholesterolemia is a key component of atherogenesis. Lipid-lowering therapy with hydroxymethyl glutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins) has been shown to improve claudication, induce stabilization of atherosclerotic lesions, and provide effective secondary prevention of cardiovascular events. Recent studies indicate that statin therapy not only reduces cardiac events but also reduces the risk for stroke and death from stroke. Early reports suggest that statins will improve outcomes in patients with PAD.

Antiplatelet agents are recommended in PAD. Treatment with aspirin (81 to 325 mg daily) reduces death and disability from stroke and myocardial infarction. The combination of aspirin and dipyridamole is not clearly better than aspirin alone. Ticlopidine is effective for reducing claudication severity and adverse cardiovascular events, but its use has declined because of its association with thrombotic thrombocytopenic purpura. Clopidogrel is slightly superior to aspirin in reducing ischemic complications related to vascular disease, but the absolute risk reduction

Constrast angiography

Contrast angiography demonstrating stenosis of the proximal left common iliac artery

is small, and the cost-effectiveness of clopidogrel versus aspirin is uncertain. In patients who cannot tolerate aspirin, clopidogrel is an effective alternative.

In intermittent claudication, exercise significantly improves maximal walking time, time until the appearance of claudication, and overall walking ability. The benefits of exercise appear to occur exclusive of a significant improvement in blood flow. With training, skeletal muscle

oxidative capacity increases, and exercise-related inflammation decreases. Exercise also improves overall cardio-respiratory efficiency, reduces insulin resistance, and has a beneficial effect on lipids. This leads to increased functional capacity as measured by improved walking distance and quality of life. The optimal exercise program for patients with PAD involves walking to near-maximal pain several times per week. An exercise program should be

continued for at least 3 months before efficacy is assessed.

Anticlaudicatory agents can also be used to improve symptoms. Two drugs are approved for claudication: pentoxifylline and cilostazol. Trials of pentoxifylline have shown mixed results, and presently pentoxifylline is not routinely recommended. Cilostazol, an inhibitor of phosphodiesterase type 3, has demonstrated benefits in symptom relief, exercise capacity, and quality of life compared with placebo and pentoxifylline. The clinical benefits are modest relative to its cost, and cilostazol should probably be reserved for patients with disabling symptoms who are not candidates for revascularization. Cilostazol is contraindicated in congestive heart failure. Gingko biloba may have some small benefit. Vasodilators, chelation, vitamin E, testosterone, and estrogen have not shown any effect and are not currently indicated.

Revascularization

Revascularization should be considered for patients who have symptoms refractory to comprehensive medical management or in individuals who cannot tolerate medical therapy because of medication side effects. Two approaches are used: percutaneous intervention and surgical bypass. The choice depends on the length of the obstruction and location of the diseased arterial segment. Regardless of the technique chosen, early referral to an experienced interventional radiologist, interventional cardiologist, or a vascular surgeon is prudent.

Percutaneous Angioplasty

Percutaneous angioplasty (with or without endovascular stent placement) of the stenoses in diseased vessels has become more common in recent years as an alternative to traditional surgical bypass. Endovascular intervention is the treatment of choice for focal stenoses less than 3 cm long. Stenoses 3 to 5 cm long are also often amenable to percutaneous approaches (Fig. 31-5).

Percutaneous revascularization for PAD remains controversial in several areas. First, the comparison of percutaneous and surgical revascularization is understudied. Second, the use of stents has revolutionized coronary revascularization and will likely also improve percutaneous revascularization for PAD, although few studies have directly compared balloon angioplasty and stenting. Third, as for percutaneous revascularization in the coronary vasculature, technical improvements have greatly improved outcomes and safety. Finally, patient preference plays a large role. The lack of clear consensus on optimum therapy and individual variation in symptoms means various patients may opt for different therapies despite angiographically similar disease.

These factors, along with more rapid recovery than from surgery, have led to a dramatic increase in the use of percutaneous approaches. Until prospective, randomized

studies are conducted, there will undoubtedly be considerable variation in practice for treating individuals with limiting symptoms from PAD.

Surgical Therapy

Surgical bypass of the atherosclerotic vessel should be considered for carefully selected patients. Because operative mortality rates range from 1% to 3%, the benefits of surgery must be carefully weighed against the risk involved. Ideally, candidates should be younger than 70 years, nondiabetic, and have little distal arterial involvement. Bypass is the intervention of choice for multifocal stenoses and segments more than 5 cm in length. Aortofemoral bypass for iliac disease results in more than 90% patency at 5 years. Infringuinal procedures such as femoral-popliteal bypass share high long-term patency rates. Localized stenosis may be corrected by endarterectomy. Patients with PAD necessitating surgery often have coexisting coronary artery disease and must be screened appropriately before surgery.

Optimum Treatment

In patients with stable symptoms of PAD, optimal treatment includes:

- Smoking cessation
- Exercise program
- Blood pressure control
- Diabetes management
- Cholesterol management with HMG-CoA reductase inhibitors
- Antiplatelet therapy
- Revascularization if lifestyle-limiting symptoms persist despite optimal medical therapy

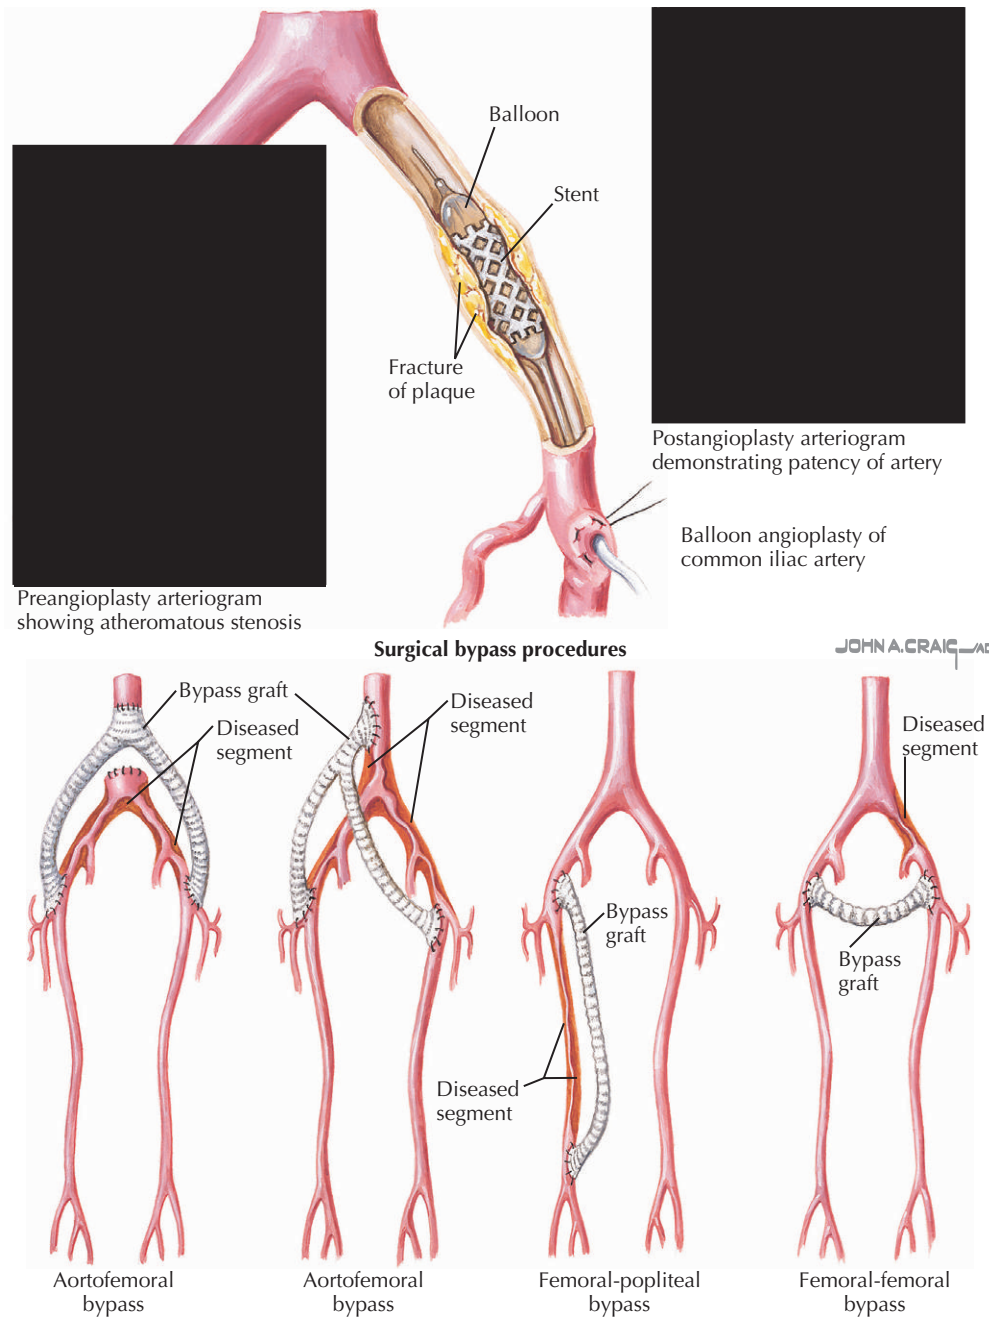

Avoiding Treatment Errors

There are several potential treatment errors to be avoided. Claudication is occasionally confused with pseudoclaudication. As noted previously, pseudoclaudication is characterized by pain and discomfort in the buttocks, legs, and feet and is positional (whereas claudication occurs with exertion). Another potential treatment error is failing to prescribe cholesterol-lowering therapy in patients with PAD. Most patients with PAD will die of myocardial infarction, and thus cholesterol-lowering therapy has the potential to improve survival as well as improve symptoms.

Future Directions

Many new medications are under investigation. Levocarnitine, prostaglandins, naftidrofuryl, defibrotide, and angiogenic factors may someday be added to the armamentarium for treatment of claudication. Advances in the

Figure 31-5 Percutaneous Peripheral Angioplasty, Surgical Bypass Procedures.

prevention and treatment of cardiovascular events will improve the prognosis of the patient with PAD. A growing body of experience with endovascular stenting may help clarify its role in therapy. Drug-eluting stents, laser recanalization, endoluminal radiation, and photoangioplasty are promising experimental modalities that may improve endovascular outcomes if proven in clinical trials. Because of these advances, individuals with symptomatic PAD will likely fare better in the coming years.

Congenital and Valvular Heart Disease

Introduction

Most patients with congenital or valvular heart disease come to medical attention when a routine examination detects cardiac abnormalities. Clinical presentation with symptoms of heart failure, an important arrhythmia, or infective endocarditis is less common. Although congenital heart disease is usually discovered in childhood, the diagnosis of atrial septal defect and minimally symptomatic, noncyanotic defects can, at times, be made for the first time in adulthood.

With the declining incidence of rheumatic fever in recent years, the most common etiologies for acquired valvular disease are now inherited conditions or age-related degenerative change. Most adult physicians will care for patients with valvular heart disease either before or after surgical repair, and this chapter focuses on these patients. Although patients with congenital heart disease should be referred to a specialist in this area, the increasing number of patients reaching adulthood with surgically corrected defects means that most adult physicians will also be exposed to this group of patients as well.

To accurately define structural disease and quantify hemodynamic abnormalities, the diagnostic approach must include transthoracic echocardiography, appropriately focused according to clinical findings, in addition to standard chest radiography and electrocardiography. Transesophageal echocardiography and cardiac catheterization may be necessary in difficult cases. This evaluation is important not only for consideration in treatment but also for important life choices. Participation in competitive athletics should be restricted in many conditions, and some patients require special consideration in the workplace. Family planning and management of pregnancy require a multidisciplinary approach.

One of the most common considerations in patients with valvular or congenital heart disease is prevention of infective endocarditis. Guidelines for the prevention of infective endocarditis have recently been revised. These guidelines emphasize maintenance of optimal oral health and hygiene in all patients with congenital and valvular heart disease. Antibiotic prophylaxis is recommended only for individuals at highest risk for adverse outcome from infective endocarditis. This includes those with previous infective endocarditis, those with prosthetic heart valves, and cardiac transplant recipients who develop valvulopathy. Individuals with unrepaired cyanotic congenital heart disease, including palliative shunts and conduits, should be treated. Antibiotic prophylaxis is also indicated for completely repaired congenital heart disease with prosthetic material or device, whether by surgery or catheter intervention, during the first 6 months after the procedure; those with residual defects at the site, or adjacent to the site, of a prosthetic patch or device should be treated indefinitely.

Antibiotic prophylaxis is recommended for all dental procedures that involve manipulation of gingival tissue or the periapical region of the teeth, or perforation of the oral mucosa. Patients undergoing procedures on the respiratory tract or infected skin, skin structures, or musculoskeletal tissue should also be treated. Antibiotic prophylaxis is not recommended, solely to prevent infective endocarditis, for genitourinary or gastrointestinal tract procedures. Those with rheumatic disease require prophylaxis for recurrent streptococcal infection.

AORTIC STENOSIS

Etiology and Pathogenesis

Congenital aortic stenosis most commonly involves a defect in the aortic valve. Congenitally bicuspid aortic valves, present in 1% to 2% of the general population, undergo accelerated degenerative change. In older individuals, age-related calcification and rheumatic disease cause acquired stenosis of normal, trileaflet valves.

Patients' nonvalvular congenital lesions can present with symptoms and examination findings indistinguishable from valvular aortic stenosis. Etiologies include the presence of either a discrete subaortic membrane or supravalvular aortic stenosis. Hypertrophic cardiomyopathy, which is covered elsewhere (see Chapter 33), can also present with symptoms and exam findings similar to those in patients with valvular aortic stenosis.

Aortic stenosis of any cause results in fixed outflow obstruction and left ventricular pressure overload. Compensatory left ventricular hypertrophy increases myocardial oxygen demand, and ischemia can develop, even in the absence of coronary artery disease. Although contractile performance is preserved, hypertrophy causes abnormal myocardial relaxation, decreased chamber compliance, and diastolic left ventricular dysfunction. For this reason, atrial contraction can be critical to diastolic filling and maintenance of cardiac output (Fig. 32-1).

Clinical Presentation

Aortic stenosis causes a midsystolic murmur, loudest in the second right intercostal space and transmitted to the neck. Signs of moderate or severe aortic stenosis include a diminished and slow-rising arterial pulse, a systolic thrill in the second right intercostal space or suprasternal notch, and a sustained apical impulse. An aortic ejection sound is present in most patients with congenital valvular disease. The second heart sound is usually normal, but reversed splitting can occur with severe obstruction.

Important symptoms of moderate or severe aortic stenosis are angina pectoris, syncope, and left heart failure. The prognosis is worst when patients with aortic stenosis present with left heart failure. The onset of atrial fibrillation can cause abrupt hemodynamic deterioration and precipitate symptoms in a previously asymptomatic individual.

Differential Diagnosis

Midsystolic murmurs can be innocent, particularly in childhood and adolescence or in high flow states (pregnancy, anemia, hyperthyroidism). Pathologic causes include any type of obstruction to ventricular outflow and dilation of the aortic root or main pulmonary artery.

Hypertrophic cardiomyopathy causes dynamic left ventricular outflow obstruction. In these patients, the carotid pulse is brisk and bifurcated in contour, and the midsystolic murmur is characteristically loudest at the left sternal edge. Distinguishing between normal and abnormal midsystolic murmurs requires careful attention to the physical examination and, often, confirmation by echocardiography.

Diagnostic Approach

Although careful physical examination and electrocardiography can detect left ventricular hypertrophy in moderate or severe obstruction, precise quantification of aortic stenosis requires echocardiography for anatomic assessment and evaluation of left ventricular wall thickness, chamber size, and contractile performance. Simultaneous Doppler studies should be performed to measure left ventricular outflow velocity, mean transvalvular pressure gradient, and valve area. Invasive assessment in the cardiac catheterization laboratory may be recommended in symptomatic patients when noninvasive tests are inconclusive or there is discrepancy between clinical and echocardiographic findings.

Management and Therapy

Optimum Treatment

In asymptomatic patients, mild aortic stenosis is an indication for annual evaluation, patient education, and in the absence of a change in clinical status or physical examination, repeat echocardiography every 3 to 5 years. Patients with moderate aortic stenosis require annual clinical examination and should undergo noninvasive studies every 1 to 2 years. Those with severe aortic stenosis should be evaluated semiannually to determine whether the patient should undergo valve replacement. Echocardiography should be performed more frequently when signs or symptoms change.

Although patients with aortic stenosis frequently have clinical risk factor profiles and valvular tissue abnormalities in common with atherosclerosis, medical treatment has not been shown to prevent, or delay progression of, aortic stenosis. Nevertheless, risk modification is important to prevent concurrent coronary artery disease. Physical activity need not be limited in asymptomatic patients with mild aortic stenosis. Those with moderate to severe aortic stenosis should avoid competitive sports that involve high dynamic and static muscular demands.

Valve replacement is indicated for patients with symptomatic severe aortic stenosis. Older patients, or any patient with a significant risk for coronary atherosclerosis, should be evaluated by coronary angiography before undergoing surgery for aortic valve replacement. Left

Figure 32-1 Valvular Stenosis and Insufficiency I.

ventricular contractile dysfunction is not a contraindication to surgery in patients with aortic stenosis, and operative results are satisfactory in symptomatic octogenarians. In selected cases, the Ross procedure is an alternative to valve replacement. Aortic balloon valvuloplasty is indicated in many children, but this technique is of limited utility in adults with calcified valves.

Avoiding Treatment Errors

Exercise testing is contraindicated in symptomatic patients with aortic stenosis. Associated systemic arterial hypertension must be treated cautiously because diuretic and vasodilating drugs can unfavorably alter well-compensated hemodynamics. Aortic valve replacement is not indicated

for prevention of sudden death in asymptomatic patients with aortic stenosis.

AORTIC REGURGITATION (INSUFFICIENCY)

Etiology and Pathogenesis

Congenitally malformed leaflets, rheumatic disease, age-related degenerative change, and infective endocarditis cause valvular aortic regurgitation. In long-standing hypertension and aging, aortic regurgitation may occur secondary to aortic root dilation. Connective tissue abnormalities, including Marfan syndrome, are associated with cystic medial necrosis of the aorta. Complications in patients with Marfan syndrome include progressive aortic root dilation, aortic dissection, and aortic regurgitation.

Chronic aortic regurgitation causes compensatory left ventricular dilation and enhanced chamber compliance, resulting in accommodation of increasing end-diastolic volumes without a rise in filling pressure. In the long term, progressive left ventricular dilation ultimately results in left heart failure. Acute aortic regurgitation, most commonly caused by infective endocarditis, aortic dissection, or trauma, does not allow time for left ventricular chamber dilation, and large regurgitant volumes result in rapidly increasing diastolic filling pressure, pulmonary edema, and shock (Fig. 32-2). In patients who are surgical candidates, it is important to consider aortic valve replacement before the development of irreversible left ventricular dilation. Guidelines for making this determination are discussed later.

Clinical Presentation

Most patients have a high-pitched, early diastolic decrescendo murmur at the left sternal edge. If the murmur is loudest at the right sternal border, aortic root disease is usually present.

Moderate or severe aortic regurgitation causes systolic hypertension, a widened pulse pressure, bifid carotid pulse, and displaced apical impulse. There is usually a midsystolic murmur caused by increased left ventricular stroke volume and turbulent flow through the outflow tract. A mid-diastolic (Austin Flint) murmur, mimicking mitral stenosis, is often audible at the mitral area. Symptoms of moderate or severe aortic regurgitation usually reflect left heart failure. Angina pectoris is less commonly a presenting symptom. Clinically silent aortic regurgitation can be detected by Doppler echocardiography.

In acute aortic regurgitation, left ventricular failure develops rapidly, and the physical signs of chronic disease are usually absent. In this circumstance, abnormal findings are limited to a soft first heart sound and short early diastolic murmur.

Differential Diagnosis

In patients with pulmonary hypertension and pulmonic regurgitation, an early diastolic decrescendo (Graham Steell's) murmur that can be difficult to distinguish from aortic regurgitation may be present. Pulmonic regurgitation after complete repair for tetralogy of Fallot causes a relatively low-pitched early diastolic decrescendo murmur.

Diagnostic Approach

Echocardiography is indicated at the time of diagnosis to identify cause, assess valve morphology and aortic root size, provide semiquantitative assessment of severity, and evaluate left ventricular dimension, wall thickness, and contractile performance. Serial measurement of left ventricular chamber size and contractile performance by echocardiography or radionuclide ventriculography is important in the long-term management of patients with chronic (mild to moderate) aortic regurgitation.

Management and Therapy

Optimum Treatment

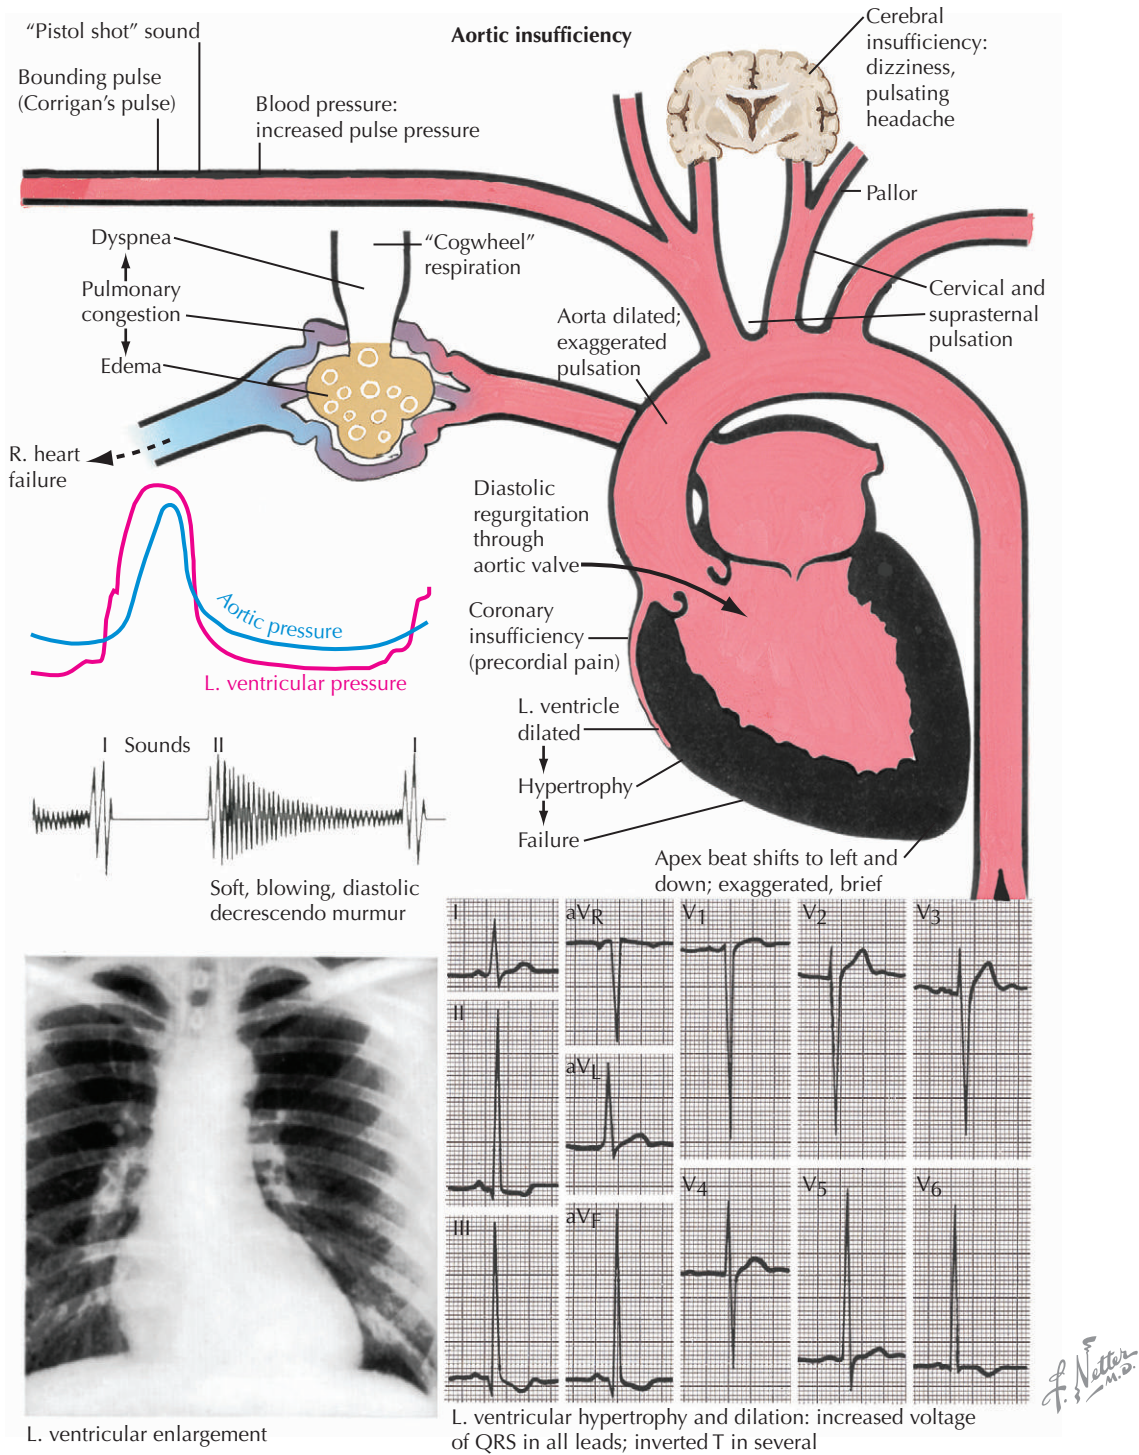

In asymptomatic patients, mild aortic regurgitation calls for annual evaluation and, in the absence of a change in clinical status or physical examination, repeat echocardiography every 2 or 3 years. An interval change in left ventricular dimensions, or contractile performance, is an indication for 3- to 6-month follow-up to differentiate progressive disease from measurement variability. Patients with moderate or severe aortic regurgitation require annual examination and a noninvasive assessment of left ventricular function. For patients with symptoms of left heart failure in addition to moderate or severe aortic regurgitation, aortic valve replacement is indicated. In acute severe aortic regurgitation, urgent surgical intervention is required.

Left ventricular contractile dysfunction can compromise long-term prognosis and operative results. Numerous studies have demonstrated that even in the absence of symptoms, aortic valve replacement is indicated for patients with severe aortic regurgitation and echocardiographically derived left ventricular end-systolic dimension of 55 mm or greater, or left ventricular ejection fraction of 50% or less.

Patients with chronic aortic regurgitation secondary to disease of the aortic root, especially those with Marfan syndrome, require annual echocardiographic evaluation. The timing of surgical intervention in these individuals is usually based on the degree and rate of root dilation (>45 mm) rather than the magnitude of regurgitant flow or left ventricular contractile performance.

Long-term vasodilator therapy is indicated for patients with severe aortic regurgitation who have symptoms of left

Figure 32-2 Valvular Stenosis and Insufficiency II.

ventricular dysfunction when surgery is not recommended because of additional cardiac risk factors or noncardiac factors. Vasodilator therapy should also be considered in asymptomatic patients with severe aortic regurgitation, left ventricular dilation, and normal ejection fraction. β -Blocker therapy is indicated to slow progression of aortic root dilation in patients with Marfan syndrome.

Avoiding Treatment Errors

Vasodilator therapy, in lieu of observation and appropriate referral for surgery, is not indicated for long-term therapy in asymptomatic patients with mild to moderate aortic regurgitation and normal left ventricular ejection fraction, or in those who meet indications and are

candidates for aortic valve replacement as outlined previously.

MITRAL STENOSIS

Etiology and Pathogenesis

Mitral stenosis is most commonly a manifestation of rheumatic heart disease characterized by commissural fusion and degenerative changes in the mitral apparatus. The obstruction in left ventricular inflow results in a compensatory increase in left atrial pressure, which can maintain left ventricular filling. However, over time, this increase in left atrial pressure results in left atrial chamber dilation, pulmonary venous congestion, and secondary pulmonary arterial hypertension. Irreversible pulmonary vascular disease can be a long-term complication of mitral stenosis (Fig. 32-3), although usually, with correction of mitral stenosis, increased pulmonary vascular pressures at least partially resolve.

Clinical Presentation

Abnormal physical findings precede the development of clinical symptoms. The earliest signs are an increase in the amplitude of the first heart sound, an opening snap, and a mid-diastolic murmur at the mitral area. About half of patients with mitral stenosis give a history of acute rheumatic fever. Symptoms of left heart failure commonly develop during pregnancy, with other hemodynamic stresses, with the development of atrial fibrillation, or simply with progression of mitral stenosis over time. The risk for systemic thromboembolism is high in patients with mitral stenosis and either chronic, or paroxysmal, atrial fibrillation.

Differential Diagnosis

Congenital malformations of the mitral valve and papillary muscles, cor triatriatum, and left atrial myxoma all can cause obstruction to left ventricular inflow, mimicking valvular mitral stenosis, even to the point of presenting with a mid-diastolic murmur at the mitral area. Mitral stenosis itself can mimic isolated severe pulmonary hypertension when decreased cardiac output causes the mid-diastolic murmur to be soft or absent in the setting of other physical examination, electrocardiographic, and radiographic evidence of pulmonary hypertension.

Diagnostic Approach

The initial echocardiographic evaluation should include an estimate of mitral valve area and pulmonary arterial systolic pressure. In patients with severe mitral stenosis, a detailed assessment of the mitral apparatus is necessary in considering whether percutaneous balloon mitral valvulo-

plasty or surgical mitral valve replacement should be performed. Critical factors include the degree and extent of degenerative change, the degree of leaflet mobility, the magnitude of associated mitral regurgitation, and the presence or absence of a left atrial thrombus. Cardiac catheterization is indicated when noninvasive tests are inconclusive, discrepant, or discordant with clinical findings.

Management and Therapy

Optimum Treatment

Echocardiography is indicated for changing symptoms or signs. Patients with mild left heart failure have a favorable prognosis and can be successfully managed with dietary sodium restriction and diuretic therapy. β -Blocking drugs can improve diastolic filling of the left ventricle by slowing heart rate at rest and during exercise. Anticoagulation and antiarrhythmic drug therapy is required for patients with atrial fibrillation. Some studies suggest that surgery should be considered with the early onset of symptoms. Carefully selected patients with significantly limiting symptoms are candidates for percutaneous balloon valvuloplasty; for those with severe valvular calcification or significant mitral regurgitation, open commissurotomy or mitral valve replacement is required.

Avoiding Treatment Errors

It is of utmost importance that physicians recognize the high risk for left atrial thrombus formation and thromboembolic complications in patients with mitral stenosis and atrial fibrillation and carefully screen patients for even paroxysmal atrial fibrillation. Percutaneous mitral balloon valvotomy and mitral valve repair, or replacement, are not indicated for patients with mild mitral stenosis. Moderate to severe mitral regurgitation and left atrial thrombus are contraindications to percutaneous mitral balloon valvotomy.

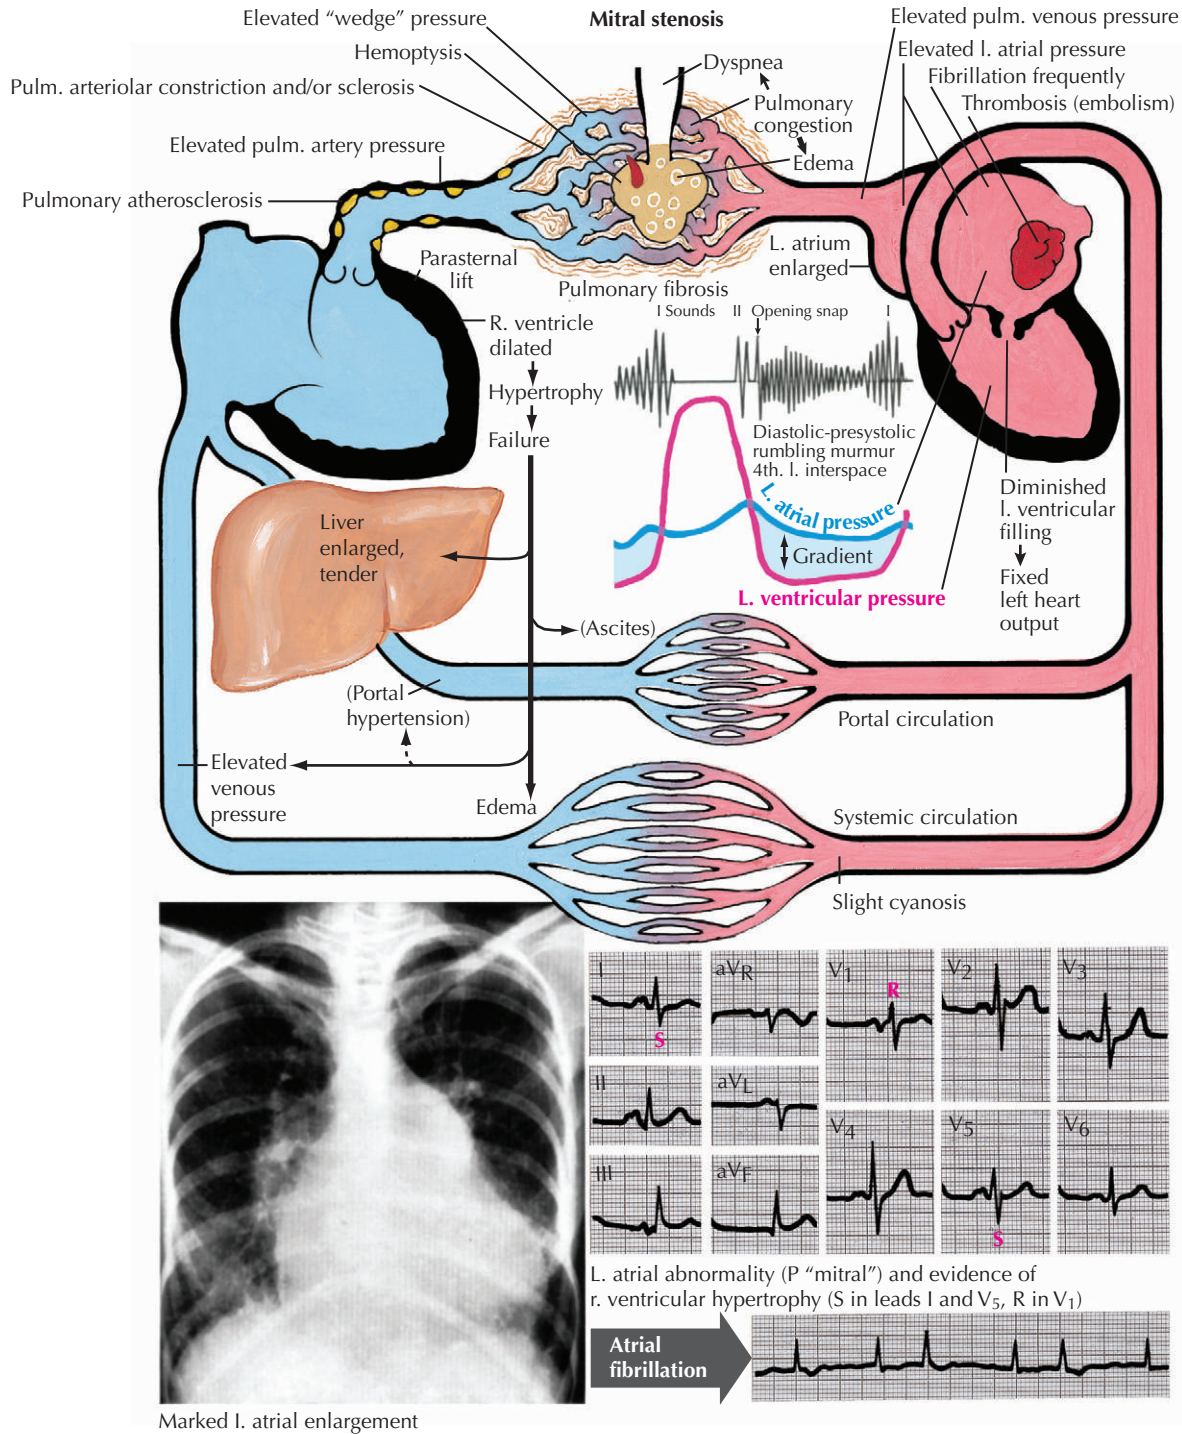

MITRAL REGURGITATION (INSUFFICIENCY)

Etiology and Pathogenesis

Congenital mitral regurgitation is rare as an isolated abnormality. Acquired causes are much more common and include papillary muscle dysfunction secondary to ischemic heart disease, myxomatous disease and prolapse of the mitral valve, rheumatic heart disease, spontaneous rupture of chordae tendineae, and infective endocarditis.

Chronic mitral regurgitation causes left atrial dilation. Because large regurgitant volumes can be accommodated at normal pressure, patients with mild to moderate mitral regurgitation are most often asymptomatic. With moderate or severe mitral regurgitation, progressive left ventricular dilation can occur, leading to increasing limitation of

Figure 32-3 Valvular Stenosis and Insufficiency III.

exercise tolerance. As noted later, it is very important that patients be carefully followed to avoid irreversible decrement in left ventricular function with significant, chronic mitral regurgitation. Acute mitral regurgitation does not allow time for left atrial dilation, and pulmonary venous pressure rises precipitously, causing irreversible pulmonary edema and shock (Fig. 32-4).

Clinical Presentation

The cardiac examination in patients with chronic mitral regurgitation characteristically shows a holosystolic murmur, loudest at the mitral area, and commonly transmitted to the axilla or left sternal edge. Clinically silent mitral regurgitation can be detected by Doppler echocar-

Figure 32-4 Valvular Stenosis and Insufficiency IV.

Electrocardiographic evidence of L. ventricular hypertrophy (large S in V₁, large R in V₄) and minor atrial abnormality (broad P)

F. Netter M.D.

diography. Moderate or severe chronic mitral regurgitation can cause lateral displacement of the apical impulse, wide splitting of S₂, and a third heart sound, S₃. Symptoms are related to left heart failure and atrial, or ventricular, arrhythmia. In acute mitral regurgitation, the systolic murmur is often abbreviated and can be soft or entirely absent.

Differential Diagnosis

The holosystolic murmur of tricuspid regurgitation can be misinterpreted as mitral regurgitation. One means to distinguish the two is that murmur of tricuspid regurgitation characteristically increases in amplitude on inspiration. A

ventricular septal defect causes a holosystolic murmur, loudest at the left sternal border.

Diagnostic Approach

Chronic mitral regurgitation requires a thorough baseline assessment of left ventricular contractile performance by echocardiography, or radionuclide ventriculography for planning initial medical therapy and long-term follow-up.

Management and Therapy

Optimum Treatment

In asymptomatic patients, mild mitral regurgitation calls for annual examination, but repeat echocardiography is not necessary unless there is a change in functional status or physical examination. Those with moderate or severe mitral regurgitation require annual examination and echocardiography or radionuclide ventriculography to assess left ventricular performance. Patients with chronic severe mitral regurgitation can develop subclinical left ventricular contractile dysfunction, which compromises operative results and long-term prognosis. For this reason, even in the absence of symptoms, operative intervention is indicated for those with echocardiographically derived left ventricular end-systolic dimension of 40 mm or greater, or left ventricular ejection fraction of 30% to 60%.

Operative intervention is also indicated for symptomatic patients with acute or chronic severe mitral regurgitation. If the mitral apparatus is suitable, valve repair is the procedure of choice. Mitral valve replacement, with preservation of the chordal apparatus, is the next best option.

Treatment of comorbid conditions, especially systemic hypertension and coronary artery disease, can help to avoid unnecessarily accelerated progression of mitral regurgitation.

Avoiding Treatment Errors

Mitral valve surgery is not indicated for patients with mild or moderate mitral regurgitation. It is reasonable to consider mitral valve repair in asymptomatic patients with chronic severe mitral regurgitation and normal left ventricular function when the likelihood of successful surgery is greater than 90%. However, operation is not indicated when there is doubt regarding the feasibility of valve repair.

FUTURE DIRECTIONS

Because of improved operative outcomes in children and aging of the population, the number of patients with congenital and valvular heart disease will continue to grow. Improved medical management and evolving catheter-based interventions will delay, or replace, the need for

cardiac surgery in some conditions. Evolving, less invasive operative techniques and increased utilization of autologous tissue, homografts, and more durable bioprosthetic valves will enhance surgical outcomes.

Cardiomyopathies

Introduction

Heart failure (HF) results from any of a large number of pathophysiologic processes that directly, or indirectly, result in myocardial dysfunction. Although some causes of HF reflect systemic metabolic (or other) abnormalities, most individuals with HF are also diagnosed with cardiomyopathy. The word cardiomyopathy stems from Greek roots: *kardia* (heart), *mys* (muscle), *pathos* (suffering). Cardiomyopathy broadly describes diseases of the myocardium associated with either systolic or diastolic ventricular dysfunction. Traditionally, cardiomyopathies have been categorized into one of three distinct types: dilated cardiomyopathy (DCM), hypertrophic cardiomyopathy (HCM), and restrictive cardiomyopathy (RCM). As defined by the World Health Organization in 1995, a fourth type of cardiomyopathy is more related to arrhythmias than to HF symptoms, namely, arrhythmogenic right ventricular dysplasia (ARVD) or arrhythmogenic right ventricular cardiomyopathy (ARVC).

A characteristic of all cardiomyopathies is altered cardiomyocyte structure or function of sufficient magnitude to cause clinical symptoms. The most common clinical presentation is heart failure symptoms and signs regardless of the type of cardiomyopathy, except for ARVC, in which the primary clinical manifestation is ventricular arrhythmias. This chapter describes the different types of cardiomyopathy and general treatment options.

Etiology, Pathogenesis, and Clinical Presentation

Dilated Cardiomyopathy

DCM is characterized by dilation and impaired contraction of the ventricle, primarily the left ventricle. This is the most common type of cardiomyopathy. Because of ventricular systolic dysfunction, gradual compensatory responses of the cardiomyocytes lead to cardiac remodeling (Fig. 33-1). Initially, cardiomyocytes respond to hemodynamic stress by becoming hypertrophied. With progressive left ventricular dysfunction and the neurohormonal changes that accompany low cardiac output (see Chapter 34), the poorly functioning ventricle gradually dilates. The increased ventricular size provides short-term relief, a compensatory effect termed the *Starling effect*. However, with progressive dilation, left ventricular function continues to worsen, resulting in DCM.

There are many etiologies for DCM (Box 33-1). The most common is ischemic heart disease (“ischemic cardiomyopathy”): coronary artery disease contributes about two thirds of all cases of heart failure. After a myocardial infarction, the infarct scar may expand to develop into a large area of nonfunctioning myocardium over hours to days;

global remodeling over days to months results in a dilated and globally poorly contractile ventricle (Fig. 33-2).

Other causes of DCM include valvular heart disease (*valvular cardiomyopathy*); infection; cardiotoxins (e.g., alcohol, chemotherapy such as anthracyclines and Herceptin); end-stage hypertension; abnormal metabolic state, such as endocrine abnormalities (e.g., hypothyroidism or thyrotoxicosis, diabetes, acromegaly, adrenal cortical insufficiency, pheochromocytoma), nutritional deficiencies, and infiltrative disease (e.g., copper deposition in Wilson’s disease, iron deposition in hemochromatosis); other infiltrative diseases (e.g., amyloidosis, sarcoidosis, leukemia); autoimmune diseases, such as connective tissue diseases (e.g., scleroderma, systemic lupus erythematosus) and giant cell myocarditis; peripartum state (*peripartum cardiomyopathy*); and familial and genetic diseases (e.g., muscular dystrophies, MELAS (mitochondrial encephalopathy, lactic acidosis, stroke-like) syndrome, and other recently discovered associated chromosomal abnormalities). When no specific cause is found, the DCM is described as *idiopathic cardiomyopathy*. In recent years, it has become increasingly evident that a significant portion (perhaps as high as 30%) of idiopathic DCMs result from a genetic predisposition. A few familial conditions have already been described, such as

Figure 33-1 Cardiac Remodeling Secondary to Volume Overload.

the muscular dystrophies (e.g., Duchenne's, Becker's), X-linked DCM (e.g., other dystrophin gene mutations), and autosomal dominant forms of familial DCM (e.g., lamin A/C gene mutation). It is likely that numerous other genetic predispositions to DCM will be elucidated in the future.

When the cardiomyopathy is thought to have been caused by an infectious agent—because of a viral-like prodrome—most often, no specific pathogen is identified. In this circumstance, the generic term *viral myocarditis* is commonly used. In cases deemed viral myocarditis or viral cardiomyopathy, a diffuse inflammatory response is often observed, with lymphocytes infiltrating the myocardium (Fig. 33-3). Specific pathogens associated with development of DCM include viruses such as Coxsackie B virus, enterovirus, adenovirus, parvovirus, HIV, and cytomegalovirus, and parasites such as trypanosomiasis in Chagas' disease (the most common cause of infectious cardiomyopathy in South America) and Lyme disease. Although no specific bacteria or fungi have been known to cause cardiomyopathy, acute ventricular systolic dysfunction has been seen in the setting of sepsis.

Hypertrophic Cardiomyopathy

HCM is characterized by left or right ventricular hypertrophy. The underlying pathophysiology is hypertrophied cardiomyocytes impairing normal relaxation or compliance of the ventricle, resulting in diastolic dysfunction. Phenotypically, the left (less commonly right) ventricular walls are markedly thickened, but the ventricular chamber size is normal or even small (Fig. 33-4). The electrocardiogram typically shows left ventricular hypertrophy. Ventricular systolic function is preserved and often hyperdynamic. Although HCM usually presents in this manner, over time, a hypertrophied ventricle may progress to the DCM phenotype in end-stage disease because of continued remodeling in the setting of chronic uncontrolled pressure or volume overload.

Unlike DCM, the potential etiologies of ventricular hypertrophy severe enough to produce HCM are few (see Box 33-1). The most common cause for HCM in older populations is severe hypertension (*hypertensive cardiomyopathy*). The ventricular hypertrophy is usually concentric and rarely causes an obstruction of blood flow through left ventricular outflow tract. There are clearly genetic (and possibly environmental) factors that predispose individuals to developing this level of left ventricular hypertrophy in the setting of hypertension because only a small percentage of patients with severe hypertension develop hypertensive HCM.

The second major cause of HCM is any of a rapidly growing number of mutations in genes important in the myocardial sarcomere. With an estimated prevalence of about 0.2% in the adult population, HCM is not rare and is the most common genetic cardiovascular disease. It is usually this cardiomyopathy that has caused unexpected sudden cardiac death in young athletes. Most young patients are asymptomatic and are diagnosed only after a screening electrocardiogram demonstrates abnormal left ventricular hypertrophy.

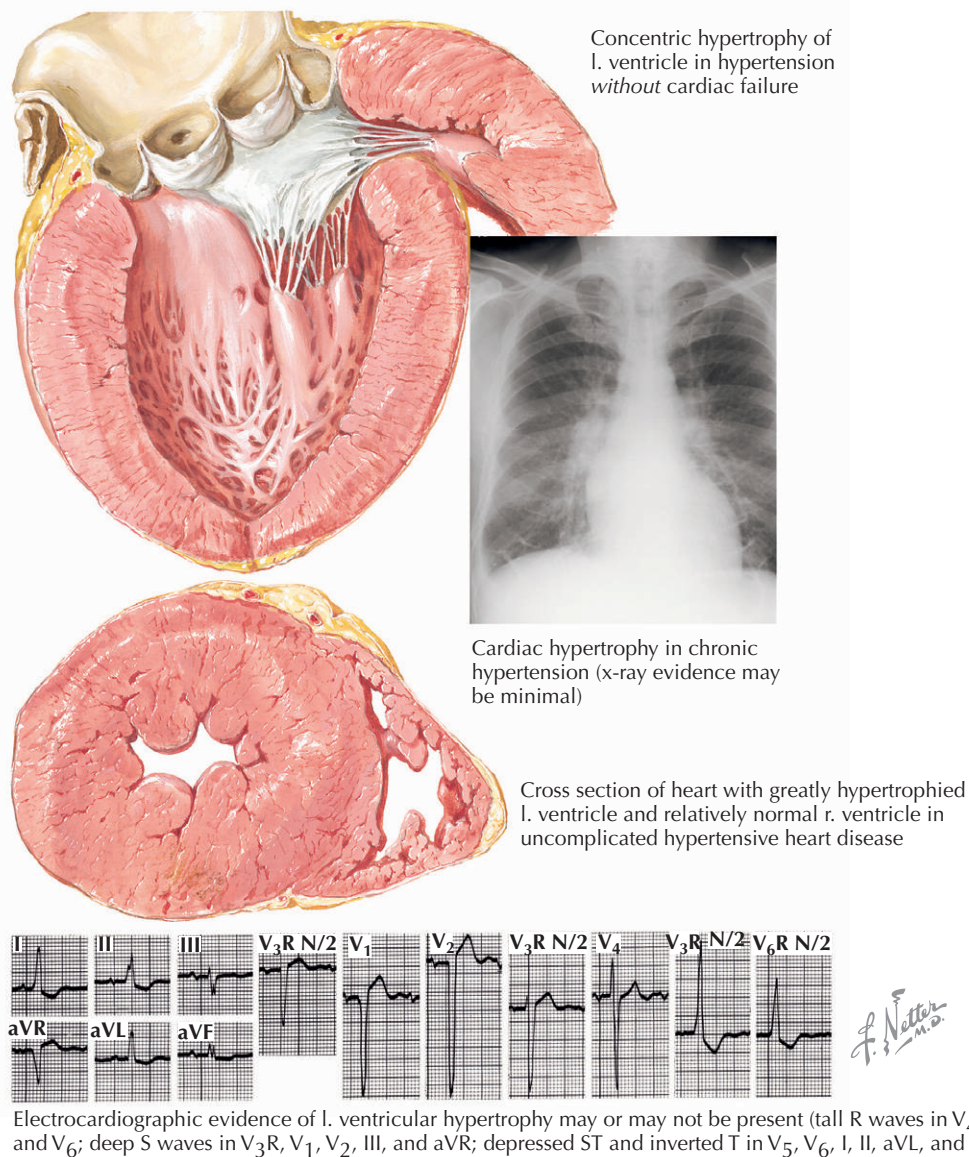

Figure 33-3 Diphtheritic and Viral Myocarditis.

Sarcomere-protein gene mutations account for most cases of genetically based HCM. More than 400 individual mutations have been identified in 11 sarcomere genes, including cardiac β - and α -myosin heavy chains; cardiac troponins T, I, and C; cardiac myosin-binding protein C; α -tropomyosin; actin; the essential and regulatory myosin light chains; and titin. Glycogen storage diseases have also been associated with HCM.

The specific degree and location of hypertrophy varies considerably among the different gene mutations and even within family members who all have a single specific mutation. This observed variation likely relates to other genetic variations and environmental factors yet to be elucidated that affect the precise phenotype that results from mutations associated with hypertrophic cardiomyopathy.

Ventricular hypertrophy may be concentric or eccentric, such as asymmetric septal hypertrophy (ASH) or

apical hypertrophy. When the septal hypertrophy causes systolic anterior motion of the anterior mitral leaflet with subsequent obstruction of the left ventricular outflow tract, a hemodynamically significant left ventricular outflow tract gradient (≥ 50 mm Hg) may be present at rest or provoked (Fig. 33-5). This left ventricular outflow tract obstruction is often a major contributor to symptoms of dyspnea, arrhythmias, and syncope. In this setting, the HCM may be called obstructive HCM, hypertrophic obstructive cardiomyopathy (HOCM), or, as initially described, idiopathic hypertrophic subaortic stenosis (IHSS) or ASH. Common complications are arrhythmias; atrial arrhythmias, most commonly atrial fibrillation, are often poorly tolerated, and ventricular tachycardia is often the cause of sudden death in young patients. However, HCM is predominantly a nonobstructive disease (75% of patients). Occasionally, young patients with HCM also have Wolff-

Figure 33-4 Heart Disease in Hypertension.

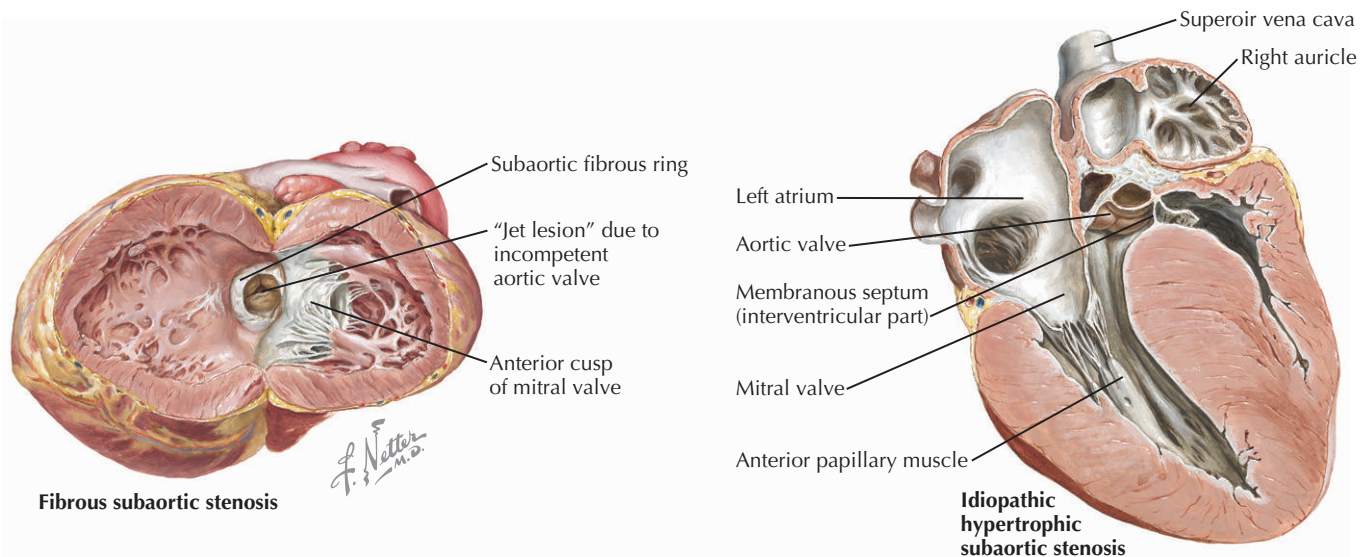

Parkinson-White syndrome. Routine exercise testing is often used for risk stratification.

Restrictive Cardiomyopathy

Similar to HCM, the underlying pathophysiology of RCM is diastolic dysfunction with impaired relaxation (reduced compliance) of the ventricle. Unlike HCM, this diastolic dysfunction is not caused by ventricular hypertrophy. Instead, the intrinsic disease process affecting the myocardium results in a stiff ventricle with a restrictive diastolic filling pattern. Ventricular systolic function is usually preserved or only mildly reduced, ventricular chamber size is normal, and the wall thickness is usually either normal or mildly increased. The phenotypic hallmark of the heart is

often marked biatrial enlargement, in which the atria are disproportionately much larger than the ventricle. Histologic examination varies depending on the primary cause of the RCM. Interstitial fibrosis and myocardial disarray are common findings in all cases. Conduction system disease (e.g., atrioventricular block) may precede the clinical heart failure symptoms from ventricular diastolic dysfunction.

The most common causes of RCM include infiltrative diseases (e.g., amyloidosis and sarcoidosis; Fig. 33-6); non-infiltrative diseases—idiopathic fibrosis of unknown cause or “primary RCM”; and endomyocardial diseases (e.g., endomyocardial fibrosis, radiation fibrosis, anthracycline toxicity) (see Box 33-1). Idiopathic RCM is often associated with a familial or genetic predilection that may have been manifested prior to the diagnosis of RCM (as in

Figure 33-5 Anomalies of the Left Ventricular Outflow Tract.

Noonan's syndrome and various muscular dystrophies). In other circumstances, the only manifestation of the familial nature of the disease is RCM in affected family members.

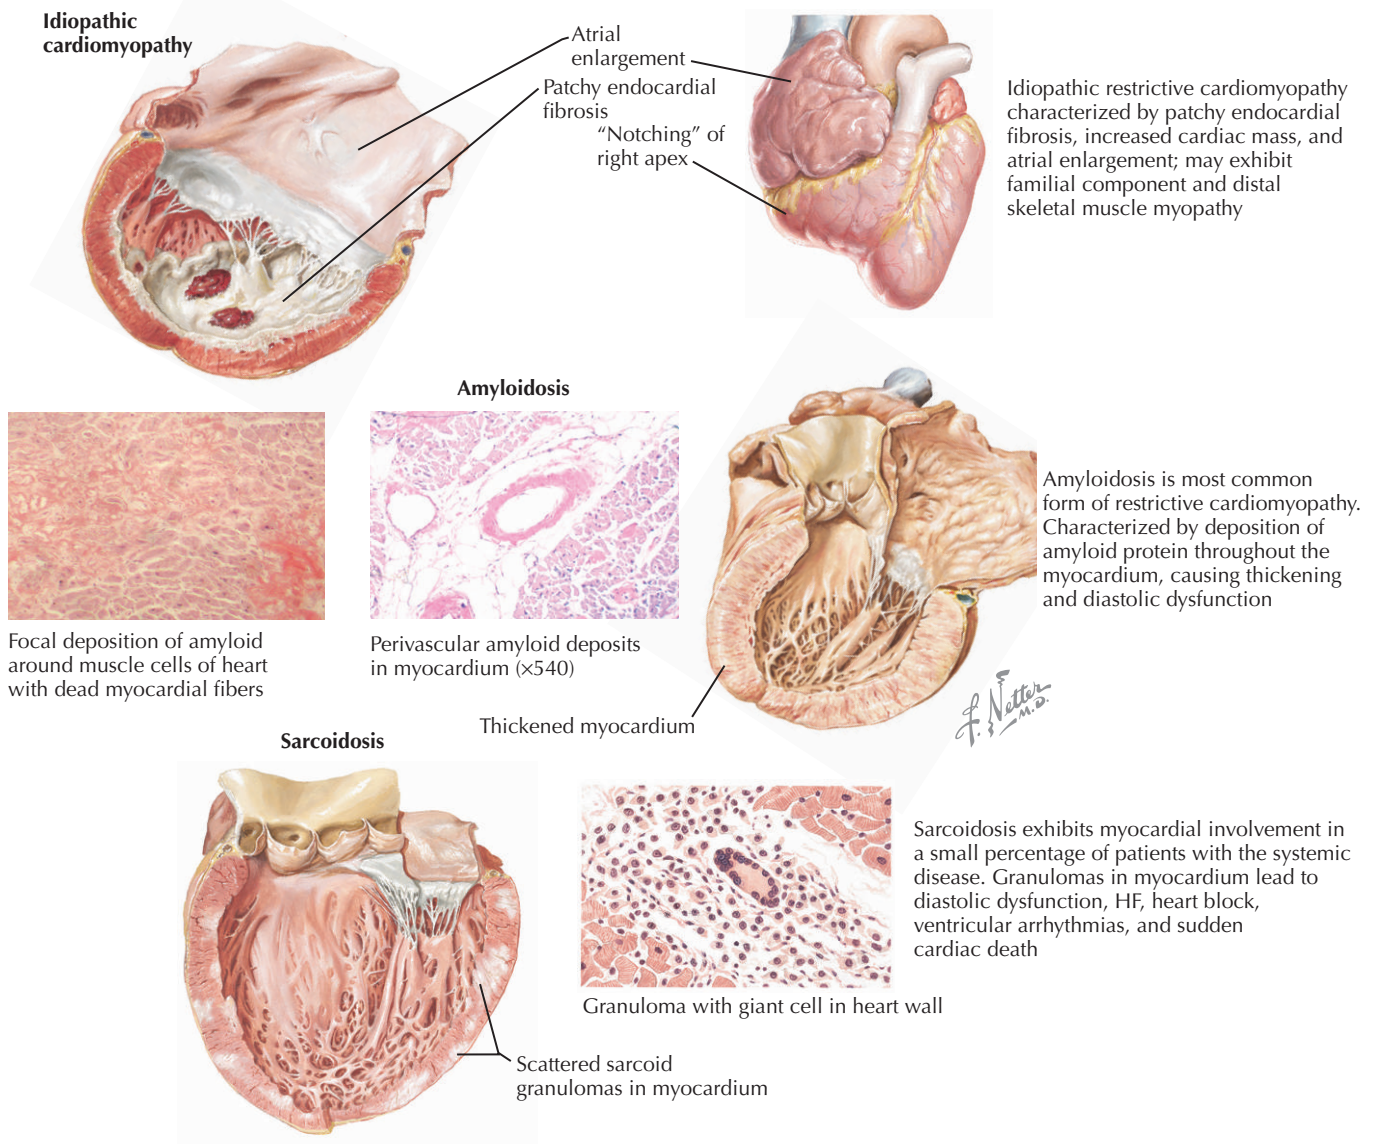

Sarcoidosis and the multiple types of amyloidosis are both systemic diseases. In all cases, although the most common initial presentation is RCM, in later stages of the disease, DCM can develop. Primary amyloidosis (AL, or light-chain-associated amyloidosis) is caused by deposition of amyloid protein that is composed of immunoglobulin light chains produced by a monoclonal population of plasma cells. Secondary amyloidosis (AA, or amyloid-associated amyloidosis) is caused by production of a non-immunoglobulin amyloid protein. Familial amyloidosis is an inherited autosomal dominant trait resulting from a variant prealbumin protein, transthyretin. This is the only type of amyloidosis for which cardiac transplantation has been shown to offer promise. Results have been mixed (some patients have recurrent amyloid heart disease after transplantation). As the genetics of the familial amyloidosis syndromes become better understood, it is likely that the role of cardiac transplantation can be refined.

For RCM, unless the underlying cause is reversible (which is uncommon), this cardiomyopathy often portends the worst prognosis. As this disease progresses to end-stage, ventricular systolic function usually does not worsen significantly, and the clinical heart failure is often considered the most difficult to treat with more limited treatment options than DCM and HCM. It should also be noted that, at times, ascertaining whether an individual has RCM or a constrictive pericardial process can be difficult, requiring multiple, complementary hemodynamic and imaging modalities.

Arrhythmogenic Right Ventricular Cardiomyopathy

ARVD is a genetic disease characterized by morphologic and functional abnormalities of the right ventricle, resulting in ventricular tachycardia. The right ventricle is usually dilated with wall motion abnormalities, but the left ventricle often appears and functions normally. The hallmark feature is progressive fibrofatty replacement of right ventricular myocardium, initially in discrete regions and ultimately globally. Rarely, the left ventricle is involved. Advances in cardiac magnetic resonance imaging have made it possible to detect these morphologic changes at an early stage. On histologic examination, inflammatory lymphocytic infiltrates may also be present.

Unlike the other cardiomyopathies that often present with heart failure symptoms, the clinical manifestation of ARVD is commonly ventricular arrhythmias and occasionally sudden cardiac death, particularly in the young. The risk for sudden death in patients with ARVD is 1% per year. There is a male predominance and a strong genetic component. ARVD is now known as a disease of desmosomal dysfunction, resulting in a disruption of myocyte binding. In evaluating patients with suspected ARVD, the other major condition that needs to be excluded is the more common condition of idiopathic ventricular tachycardia arising from the outflow tract (e.g., right ventricular outflow tract tachycardia), where there is no structural heart abnormality. Treatment is targeted to control the ventricular arrhythmias with either medications or catheter ablation and defibrillator implantation. The only curative therapy is cardiac transplantation, which should be considered on an individual basis.

Figure 33-6 Idiopathic and Infiltrative Causes of Restrictive Cardiomyopathy.

Unclassified Cardiomyopathies

There are scattered cases of cardiomyopathies that do not fit into any of the previously defined classifications. These include fibroelastosis, noncompaction of the left ventricle, and mitochondrial diseases.

Diagnostic Approach

Specific treatment should be directed toward the underlying cause of the cardiomyopathy if identified, especially if that cause can be reversed. Thus, the diagnostic evaluation begins with determination of the characteristics of an individual's cardiomyopathy. Is it global, regional, dilated, or restrictive (or both), and is coronary artery disease present?

(Table 33-1). For example, a thorough family history should be obtained, and obstructive coronary artery disease should be excluded because ischemic heart disease is the most common cause for heart failure. Some specific tests may be useful only for some etiologies of cardiomyopathy; for example, cardiac magnetic resonance imaging may only be useful for myocardial viability (ischemic cardiomyopathy), diffuse patchy defects (sarcoidosis), or fatty infiltration (ARVD). Endomyocardial biopsy is now rarely performed to determine the cause of the cardiomyopathy, but it may be helpful in diagnosing certain conditions that dictate specific therapies, such as giant cell myocarditis or acute fulminant myocarditis, in which immunosuppression could be considered in severe cases, acknowledging the generally unfavorable results from clinical trials.

Table 33-1 Diagnostic Approach for Unexplained Cardiomyopathy*

	Dilated Cardiomyopathy	Hypertrophic Cardiomyopathy	Restrictive Cardiomyopathy	ARVC
History				
Past medical history	Etiology	Etiology (HTN)	Etiology	Etiology
Family history	Familial	Familial	Familial	Familial
Cardiac Assessment				
Physical examination	+S ₃ , ±S ₄ , ±murmur, L- and R-sided HF	±S ₄ , ±murmur, L-sided HF	+S ₃ , ±S ₄ , murmur, R > L-sided HF, Kussmaul's sign	(Nonspecific)
Electrocardiography	Abnormal ST and T wave, old MI	Abnormal ST and T waves, LVH	Low voltage, abnormal ST and T, ±atrial fibrillation	Repolarization and depolarization abnormalities, conduction abnormalities, ±RBBB, PVCs
Echocardiography	Dilated LV; systolic dysfunction ± diastolic dysfunction; valve disease	Small LV size, LVH; diastolic dysfunction; initially normal LVEF, later systolic dysfunction; LVOT gradient	Normal LV size, ±LVH, marked biatrial enlargement; diastolic dysfunction (restrictive filling), normal LVEF; mitral and tricuspid regurgitation	Dilated RV with systolic dysfunction; occasionally dilated LV with systolic dysfunction
Stress test	CAD	CAD if +HTN		Risk stratification
Coronary angiography or (rare) cardiac computed tomographic angiography	CAD	Risk stratification CAD if +HTN LVOT gradient		
Right heart catheterization	↓ Cardiac output, ↑ filling pressures	↑ Filling pressures, normal vs. ↓ cardiac output	↓ Cardiac output, restrictive filling (square root sign), ↑ filling pressures Sarcoidosis	↓ Cardiac output (right-sided)
Cardiac magnetic resonance imaging	Myocardial viability, fibrosis	—		Fibrofatty replacement

Management and Therapy

Dilated Cardiomyopathy

The treatment goals for patients with cardiomyopathy generally reflect therapy for the resulting heart failure symptoms and for reducing the risk for disease progression and sudden cardiac death. Thus, treatment is directed toward management of heart failure symptoms and signs and to reversing the cardiac remodeling where possible. As detailed in Chapter 34 and in the Practice Guidelines from the American College of Cardiology/American Heart Association and the Heart Failure Society of America, standard treatment includes behavioral and lifestyle modifications, such as low-salt diet, fluid restriction, and minimizing coronary risk factors; medications, both oral and intravenous; electrophysiologic devices, such as implantable defibrillators and cardiac resynchronization therapy; and surgical therapies where indicated, such as revascularization, valve surgery, mechanical cardiac support, and cardiac transplantation. The best approach involves optimizing medications to at least target doses as tolerated and appropriate use of the various electrophysiologic device or surgical therapies available. Certain cardiomyopathies require more aggressive use of some therapies (e.g., defibrillators for ischemic cardiomyopathy, some hypertrophic cardiomyopathies, ARVD), and conversely, other therapies are not appropriate in a given type of cardiomyopathy (e.g., inotropes in ARVD, biventricular pacemakers in nondilated cardiomyopathies).

Hypertrophic Cardiomyopathy

Treatment of HCM is directed at regression or at least the prevention of progression of the ventricular hypertrophy and blood pressure control (because elevated blood pressure can promote further hypertrophy) for those with hypertension. Usual medications include β -blockers and calcium channel blockers (verapamil). Disopyramide has been useful in decreasing outflow gradient and improving exercise tolerance and is used occasionally for this indication. Pacemakers were more commonly used in the past in an effort to reverse remodeling, but this approach is now not considered to be efficacious. Arrhythmias are poorly tolerated and potentially even fatal. Defibrillator implantation should be considered in HCM patients at high risk for sudden death. Risk factors for sudden death include prior cardiac arrest, sustained ventricular tachycardia, frequent nonsustained ventricular tachycardia on serial Holter electrocardiographic monitoring, positive family history of premature HCM-related death, history of syncope, abnormal (hypotensive) blood pressure response to exercise, and severely increased left ventricular wall thickness (≥ 30 mm). Symptomatic patients with obstructive HCM should be considered for surgical myectomy of the septum or alcohol septal ablation.

Avoiding Treatment Errors

Avoiding treatment errors in this group of patients necessitates careful monitoring. For example, patients need to be assessed regularly for hyperkalemia, given the efficacy in heart failure of multiple agents that can elevate serum potassium levels (angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and aldosterone blockers). Patients should be assessed regularly for symptoms and signs of hypotension, given the potential for all the above medications and β -blockers to lower blood pressure. Finally, consideration should always be given to timely referral for specific therapies for refractory or stage D heart failure (e.g., ventricular assist device [VAD] or cardiac transplantation before disease is truly end-stage).

Cardiac Transplantation

Considered the only definitive cure for heart failure, more than 73,000 heart transplantation surgeries have been performed in more than 200 hospitals worldwide. In the United States, more than 2000 transplantations are performed per year in about 134 centers. This surgery requires a median sternotomy, cardiopulmonary bypass, recipient cardiectomy, and donor implantation. The most common anastomosis of the donor heart to the recipient cardiac tissues has been either a biatrial technique, in which the donor left and right atria are sutured to the respective remnant atria of the recipient (Fig. 33-7), or a bicaval technique, in which the anastomoses are between donor's and recipient's vena cava and left atria.

Although the first transplantations were performed more than 30 years ago (December, 1967 in South Africa by Dr. Christiaan Barnard, and January, 1968 at Stanford University by Dr. Norman Shumway), rejection and infection in immunosuppressed patients remained major problems and limited the number of operations. In 1983, with the availability of the first calcineurin inhibitor (cyclosporin A), the ability to manage rejection and immunosuppression improved dramatically, and the number of cardiac transplantations again increased. The numbers of transplantations have now reached a plateau (and have even slightly declined) since the mid-1990s (about 4000 per year) because of the limited availability of donor hearts. This limited availability has resulted in the need for stringent selection of patients for consideration of cardiac transplantation.

Current indications for cardiac transplantation are end-stage heart failure or cardiomyopathy, with New York Heart Association class III or IV symptoms, and failure of maximal medical therapy not due to patient noncompliance or inadequate treatment. Contraindications include advanced age; active infection; significant other organ dysfunction (unless cured by combined organ transplantation, e.g., heart-kidney); recent malignancy; excessive obesity; major chronic disabling disease; active mental illness; active or recent substance abuse; noncompliance; lack of social

Figure 33-7 Technique of Orthotopic Biatrial Cardiac Transplantation.

support; and lack of medical insurance. Invasive hemodynamics, including reversibility of secondary pulmonary hypertension, and peak exercise oxygen consumption are objectively measured to assess patient's eligibility and timing for transplantation. Median survival is about 10 years. Common complications and comorbidities include cardiac rejection, infection (opportunistic and nonopportunistic), hypertension, hyperlipidemia, renal dysfunction, diabetes, and coronary allograft vasculopathy. Care of the transplant recipient involves aggressive preventive care based on chronic immunosuppression, prophylactic antimicrobials as needed, timely health maintenance, and management of comorbidities.

Mechanical Cardiac Support

Because cardiac transplantation is not available or appropriate for everyone with end-stage cardiomyopathy, a

number of other treatment modalities have been developed and are available to the end-stage patient. Intravenous inotropes have been used for both palliative care and as a bridge therapy for transplantation. Except for acute exacerbations treated in an intensive care setting, the use of intravenous inotropes is controversial because of their potential to exacerbate cardiac arrhythmias and the limited data supporting outpatient efficacy. Mechanical cardiac support for the failing heart has been available for decades for use as a bridge to transplantation or as a bridge to recovery. The first types of mechanical cardiac support were extracorporeal membrane oxygenators (ECMO) and percutaneous intra-aortic balloon pumps; both are short-term therapies. Surgically placed ventricular assistive devices (VADs) have evolved into sophisticated machines to unload and support the ventricle, many of which are now portable and can be used for at least a few years. Like ECMO and balloon pumps, VADs have served primarily

as a bridge to transplantation or as a bridge to recovery. Since 2002, left ventricular assistive devices are now available for destination therapy for the patient who is not eligible or not interested in heart transplantation. Thus, mechanical support has become an alternative to hospice. As mechanical devices continue to improve, it is possible that some patients who previously would have undergone cardiac transplantation will be considered, instead, for VAD placement. Limited studies have even indicated that left ventricular function can improve after sustained support with a VAD.

Future Directions

As medical technology continues to evolve, we anticipate future tools for both diagnostics and therapeutics for all types of cardiomyopathy. Genetic advances will allow easier diagnosis of otherwise unexplained cardiomyopathy presumed to be familial. Although purely investigational at the current time, treatment with novel drugs, stem cells, and total artificial hearts may provide even more hope to the patient with end-stage disease. Finally, as noted earlier, there will likely continue to be improvement in implantable devices for this group of patients.

Heart Failure

Introduction

Heart failure (HF), the accepted term for a constellation of syndromes previously referred to as congestive heart failure, is caused by cardiac dysfunction. Most commonly, HF results from myocardial muscle dysfunction with accompanying dilation or hypertrophy of the left ventricle (LV) and neurohormonal activation. HF can be divided into two primary types. Systolic HF is the inability of the ventricle to empty normally, with reduced ejection fraction ($EF \leq 40\%$), usually accompanied by ventricular dilation. HF with preserved systolic function (HF-PSF), sometimes referred to as *diastolic HF*, is the inability of the ventricle to relax or fill normally. In HF-PSF, ventricular size and systolic function (as measured by EF) are often normal, but left ventricular end-diastolic pressure is elevated.

HF affects 5 million Americans, with an incidence of 550,000 cases per year, increasing significantly with age. HF is the most common cause of hospitalization for patients 65 years of age and older, and the annual health care cost of patients with HF exceeds \$29 billion. With appropriate therapy, patients with HF can be stabilized and have significant improvement in their symptoms. However, despite therapeutic advances, the mortality rate of patients with HF is about 50% at 5 years. It is likely that more broad use of evidence-based approaches for the treatment of patients with HF will lead to reduction in mortality. More aggressive efforts for risk factor modification, especially for coronary heart disease risk factors, are of importance given that HF following myocardial infarction is common. Recent studies have demonstrated that treating hypertension, vascular disease, or high-risk diabetics significantly reduces the development of HF.

Risk factors for developing HF include a history of hypertension, atherosclerosis, hyperlipidemia, diabetes, valvular disease, obesity, physical inactivity, excessive alcohol intake, exposure to cardiotoxins, family history of cardiomyopathy, sleep-disordered breathing, and smoking.

Etiology and Pathogenesis

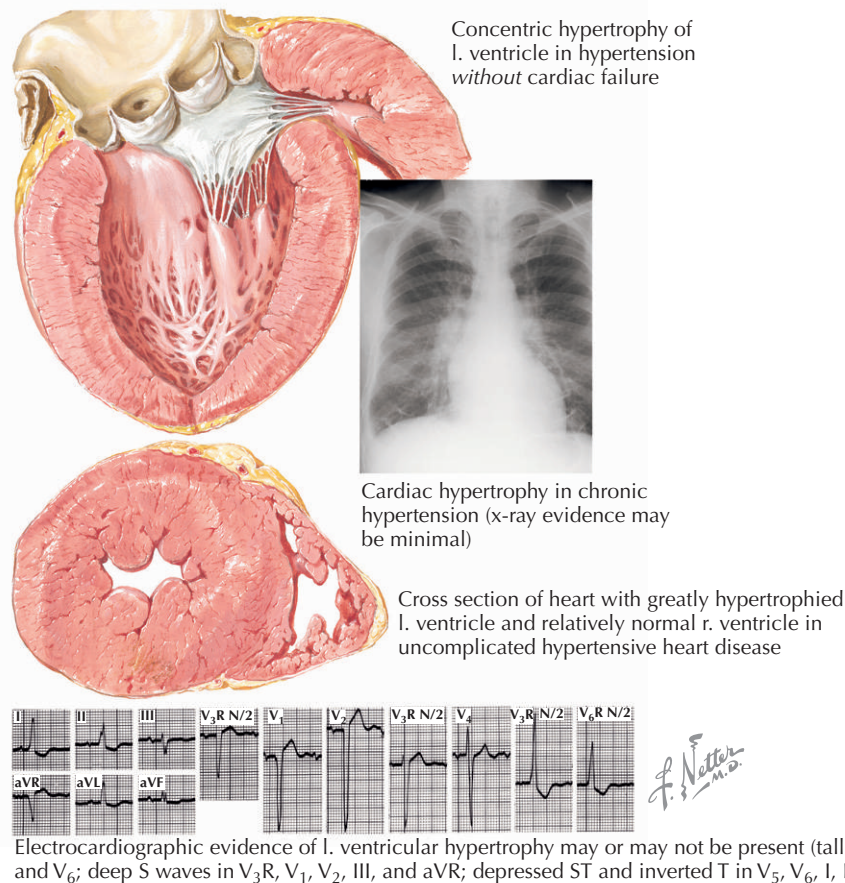

Coronary artery disease (CAD) accounts for 50% of the incidence of HF worldwide. Patients with previous myocardial infarction can exhibit both decreased systolic performance and diastolic impairment due to interstitial fibrosis and scar formation. Hypertension is a common cause of HF, especially in African Americans and older women (Fig. 34-1). A common cause of initially unexplained HF (following exclusion of CAD) is idiopathic cardiomyopathy. Familial cardiomyopathies may account for up to one third of cardiomyopathies thought to be idiopathic. Other etiologies of dilated cardiomyopathy include thyroid disease, chemotherapy (doxorubicin or Herceptin), myocarditis, infection due to HIV, diabetes, alcohol, cocaine, connective tissue disease, peripartum cardiomyopathy, and arrhythmias. Hypertrophic and restric-

tive cardiomyopathies can cause HF, but this is less common. Refer to Chapter 33 for further information on these cardiomyopathies.

Systolic Heart Failure

Systolic dysfunction ($EF \leq 40\%$) results in a reduction in cardiac output that is perceived as “hypovolemia” by the kidneys and triggers activation of the renin-angiotensin system (RAS). With RAS activation, salt and water retention occurs. Initially, this results in increased preload, transiently improving cardiac output. Over longer periods of time, chronic activation of the RAS results in volume overload and symptoms of HF.

Declining blood pressure due to decreased cardiac output also triggers activation of the sympathetic nervous

Figure 34-1 Heart Failure with Preserved Ejection Fraction Due to Hypertension.

system. This, along with RAS activation and increased circulating levels of endothelin and vasopressin, results in systemic vasoconstriction. The short-term benefit of vasoconstriction—increased perfusion of critical organs—is followed by worsening HF due to chronically increased LV afterload that ultimately causes worsening HF. Sympathetic nervous system activation can also precipitate ventricular arrhythmias, a common cause of death in patients with HF.

HF generally follows an injury to the myocardium (due to ischemia, a toxic effect, or an increased volume or pressure load on the LV). LV remodeling, a maladaptive response, follows, with resulting changes in cardiac size, shape, and function (Fig. 34-2). Myocyte length may increase, with a resulting increase in chamber volume, which preserves stroke volume. Myocyte hypertrophy also occurs, along with a loss of myocytes due to apoptosis or necrosis, and fibroblast proliferation and fibrosis. As the heart remodels, it becomes less elliptical and more spherical, hence more dilated. The mitral valve annulus may become dilated, resulting in mitral regurgitation and further increased wall stress.

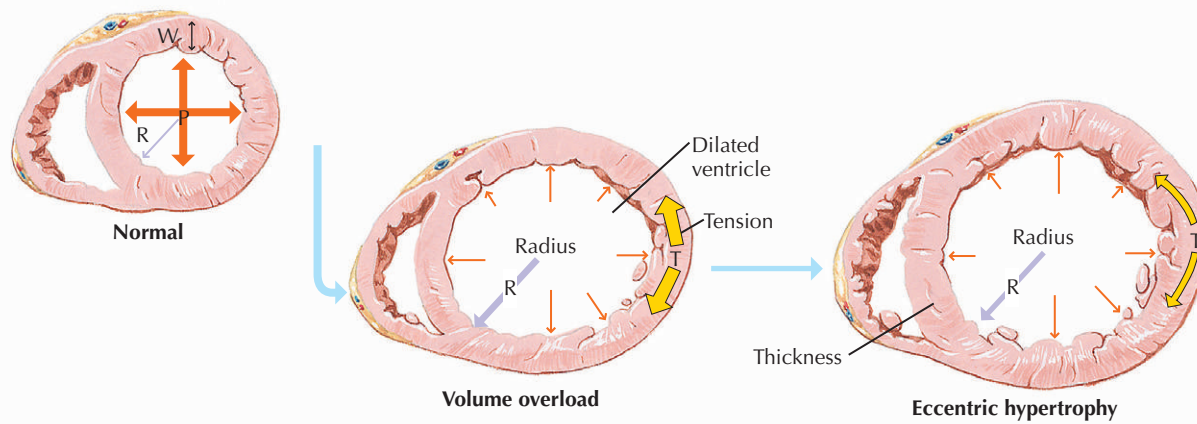

The success of angiotensin-converting enzyme inhibitor (ACE-I), angiotensin II receptor blockers (ARB), β -

blockers, and aldosterone antagonists in reducing mortality in patients with HF almost certainly relates to their ability to interrupt the cycle of LV remodeling and dilation by blocking the neurohormonal activation that occurs early in HF. All have been shown to attenuate and even reverse remodeling.

Heart Failure with Preserved Ejection Fraction

HF-PSF accounts for 40% to 50% or more of HF cases and, until recently, resulted in considerable confusion and debate about treatment. It is now clear that the morbidity and mortality of patients with HF-PSF is similar to that of patients with HF due to systolic dysfunction. HF-PSF affects older patients, especially women. Ischemic heart disease and hypertension are the most common causes of isolated HF-PSF. In the typical patient with HF-PSF, the ventricular size is normal. However, ventricular dilation occurs in mitral and aortic regurgitation as well as in high-output HF caused by anemia or thiamine deficiency.

Restrictive and hypertrophic cardiomyopathies can result in similar clinical presentations (see Chapter 33), as can constrictive pericarditis. Indeed, distinguishing these

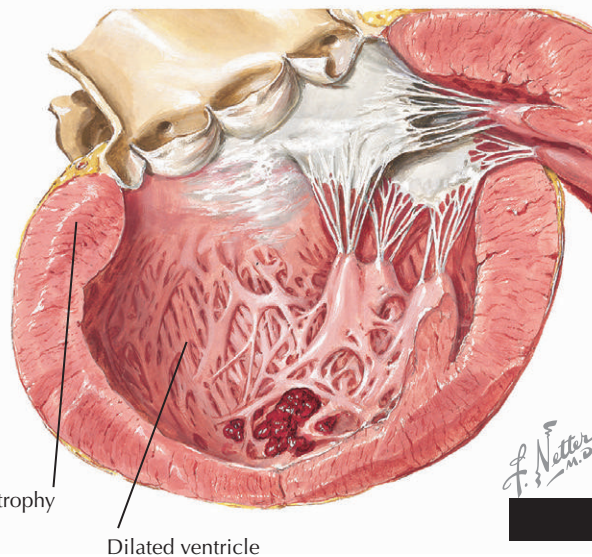

Figure 34-2 Cardiac Remodeling Secondary to Volume Overload.

Elevated pressure (P) or volume causes proportionate increases in wall thickness (W) and chamber radius (R); wall tension (T) increases

LA indicates left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle

entities can be difficult, requiring extensive noninvasive and invasive hemodynamic assessment. The distinction is of importance, however. For instance, in patients with diastolic dysfunction related to the constraining effect of a thickened and rigid pericardium, surgical removal of the pericardium can produce profound relief of symptoms and findings of HF.

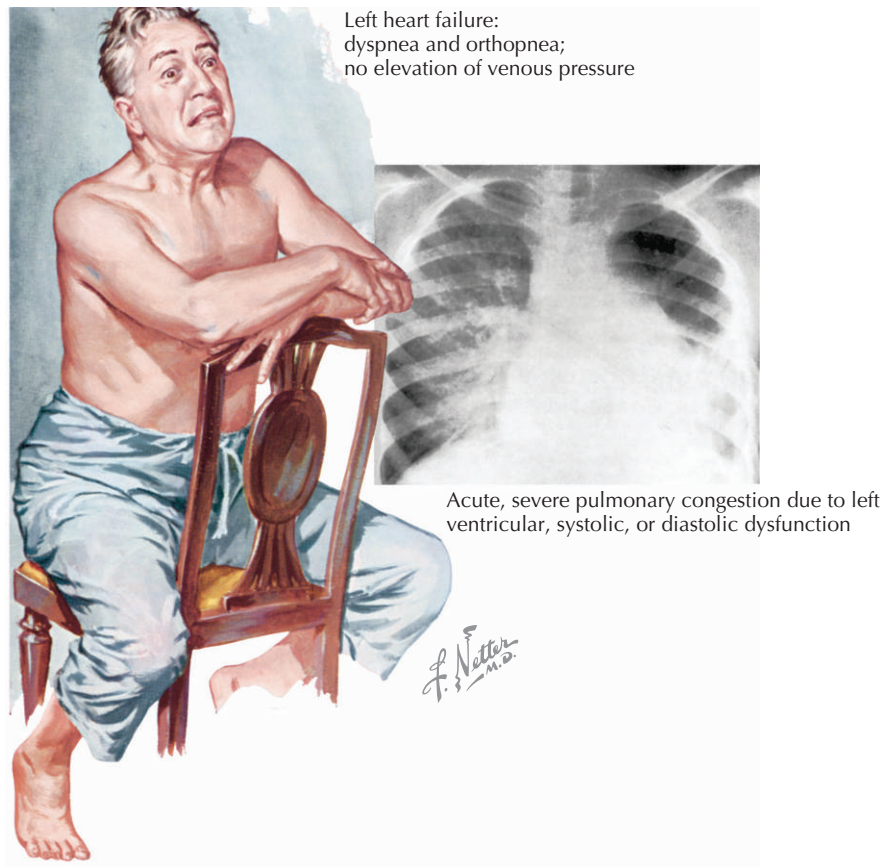

The pathophysiology of HF-PSF has not been entirely elucidated, nor is it precisely the same in all patients. The LV in typical patients with HF-PSF is characterized by hypertrophy, increased extracellular matrix, and abnormal calcium handling. Activation of the RAS and sympathetic nervous system is common in patients with HF-PSF.

Clinical Presentation

The presentation of patients with HF includes signs and symptoms of pulmonary congestion, systemic fluid reten-

tion, exercise intolerance, or inadequate organ perfusion. Symptoms include dyspnea on exertion, exercise intolerance, orthopnea, paroxysmal nocturnal dyspnea, cough, chest pain, weakness, fatigue, nausea, abdominal pain, nocturia, oliguria, confusion, insomnia, depression, and weight loss. Physical examination findings that should be systematically assessed include engorged neck veins, rales, pleural effusion, displaced point of maximal intensity, right ventricular heave, S_3 , S_4 , murmurs, hepatomegaly, low-volume pulses, and peripheral edema.

The clinical presentation may be indistinguishable between patients with HF and HF-PSF (Fig. 34-3). The cardiac silhouette is usually enlarged in both circumstances, with cardiomegaly due to ventricular dilation in HF with systolic dysfunction due to hypertrophy in patients with HF-PSF. Assessment of LV function is essential in designing the appropriate approach to therapy.

Figure 34-3 Left Heart Failure and Pulmonary Congestion.

Differential Diagnosis

The difficulty in arriving at a new diagnosis of HF lies in its vague symptoms and exam mimickers (Box 34-1). Symptoms of dyspnea and exercise intolerance can be attributed to many diagnoses: lung disease (including chronic obstructive lung disease, reactive airways diseases, thromboembolic pulmonary disease, pulmonary hypertension, and others), thyroid disease, arrhythmias, anemia, obesity, deconditioning, and cognitive disorders. Signs of volume overload are not specific to HF. Sodium-avid states of nephrosis and cirrhosis, as well as pericardial disease, can present with similar findings of jugular venous distention, hepatomegaly, and edema.

Diagnostic Approach

The diagnosis is made by taking a careful history, performing a directed exam, and assessing systolic and diastolic ventricular function. Laboratory evaluation and pulmonary function testing will eliminate most noncardiac diagnoses (Box 34-2). Measurement of serum brain natriuretic peptide (BNP >500 pg/mL) or N-terminal prohormone brain natriuretic peptide (pro-BNP >450 pg/mL in individuals <50 years old or ≥900 pg/mL in individuals >50

years old) can be very helpful in the acute setting. These markers correlate with elevated filling pressures and are particularly helpful in the evaluation of patients with dyspnea. Although an elevated level of BNP or pro-BNP does not rule out pulmonary causes of dyspnea, normal levels argue against HF as the predominant cause of dyspnea. Even though levels are generally higher in cases of systolic HF, these tests cannot distinguish between systolic HF and HF-PSF.

Determining the Type and Degree of Left Ventricle Dysfunction

Echocardiography is the most common method for initial assessment of LV function. EF, valve function, hypertrophy, and diastolic function can all be rapidly assessed. Most patients with HF-PSF have impaired LV relaxation with or without reduced LV compliance and preserved EF. The most reproducible and validated method of diagnosing diastolic dysfunction combines echocardiographic two-

dimensional M-mode Doppler measurements of mitral valve inflow with the sensitive, relatively load-independent measure of LV relaxation (e' velocity) obtained by tissue Doppler imaging of the mitral annulus. This approach has resulted in four classifications of diastolic function: normal, mild dysfunction (impaired relaxation, normal filling pressure), moderate dysfunction (impaired relaxation or pseudonormal with moderately elevated filling pressure), and severe dysfunction (restrictive or advanced with reduced compliance) (Fig. 34-4).

Radionuclide ventriculography is often used to determine EF in obese patients and in those with significant chronic obstructive pulmonary disease. Magnetic resonance imaging is a newer imaging modality that provides EF, allows assessment of myocardial viability, and can identify infiltrative disease.

Defining the Etiology of Heart Failure

The degree of reversibility and, hence, the progression and management of HF differ depending on the underlying cause. Many underlying causes of HF are largely reversible. Treatment of uncontrolled hypertension, thyroid disease, and active ischemia may result in significant improvement in LV function. Conversely, patients with prior myocardial infarction and systolic dysfunction; patients who are older, are male, and have a marked reduction in LV function; and patients who have hyponatremia, anemia, renal dysfunction, or New York Heart Association (NYHA) class III or IV disease have a worse prognosis.

Box 34-3 New York Heart Association Classification

Class I: Symptoms at exertion levels similar to normal individuals
 Class II: Symptoms with ordinary exertion
 Class III: Symptoms with less than ordinary activity
 Class IV: Symptoms at rest or with any physical activity

Ischemic heart disease should be excluded in every patient. Focal wall motion abnormalities do not always represent CAD, and conversely, global LV dysfunction does not rule out an ischemic cause. Testing options include cardiac catheterization, exercise or pharmacologic echocardiographic or nuclear stress testing. Patients with left bundle branch block should not be evaluated with stress echocardiography because the conduction delay can result in a false-positive test result. Newer imaging techniques include computed tomographic angiography, which can identify CAD, and cardiac magnetic resonance imaging, which can also provide assessment of viability.

Determining NYHA classification is important for assessing prognosis, medical management, indication for device placement, and for longitudinal follow-up and evaluation of response to therapy (Box 34-3).

Management and Therapy

As a first step, it is important to correct precipitating factors, such as dietary noncompliance, ischemia, uncontrolled hypertension, atrial fibrillation, hypoxemia, thyroid disease, anemia, and the presence and causes of medication nonadherence, including financial disability. An overall approach to management is shown in Figure 34-5.

Revascularization should be considered in ischemic patients. Observational studies suggest that patients with reversible ischemia, even with marked systolic dysfunction, improve with revascularization. The ongoing National Institutes of Health–sponsored Surgical Treatment for Intracerebral Hemorrhage (STICH) trial will provide evidence for the efficacy of revascularization with or without surgical ventricular restoration in patients with CAD and an EF of 35% or less.

Optimum Treatment for Systolic Heart Failure

For systolic HF, blockade of the RAS with ACE-I or ARB therapy is recommended in all patients. Improved survival, decreased frequency of hospitalization, and improved quality of life have been demonstrated in patients with NYHA class I to IV HF and in post–myocardial infarction patients treated with target doses of ACE-Is or ARBs (Table 34-1). Contraindications to ACE-I or ARB therapy

include moderate to severe aortic stenosis, bilateral renal artery stenosis, and hyperkalemia ($K > 5.5$ mEq/dL).

ACE-I therapy can cause intractable cough or, rarely, angioedema. An ARB can generally be substituted for ACE-I therapy, although angioedema has been reported rarely with an ARB. Both agents have an equivalent effect on renal function. In patients with significant renal dysfunction and hyperkalemia ($K > 5.5$ mEq/dL), the combination of isosorbide dinitrate (160 mg daily in four divided doses) and hydralazine (300 mg daily in four divided doses) is an alternative, although not as effective as ACE-I therapy. All patients with CAD should be treated with aspirin (81 to 325 mg/day) unless there is a contraindication.

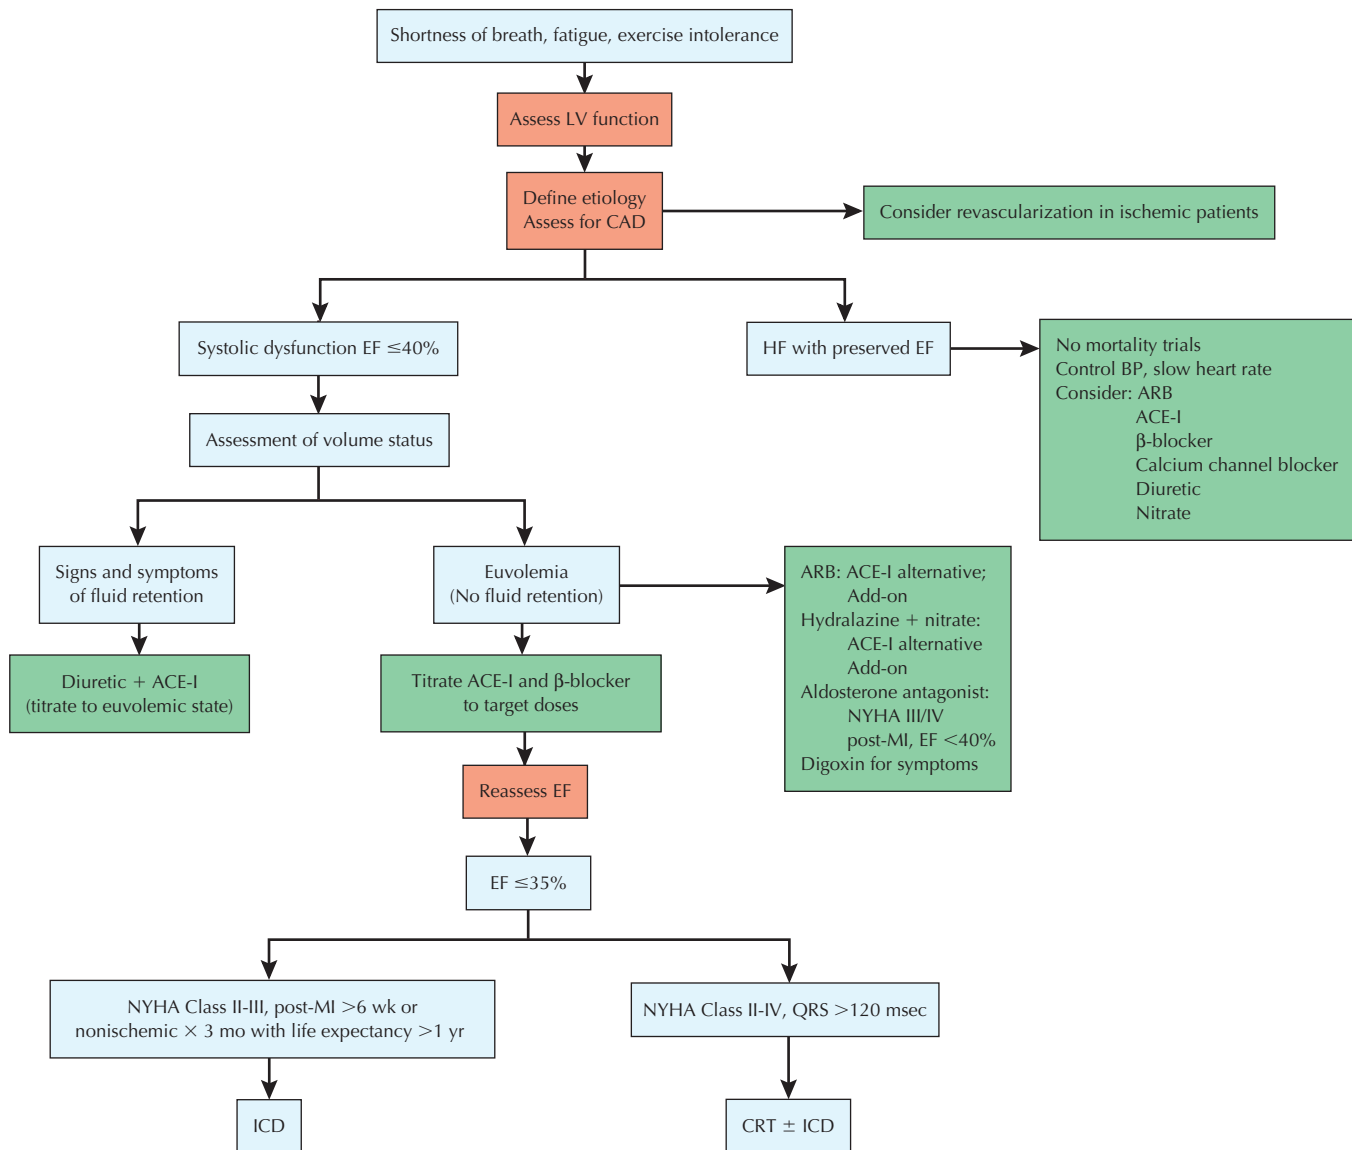

β -blockers should be added to ACE-I therapy in all patients who do not have evidence of fluid overload. Improved survival and EF, reduction in sudden death, and hospitalizations have been demonstrated in patients with NYHA class II to IV symptoms, and in all post–myocardial infarction patients at target doses (see Table 34-1). Contraindications include severe reactive airway disease in patients receiving inhaled daily β -agonists, severe bradycardia, or advanced heart block. β -blockers should be started at a low dose and titrated up every 2 weeks. Most patients require diuretic therapy during β -blocker initiation and up-titration to prevent fluid overload. β -blockers should not be initiated or titrated in patients exhibiting volume overload; these patients should be treated for fluid overload first. Side effects (transient fatigue, weight gain, and diarrhea) are more common with the first few doses. If patients have difficulty tolerating the drug, dose titration can be slowed by increasing the time between titrations or by increasing the dose by a smaller amount. Although target doses should be the goal, lower doses (i.e. carvedilol 6.25 mg twice daily) also confers a mortality and morbidity benefit. Studies indicate that at least 80% of patients tolerate β -blocker therapy. ACE-I and β -blocker up-titration can be alternated, rather than titrating ACE-I to the target dose before adding a β -blocker.

Aldosterone antagonists can be added to therapy in patients with NYHA class III (previously class IV) or IV chronic HF, and in post–myocardial infarction patients with an EF less than 40%. Therapy should only be initiated in patients whose potassium is less than 5 mEq/mL, serum creatinine 2.5 mg/DL or less and creatinine clearance > 30 ml/min. The serum potassium level often increases with treatment, especially in diabetic and older patients, and regular monitoring is necessary. Potassium and creatinine should be reassessed at least 1 week and 1 month after initiation or change in dose.

The combination of isosorbide dinitrate and hydralazine added to standard therapy of ACE-I or ARB and β -blocker therapy has been shown to provide additional mortality and morbidity benefit in African American patients. The target doses from the largest clinical trial were isosorbide dinitrate, 40 mg three times daily, and hydralazine, 75 mg three times daily.

Figure 34-5 Algorithm for Management.

ACE-I, angiotensin-converting enzyme-I; ARB, angiotensin II receptor blockers; BP, blood pressure; CAD, coronary artery disease; CRT, chronic resynchronization therapy (also called a biventricular pacemaker); EF, ejection fraction; HF, heart failure; ICD, implantable defibrillator; LV, left ventricle; MI, myocardial infarction; NYHA, New York Heart Association; QRSI, QRS integral.

Diuretics such as hydrochlorothiazide, furosemide, and bumetanide are prescribed in most patients to alleviate fluid overload. Because they activate the RAS, the minimal effective dose should be used. In patients with severe HF, combination therapy (a loop diuretic and hydrochlorothiazide or metolazone) can be used, but potassium and magnesium levels must be carefully monitored.

Digoxin reduces hospitalization and improves symptoms. However, there is no survival benefit. Higher serum concentration (≥ 1.2 ng/dL) is associated with poor outcome. Therefore, low-dose digoxin, generally 125 μ g daily, is recommended, with a goal concentration of less

than 1 ng/dL. Digoxin doses should be reduced by half and monitored closely if amiodarone or warfarin is initiated.

Nitrates reduce preload and are prescribed as antianginal agents. At higher doses, systemic and pulmonary vasodilation occurs. Nitrate tolerance can be prevented acutely by increasing the dose and chronically by allowing a nitrate-free interval of at least 8 hours. The addition of hydralazine also mitigates nitrate tolerance.

Amlodipine and felodipine are used to treat hypertension and angina unresponsive to ACE-Is and β -blockers. Nifedipine, verapamil, and diltiazem should not be used in

Table 34-1 Drug Therapy for Systolic Heart Failure

	Starting Dose	Target Dose
Angiotensin Converting Enzyme Inhibitors		
Generic		
Enalapril	2.5-5 mg twice a day	10 mg twice a day
Lisinopril	2.5-5 mg once a day	20-40 mg once a day
Captopril*	6.25-12.5 mg three times a day	50 mg three times a day
Nongeneric		
Ramipril	2.5 mg every day to twice a day	5 mg twice a day/10 mg once daily

† Not approved by the U.S. Food and Drug Administration for treatment of heart failure.

patients with systolic HF because of their negative effect on contractility.

Intravenous diuretic therapy should be considered in acute decompensated HF with volume overload. Continuous furosemide infusion can result in a steady diuresis, particularly in patients who are resistant to initial intravenous diuretics. Metolazone, spironolactone, or intravenous chlorthalidone (500 mg twice daily) can be added in refractory cases.

In the absence of symptomatic hypotension, one should consider nitroglycerin, nitroprusside, or nesiritide in patients who are refractory to diuretics. Nitrate therapy is particularly effective in acute myocardial infarction with pulmonary edema. Compared with nitroglycerin, nitroprusside is a more powerful afterload-reducing agent for the same degree of preload reduction. Nesiritide is a vasodilator and natriuretic agent that can be useful in hospitalized patients, particularly those who have been shown to be unresponsive to intravenous diuretics. Because a meta-analysis reported an increase in 30-day mortality in patients who received nesiritide, it is not a first-line agent.

Renal function should be monitored closely because worsening renal function has been reported.

Intravenous inotropes, such as dobutamine or milrinone, may be considered to relieve symptoms in patients with advanced systolic HF and diminished peripheral perfusion, referred to as *low-output syndrome*. Dobutamine is an inotrope with limited vasodilator activity. Milrinone, a phosphodiesterase inhibitor, is both an inotrope and vasodilator and, for this reason, may worsen hypotension in patients with severe HF. Nonetheless, both agents can be helpful but must be initiated carefully. Heart rate, assessment of angina, and heart rhythm must be monitored. If systolic pressure is less than 90 mm Hg or mean arterial pressure is less than 65 mm Hg, nitroglycerin, nitroprusside, milrinone, and nesiritide should be used with caution. Bolus dosing is usually not given. Although routine invasive hemodynamic monitoring is not recommended, placement of a Swan Ganz catheter is considered in patients whose filling pressures is unclear, who are refractory to standard therapy, who have symptomatic hypotension (i.e., systolic pressure <80 mm Hg) or worsening renal function,

or who need documentation of improved hemodynamics when an inotrope is considered for chronic therapy. Inter-mittent chronic administration of dobutamine or milrinone has not resulted in improved outcomes in patients with HF.

Device Therapy for Systolic Heart Failure

Implantable cardiac defibrillators (ICDs) are indicated in all patients who have survived a cardiac arrest. ICD placement also reduces mortality in NYHA class II and III patients with an EF of 35% or less, whether the HF is ischemic or nonischemic. Biventricular pacemakers improve survival and quality of life and reduce hospitalization in class III and IV patients with reduced EF and a prolonged QRS duration. These devices should be considered only in optimally treated patients, that is, those receiving ACE-I and β -blocker therapy. It is important to reassess LV function after reaching the target or maximum dose before device implantation because EF may have improved.

LV assist devices are most often used as a bridge to cardiac transplantation but are also approved as destination therapy for end-stage patients who are not transplantation candidates.

Treatment of Heart Failure with Preserved Ejection Fraction

There are no completed randomized trials indicating a medical regimen that improves survival in patients with HF-PSF, but several studies have demonstrated an improvement in symptoms and morbidity. Candesartan, an ARB, reduced subsequent HF hospitalizations in patients admitted for a cardiac reason whose EF was more than 40%. Nebivolol, a β_1 -selective β -blocker, significantly reduced the combined outcome of mortality or cardiovascular hospitalization in patients 70 years and older admitted with HF regardless of EF.

Blood pressure control is essential. ARB, β -blockers, ACE-I, calcium channel blockers, and aldosterone antagonists cause regression of LV hypertrophy. Agents that reduce preload, such as diuretics and nitrates, are commonly prescribed. Nitrates are also used to treat ischemia. Calcium channel blockers, particularly verapamil, improve ventricular relaxation. Agents that decrease heart rate (increasing diastolic filling time), including verapamil, diltiazem, and β -blockers, are usually beneficial. Smaller studies have demonstrated a benefit of daily, moderate exercise.

Maintaining atrial contraction is important. Atrial contraction contributes up to 50% of ventricular filling in patients with decreased compliance, explaining why the loss of atrial contraction in atrial fibrillation results in acute decompensation. Cardioversion treatment with anti-arrhythmic agents or radiofrequency ablation are options that should be considered on an individualized basis.

Avoiding Treatment Errors

Prescribing an ACE-I plus ARB plus an aldosterone antagonist is not recommended because of the increased danger of hyperkalemia. Regular monitoring of potassium and renal function is strongly recommended in patients receiving any of these drugs.

Routine administration of nonsteroidal agents is not recommended in patients with HF because of the increased risk for fluid retention and worsening renal function. Nifedipine, verapamil, and diltiazem should not be used in patients with systolic HF because of their negative effect on contractility. Digoxin has not been shown to have a benefit in patients with HF-PSF unless they are in atrial fibrillation.

Drug Cost

HF patients take an average of 9 to 10 medications daily. The huge financial cost of medications often leads to medication nonadherence. Even if patients have insurance or receive Medicare Part D benefits, nongeneric medications can cost as much as \$40 per prescription. It is important to determine how patients pay for their medications and to estimate their monthly drug bill. Prescribing generics when available will reduce cost (see Table 34-1). Mail-order companies may also offer reduced pricing.

Nonpharmacologic Strategies

Daily exercise, salt restriction of less than 2.5 to 3 g daily, fluid restriction, and daily weights should all be in the patient's care plan. Obese HF patients benefit from weight loss, and all benefit from discontinuation of alcohol and from smoking cessation. Every patient should receive an annual flu shot. Educate the patient and family about the symptoms and signs of the disease, prognosis, medications, and when to contact a health professional.

HF specialists can be helpful in the care of complex HF patients. Those who may benefit include patients who remain severely limited on an optimized medical regimen, do not tolerate medication up-titration, are transplantation candidates (refractory HF, EF <20%, without significant comorbid disease, compliant, psychologically stable with good social support), or are candidates for clinical trials or an LV assist device.

Treatment of Comorbid Disease

Aggressive management of hypertension, hyperlipidemia, diabetes mellitus, obstructive sleep apnea, and depression is part of routine care.

Future Directions

Passive mechanical devices are under development to prevent the progressive LV dilation and shape changes that

occur during the evolution of HF. The effects of intracoronary injection of autologous bone marrow cells on LV function in patients with acute myocardial infarction have yielded contradictory results. Gene therapy approaches hold promise for the future with ongoing improvements in vector technology, cardiac gene delivery, and understanding of molecular pathogenesis. Disease prevention by aggressive modification of risk factors and early detection continue to have an enormous impact on cardiovascular disease leading to HF.

5. Owan TE, Hodge DO, Herges RM, et al: Trends in prevalence and outcome of heart failure with preserved EF. *N Engl J Med* 355(3):251-359, 2006.

This article reviewed the secular trends in the prevalence and mortality of 4596 heart failure patients followed at the Mayo Clinic over a 15-year period (1987-2001). The prevalence of heart failure with preserved ejection fraction increased over this period, while the mortality rate remained unchanged. In contrast, survival of patients with systolic heart failure improved over this time period but remained lower compared with that of patients with preserved ejection fraction.

Hypercholesterolemia: Evaluation and Treatment

Introduction

Cholesterol is found in cell membranes and is a precursor of steroids and bile acids. It is a particularly important lipid because it is a major component of atherosclerotic plaques and because elevated blood cholesterol concentration is a major, and reversible, cause of coronary heart disease (CHD).

Cholesterol is primarily synthesized in the liver and is excreted as bile salts (Fig. 35-1). Individuals on the average Western diet absorb 20% to 40% of their cholesterol intake, on average about 300 to 700 mg daily. In average individuals, up to 1000 mg is recirculated each day by secretion and reabsorption as bile salts. Blood levels of cholesterol are determined by dietary intake of cholesterol, inheritance, physical activity, and intake of dietary fats, particularly saturated fats.

Cholesterol is transported in the blood as macromolecules of lipoproteins, with the nonpolar lipid core surrounded by a polar monolayer of phospholipids, the polar portion of cholesterol, and apolipoproteins. Specific lipoproteins differ in lipid core content, the proportion of lipids in the core, and the proteins on the surface. Lipoproteins are commonly classified by density as chylomicrons, chylomicron remnants, very-low-density lipoprotein (VLDL), low-density lipoprotein (LDL), intermediate-density lipoprotein (IDL), or high-density lipoprotein (HDL) cholesterol.

Triglycerides are esters of glycerol and long-chain, saturated, and desaturated fatty acids. They are found in all plasma lipoproteins but are the major constituent of chylomicrons, chylomicron remnants, VLDL, and IDL. Most triglycerides are contained in VLDL, which makes up 10% to 15% of the total cholesterol. The precise relationship of plasma triglycerides and atherosclerotic disease is uncertain because of the strong association of elevated triglycerides with low HDL as well as with other atherogenic factors (e.g., diabetes, smoking, and hypertension). If triglyceride-rich particles are present in sufficiently high

concentration (>400 mg/dL), the plasma is turbid or opalescent. Severe elevations of triglycerides (1000 mg/dL) are associated with pancreatitis and eruptive xanthoma.

HDL cholesterol (HDL-C) is a family of lipoproteins that usually constitutes 20% to 30% of the total cholesterol. HDL-C shows a strong, inverse association with CHD risk and may facilitate reverse cholesterol transport from tissue. HDL-C is decreased by diets high in polyunsaturated fats, obesity, smoking, diabetes, and drugs (diuretics, anabolic steroids, and progestins). Physical activity and alcohol increase HDL-C. However, HDL-C concentration fluctuates considerably as a result of physiologic and analytic variation. Thus, a single measurement of the HDL-C may not be sufficient to determine a patient's usual HDL-C.

LDL cholesterol (LDL-C) makes up one half to two thirds of the total cholesterol and is thus the major determinant of the total serum cholesterol. As commonly measured, LDL is not a unique molecule but a population of particles similar in chemical and physical properties. For example, IDL cholesterol and lipoprotein (a) cholesterol, both of which appear to be atherogenic, generally constitute 2% to 4% of the total cholesterol and are encompassed in the LDL-C value.

LDL-C shows a strong and consistent epidemiologic, experimental, and clinical link to the rate of CHD (Fig. 35-2). Lowering of LDL-C cholesterol by diet, exercise, or pharmacologic therapy slows atherosclerotic vascular disease progression and lowers the risk for coronary events. This strong link of LDL-C cholesterol with CHD makes management of elevated LDL-C a critical focus for medical

Figure 35-1 Hypercholesterolemia: Cholesterol Synthesis and Metabolism.

APO, apolipoprotein.

Cholesterol is transported in blood as macromolecules of lipoproteins, with the nonpolar lipid core surrounded by a polar monolayer of phospholipids and the polar portion of cholesterol and apolipoproteins (APO). Specific lipoproteins differ in lipid core content, proportion of lipids in core and proteins on the surface. Lipoproteins are classified by density as chylomicrons, very-low-density lipoprotein (VLDL), low-density lipoproteins (LDL), and high-density lipoproteins (HDL).

treatment. Although independent interventions to lower triglycerides and raise HDL-C should also be considered, therapies that lower LDL-C (e.g., statins and niacin) often positively affect triglycerides and HDL-C. However, to date, new pharmacotherapies aimed solely at raising HDL-C have been associated with increased adverse events.

Etiology and Pathogenesis

CHD may result from high LDL-C levels in patients without other risk factors for coronary artery disease, par-

ticularly children and young adults who have inherited a lack of sufficient cell membrane receptors to remove LDL-C from circulation. These forms of familial hypercholesterolemia, present in 1 in 500 individuals who are heterozygous and 1 in 1,000,000 who are homozygous, are characterized by a twofold to fourfold increase in LDL-C levels in heterozygotes and much greater increases in homozygotes. Familial combined hypercholesterolemia occurs in about 1 in 100 people and is characterized by overproduction of apolipoprotein B. In all these individuals, the coronary risk conferred by an elevated LDL-C is

Figure 35-2 Hypercholesterolemia as Risk Factor in Coronary Artery Disease.

further increased by the presence of additional coronary risk factors, as described later.

The mechanisms by which LDL-C accelerates coronary atherosclerosis are complex. Coronary atherosclerosis appears to be part of an inflammatory response to endothelial injury in which monocytes infiltrate the arterial intima and promote cholesterol oxidation and conversion of monocytes into tissue macrophages and eventually to lipid-laden foam cells (see Fig. 35-2). These cells initially deposit in fatty streaks below the endothelial layer. With

further accumulation, an eccentric lipid-rich plaque develops. Smooth muscle cells form a fibrous cap over the lipid core that repeatedly fissures, leading to thrombus formation and plaque growth. Eventually, a major fissure occurs, and a thrombus partially or completely obstructs the coronary artery, leading to unstable angina, myocardial infarction, or sudden cardiac death. The forces that precipitate plaque rupture, and the means to detect the propensity of such an event in the immediate future, are being actively investigated.

Clinical Presentation

Individuals with lipid abnormalities may present in one of several ways, but ultimately hypercholesterolemia is a diagnosis made by laboratory analysis. Because cholesterol-lowering drugs are efficient in reducing coronary risk, any individual who presents with chronic or acute coronary syndromes, “high-risk” family history, or has diabetes mellitus or multiple cardiac risk factors is deemed to be at increased risk and should be screened. Historically, screening was underutilized, but with increased public emphasis, this has improved substantially.

In some settings, patients not known to be at increased risk but with hypercholesterolemia can be identified. Patients with familial hypercholesterolemia may present with physical findings that reflect long-standing hypercholesterolemia. These findings include subcutaneous cholesterol deposits, most frequently tendinous xanthomas or xanthelasmas. Arcus senilis, once thought to be indicative of hypercholesterolemia, is far less specific, particularly in elderly people. Patients may also be identified when turbid serum is found on routine blood work.

Differential Diagnosis

Secondary causes of elevated cholesterol are common. These include poorly controlled diabetes, hypothyroidism, and the nephrotic syndrome. Estrogen replacement therapy may elevate triglycerides, and HDL may be dramatically lowered by progestins and anabolic steroids.

Diagnostic Approach

The primary blood test required for diagnosis and treatment of elevated cholesterol measures the fasting total cholesterol, triglycerides, and HDL-C. These values are then used to calculate the LDL-C [total cholesterol – (HDL-C + triglycerides/5)]. This method is useful only if the triglycerides are lower than 400 mg/dL. Direct measures of LDL-C and estimation of LDL and other lipid fraction particle size and particle number are also available but are not commonly necessary or used. Blood samples should be measured after a 12-hour fast because chylomicrons interfere with the estimation of LDL-C.

Established CHD and atherosclerotic vascular disease in other vascular beds dramatically increase the risk associated with elevated LDL-C. In addition, diabetes mellitus is a coronary risk equivalent, and patients with known diabetes should be evaluated and treated as if they have diagnosed CHD because of the increased risk associated with diabetes. These clinical situations require aggressive management of LDL-C. For patients who are not in this highest-risk group, the goal of lipid management is to delay the complications of coronary artery disease, and less aggressive therapy is warranted. For these reasons, a search for the major, established risk factors for CHD should be performed. Any change in exercise capacity, chest pain, or

angina should be assessed by appropriate historical information or diagnostic tests (e.g., treadmill, nuclear imaging, and cardiac angiography).

The accepted major risk factors for CHD include age older than 45 years in men and older than 55 years in women, a history of premature CHD in first-degree relatives (sudden death or coronary disease onset before age 55 years for men or 65 years for women), current smoking, presence and severity of hypertension, physical inactivity, and dietary patterns. Life habit risk factors including obesity (body mass index >30), physical inactivity, and an atherogenic diet should also be assessed. Screening for elevated glucose may be particularly appropriate if the metabolic syndrome (central obesity, hypertension, glucose intolerance with low HDL-C, elevated triglycerides, and modestly elevated LDL-C) is suspected. Assessment of proteinuria, serum creatinine, and liver function studies may also help guide therapy. Additional risk factors for CHD, including lipoprotein (a), homocysteine, and prothrombotic and proinflammatory factors (C-reactive protein), are not routinely measured but may be helpful in situations in which a family history or established CHD occurs in the absence of a markedly elevated LDL-C. These latter risk factors are emerging as potentially important causes of coronary disease.

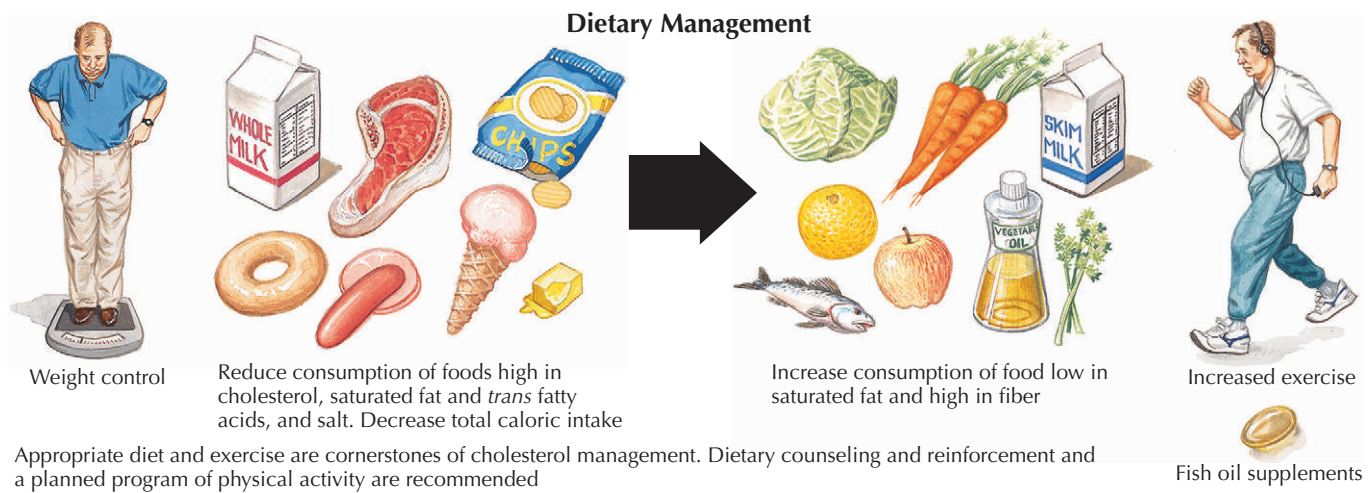

Lowering the LDL-C should be the primary goal of therapy. For patients with CHD, other vascular disease, diabetes, or a 10-year Framingham risk for CHD events of more than 20%, the target LDL-C should be less than 100 mg/dL. In higher-risk patients, an optimal target LDL-C of 70 mg/dL is supported by more aggressive clinical trials and advisory groups. Ideal values of HDL-C are more than 40 mg/dL in men and more than 50 mg/dL in women, and triglycerides should be less than 150 mg/dL. For patients with increased triglycerides (>200 mg/dL), non-HDL-C may be used to guide therapy, with a target level of 30 mg/dL greater than the recommended LDL-C target.

Management and Therapy

Optimum Treatment

Appropriate diet and exercise are the cornerstones of cholesterol management (Fig. 35-3). All patients who have elevated cholesterol should receive dietary counseling and dietary reinforcement to help them achieve their cholesterol goals. Although there remains some controversy about the optimal diet to reduce the risk for CHD, the strongest data available today support either of two approaches. The modified step II American Heart Association (AHA) diet of less than 7% of calories from saturated fat and less than 200 mg/day of dietary cholesterol focuses on reduction in cholesterol intake and low total fat intake. Plant sterols and stanols of 2 g/day can be encouraged; these plant analogues of cholesterol displace cholesterol from bile salts and lower cholesterol, as do soluble fibers.

Figure 35-3 Hypercholesterolemia: General Management Measures.
PPAR, peroxisome proliferator-activated receptor.

Actions of Lipid-Lowering Medications

Statins

Statins (HMG-CoA reductase inhibitors) inhibit cholesterol synthesis and increase LDL receptor uptake of LDL

Ezetimibe

Selectively inhibits cholesterol absorption at the intestinal villi, decreasing the delivery of dietary cholesterol to the liver

Bile Acid Sequestrants

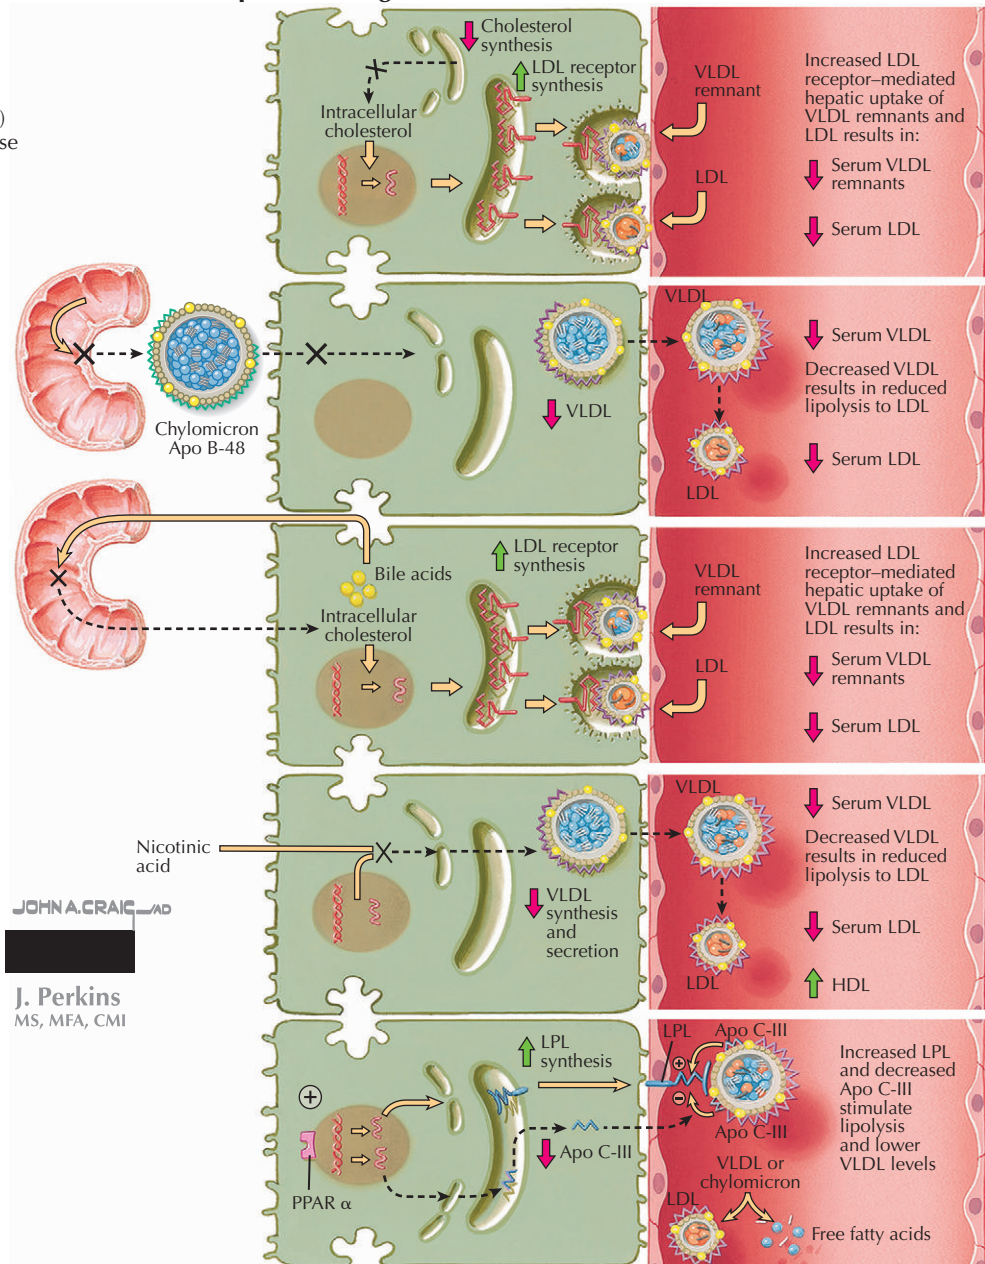

Sequestrants prevent bile acid reabsorption and increase uptake by hepatic LDL receptors

Nicotinic Acid

Drugs reduce tissue lipase activity and impair synthesis of VLDL

Fibric Acid Derivatives

Act via stimulation of lipase to increase lipolysis by lipoprotein lipase (LPL) thereby decreasing VLDL

JOHN A. CRAIG, MD
J. Perkins
MS, MFA, CMI

An alternative approach to the AHA diet is the Mediterranean Diet, which encourages increased intake of fish and a variety of other foods that are low in saturated fats, but not as low as the American Heart Association diets in total fat. Low carbohydrate and low glycemic index diets have also gained popularity, and somewhat surprisingly, in initial studies no negative impact on plasma lipid profiles has been reported. A planned program of daily physical activity should be started and reinforced.

Fish oil (eicosapentaenoic acid and docosahexaenoic acid) is a promising dietary intervention that appears to reduce hepatic triglyceride synthesis. Dietary supplements of fish oil containing 2 to 5 g of omega-3 fatty acid may decrease triglycerides by up to 30% and VLDL by 40%, with resulting modest changes in LDL cholesterol and increases in HDL cholesterol. Gastrointestinal complaints (bloating, diarrhea), increased bleeding time, and effects of hypervitaminosis A and D (dermatitis or hypercalcemia) may occur with high doses of fish oil. The routine use of high-dose vitamins or antioxidant supplements is not recommended.

Initiation of drug therapy is based on the absolute risk of a patient developing a CHD and the LDL-C value following diet therapy (see Fig. 35-3). If the 10-year Framingham risk is more than 20% or the patient has a CHD risk equivalent, drug therapy should be initiated if the LDL-C exceeds 100 mg/dL. If the patient has a 10-year risk of less than 20% and has two or more risk factors, drugs should be considered if the LDL-C exceeds 130 mg/dL. If the patient has only one other risk factor and the 10-year risk is less than 10%, drugs are often initiated if the LDL-C is 160 mg/dL or higher.

Drug therapy with hydroxymethyl glutaryl coenzyme A (HMG-CoA) reductase inhibitors (statins) is highly effective at lowering LDL-C. Statins inhibit cholesterol synthesis and increase LDL receptor uptake of LDL. In addition, statins lower triglycerides by up to 30% and can be expected to raise HDL-C by up to 15%. These drugs include lovastatin (10 to 80 mg/day), pravastatin (20 to 80 mg/day), simvastatin (10 to 80 mg/day), fluvastatin (20 to 80 mg/day), atorvastatin (10 to 80 mg/day), and rosuvastatin (10 to 40 mg/day). There is a predictable dose-response relationship with these drugs such that doubling the dose of the statin results in an approximate 6% additional LDL cholesterol reduction from the initial baseline level. These drugs are, in general, well tolerated. There is a small risk for myopathy with higher doses or when statins are combined with fibrates or with drugs that interfere with metabolism of the statin. A modest but dose-dependent increase in the probability of elevated liver enzymes also occurs. The therapeutic benefit of statins in lowering LDL cholesterol can be potentiated by bile acid sequestrants, plant stanols, and intestinal cholesterol-absorber blockers like ezetimibe.

Second-line medications include bile acid sequestrants: cholestyramine (4 to 16 g/day), colestipol (2 to 16 g/day),

and colesvelam (4 to 6 tablets of 625 mg each/day). These drugs prevent bile acid reabsorption and increase uptake by liver LDL receptors. They can reduce LDL-C by up to 30% in a dose-dependent manner and can increase HDL-C by 5% but may also increase triglycerides. They should not be used in patients with dysbetalipoproteinemia or elevated triglycerides. They are not systemically absorbed, and side effects are generally limited to their potential to interfere with decreased absorption of other drugs, constipation, dyspepsia, and bloating.

Nicotinic acid reduces tissue lipase activity and impairs VLDL synthesis. It lowers LDL-C by up to 25%, decreases triglycerides by up to 50%, and raises HDL-C by up to 35%. Side effects include flushing, elevated blood glucose, hyperuricemia, abdominal pain, and hepatotoxicity. Nicotinic acid should not be used in patients with severe gout, peptic ulcer disease, or liver disease and should be used only with close monitoring in patients with diabetes or insulin resistance. Nicotinic acid is available in three forms: immediate release (target dose of 1.5 to 2 g/day), extended release (500 mg to 2 g/day), and sustained release (not recommended). Although nicotinic acid is highly effective and has a demonstrated safety record, compliance is not good unless supportive counseling is provided.

The fibric acid derivatives gemfibrozil (600 mg twice daily) and fenofibrate (48 to 145 mg/day) decrease VLDL and triglyceride levels by increasing lipolysis by lipoprotein lipase, thereby increasing catabolism of triglyceride-rich particles. They can be expected to lower LDL-C by up to 20%, to raise HDL-C by up to 20%, and to lower triglycerides by up to 50%. Side effects include dyspepsia, gallstones, and a propensity toward myopathy when combined with statins. These drugs are contraindicated in renal or hepatic disease. Ezetimibe (10 mg/day) is a selective inhibitor of cholesterol absorption at the intestinal villi and can reduce LDL-C by 20%; it can also be combined with statins to further reduce LDL-C.

Specific Dyslipidemia

When LDL-C is extremely high (>190 mg/dL), a genetic disorder should be suspected and family screening undertaken. Monogenetic familial hypercholesterolemia, familial defective apolipoprotein B100 synthesis, or polygenic hypercholesterolemia is likely. Therapy almost always requires a statin in high doses or a statin combined with another drug. Occasionally patients require plasma apheresis, particularly in the rare homozygous forms of hypercholesterolemia.

Treatment of other lipid factors may also be required. Elevated triglycerides may be caused by obesity, physical inactivity, cigarette smoking, excess alcohol intake, failure to fast before the lipid test, a high-carbohydrate (>60% of energy intake) diet, type II diabetes, chronic renal failure, and nephrotic syndrome. Certain drugs (corticosteroids, estrogens, retinoids, high-dose β -blockers) and genetic

dyslipidemia may also be implicated. When the triglycerides exceed 500 mg/dL, triglyceride-lowering therapy should be undertaken to avoid pancreatitis or eruptive xanthomas. Dietary counseling is essential and should focus on very-low-fat diets (less than 15% of calories) and restrictions of sugars and simple carbohydrates. Fibrates, nicotinic acid, and fish oil dietary supplements, along with tight diabetic control, can all be helpful in treatment of hypertriglyceridemia.

Avoiding Treatment Errors

Combination therapy and high-dose statins may often be required in patients with severely elevated LDL-C to achieve guideline recommended levels. The combination of a statin with a fibric acid should be considered only in the most refractory circumstances because some such combinations carry an increased risk for serious side effects. In most patients, additional dietary considerations, or exercise or counseling to improve compliance, will further improve their lipid management.

Optimal and safe pharmacotherapy of lipid disorders requires careful and ongoing monitoring of the medical literature. Specific dosing recommendations often change and depend on a given patient's set of medical problems. Moreover, there is a high potential for drug interactions, and starting and maintenance doses may differ substantially.

Future Directions

New drugs and new therapies are rapidly being developed for managing dyslipidemia and diagnosing atherosclerosis earlier in its course. Diagnostic tests to more accurately predict the risk for developing coronary events include measurement of the C-reactive protein and multiple other serum and genetic biomarkers, measurement of lipid particle size and density, and use of electron-beam tomography to access calcium levels in the coronary arteries and high-resolution computed tomographic angiography. Other noninvasive tests to assess the extent of atherosclerosis and establish risk for future events include carotid Doppler ultrasound to determine intima-to-media thickness ratio, and the ankle-brachial index, a measurement of the extent of peripheral vascular disease that provides important cardiovascular prognostic information. Invasive techniques include intracoronary ultrasound to assess the plaque burden and lipid density and the possible propensity of coronary artery to plaque rupture.

Drugs that raise HDL-C remain under development despite initially disappointing results. One example of a new approach now available for treating patients is ezetimibe, a selective inhibitor of cholesterol absorption at the intestinal villi that can be readily combined with statins. Other promising therapies are in clinical trials, and it is likely that, in the future, lipid disorders will be managed more effectively with fewer side effects, thereby more effectively reducing cardiovascular risk.

This article updates the ATP III guidelines based on key clinical trials not available at the time of the panels meeting. These studies endorse the importance of focusing on LDL-C as the primary target and suggest the need for more aggressive LDL-C targets.

Cardiac Arrhythmias

Introduction

Cardiac arrhythmias are abnormal and usually symptomatic changes in heart rhythm. Cardiac rhythm disturbances may involve abnormally fast (tachycardias) or slow (bradycardias) heart rates and may be either regular or irregular. Patients use various terms to describe symptoms associated with cardiac arrhythmia (which may also be asymptomatic), the most common of which is the term *palpitations* or a synonymous description. In general, the diagnosis and treatment of tachyarrhythmias is more complex than that of bradyarrhythmias.

Etiology and Pathogenesis

Tachycardias can be divided into two broad categories, supraventricular or ventricular tachycardia (VT), each of which can be due to any of several underlying etiologies.

Supraventricular tachycardia (SVT) is an often benign tachycardia that initiates above the bundle of His. Most SVTs involve two discrete pathways or limbs with different conduction and refractory properties. The pathways are composed of conducting cells, and in many cases, a portion of the pathways is due to the presence of conducting cells in an atypical anatomic location. Atrioventricular nodal reentrant tachycardia (AVNRT) has so-called fast and slow pathways, both of which are located in or very near the atrioventricular (AV) node. Atrioventricular reentrant tachycardia (AVRT) requires an accessory pathway that is present in another location from the AV node. Atrial tachycardia usually arises from a focal collection of rapidly depolarizing cells located in the right (or sometimes left) atrium. Atrial flutter occurs as a reentrant circuit usually in the right atrium.

Atrial fibrillation is the most common arrhythmia and can present with rapid, normal, or slow ventricular conduction. Atrial fibrillation occurs in a broad spectrum of patients with many underlying etiologies. The incidence of atrial fibrillation increases with age, and with the increased age of the population, age-related atrial fibrillation is common. Once a patient develops atrial fibrillation, it is very likely to recur.

Any SVT can become dangerous in settings in which myocardial function is impaired at high heart rates, includ-

ing coronary artery disease, congenital heart disease, congestive heart failure (CHF), and hypertrophic cardiomyopathy. Atrial fibrillation also carries the risk for left atrial thrombus formation and thromboembolism—most commonly resulting in transient ischemic attack or cerebrovascular accident. For this reason, in addition to considering dangers relating to atrial fibrillation with a rapid ventricular response, care providers must also consider anticoagulation to prevent thromboembolic events.

VT usually originates from scar tissue in patients with a previous myocardial infarction or from abnormal ventricular tissue found in various forms of cardiomyopathy, including dilated, hypertrophic, or infiltrative pathologies. Rarely, exercise-induced VT (the so-called verapamil- or adenosine-sensitive VT) can occur in patients with normal hearts. Ventricular fibrillation (VF) usually occurs in the setting of ongoing ischemia. VF is uniformly fatal unless treated immediately. VT, although often lethal, may present in other ways if it is episodic and nonsustained, or is stable at heart rates below 150 beats per minute.

The long QT syndrome and Brugada's syndrome are examples of arrhythmias resulting from inherited channelopathies. Brugada's syndrome is characterized by ST elevation beginning at the terminal R wave with a slowly descending ST segment and continuing with a flat or negative T wave appearing spontaneously in leads V₁ to V₃. Both conditions are associated with sudden cardiac death.

Bradycardias result from either permanent or transient heart block at the level of the AV node or bundle of His, sinus arrest, or neurocardiogenic factors (as in vagally mediated bradycardias). The severity of a given bradycar-

dia depends on how slow the heart rate is. This varies considerably with the type of bradycardia and the individual. Any heart rate less than 60 beats per minute in adults is bradycardia by definition. However, bradycardia can be normal in athletes and well-trained individuals. Many modest bradycardias require no therapy. Marked bradycardia can be life threatening and require hospitalization.

Clinical Presentation

In addition to palpitations, patients may present with other symptoms, including dyspnea, dizziness, lightheadedness, chest pain, syncope, weakness, fatigue, sudden cardiac death (SCD), or the consequences of injuries that result from the arrhythmia. Symptom severity depends on a complex interaction between the hemodynamic consequences of the arrhythmia and the underlying cardiac function. Syncope, per se, does not distinguish a benign from a malignant arrhythmia. The occurrence of palpitations, syncope, or presyncopal symptoms during exertion requires urgent evaluation.

SCD merits additional description because this is a term that has been used variably in recent years. SCD is most commonly defined as an abrupt loss of consciousness within 1 hour of the onset of acute symptoms resulting in natural death. If SCD is witnessed, it may be possible to resuscitate the individual. The most effective therapy is electrical cardioversion, in combination with other resuscitative efforts. Individuals who have been resuscitated and survived an episode of SCD are at highest risk for death from arrhythmia and should be immediately hospitalized and aggressively treated.

Diagnostic Approach

Patient Evaluation

In evaluating a cardiac arrhythmia, details of the presenting history, including the associated circumstances, family history of arrhythmia or SCD, medications (including recent dose changes or additions), recent illnesses or surgeries, and physical examination are crucial (Box 36-1). A baseline electrocardiogram (ECG) may help in identifying the abnormal arrhythmia and may exclude AV conduction abnormalities, preexcitation of Wolff-Parkinson-White (WPW) syndrome (delta wave, short PR interval, and a wider QRS complex), long QT syndrome, Brugada syndrome, and abnormalities in ventricular conduction. The laboratory tests chosen will vary from patient to patient and should be tailored accordingly. In almost every setting, one should screen for electrolyte abnormalities. In a patient with bizarre behavior, blood alcohol and urine toxicology screening should be performed. Elderly patients, in particular, should also be screened for toxic levels of prescribed medications.

Box 36-1 Evaluation of a Patient with a Cardiac Arrhythmia

- History and physical examination: family history of sudden death, medications
- Electrocardiogram: baseline and during event
- Laboratory may include complete blood cell count, electrolytes, blood glucose, serial cardiac enzymes, thyroid-stimulating hormone, digoxin, blood and urine drug screen, and alcohol levels
- Echocardiogram to document cardiac function and rule out valvular abnormality and cardiomyopathy
- Ambulatory Holter monitoring
- Patient-activated monitoring device: may include event, loop, or insertable loop recorder
- Procainamide provocative test
- Electrophysiology study

Adapted from Sheahan RC: Syncope and arrhythmias: Role of the electrophysiological study. Am J Med Sci 322:37-43, 2001.

Symptom Rhythm Correlation

A 12-lead ECG during the arrhythmia provides the gold standard of a symptom rhythm correlation. This is an elusive goal because symptoms are most commonly paroxysmal and occur infrequently. Holter monitoring over a 24- or 48-hour period can be used to document rhythms that occur almost daily. A loop recorder over a 1- to 2-month interval may record rhythms that occur once every 4 weeks. The use of these devices for longer periods is unlikely to yield a diagnosis due to decreasing patient motivation and contact dermatitis caused by the gel contained in the recording electrodes. In circumstances in which the diagnosis of a suspected arrhythmia is particularly elusive, an insertable loop recorder can be used to correlate symptoms with the cardiac rhythm. This is a recording device that is implanted under the skin in the anterior chest wall and can be activated by the patient or automatically. The automated features record heart rates of less than 40 beats per minute or greater than 145 beats per minute, or ventricular asystole of greater than 3 seconds. The insertable loop recorder is an option for patients with infrequent but significant symptoms, after structural heart disease and other obvious causes have been excluded.

Ventricular arrhythmias require further evaluation of myocardial function and evaluation for significant coronary artery disease. An echocardiogram, nuclear ventriculogram, or magnetic resonance imaging can be used to detect segmental wall motion abnormalities, hypertrophic cardiomyopathy, dilated cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy (ARVC), valvular abnormalities, and atrial dimensions (in atrial fibrillation). Coronary angiography is usually recommended to rule out significant coronary artery disease and myocardial ischemia as a cause for ventricular arrhythmias.

In patients presenting with syncope and left ventricular dysfunction (ejection fraction [EF] <35%), an implantable cardioverter defibrillator (ICD) is usually recommended because these patients are at a higher risk for sudden cardiac death. Revascularization, if required, should also be performed.

Management and Therapy

Optimum Treatment

Acute Management of Arrhythmias

Rhythm recognition in conjunction with the hemodynamic consequences of the arrhythmia determines the immediate therapeutic approach to managing acute sustained arrhythmias (Table 36-1). If a patient has SVT with a blood pressure less than 80 mm Hg and is presyncopal, then an immediate synchronized direct current (DC) cardioversion is required. While preparing for cardioversion, one can consider an intravenous bolus of adenosine (6 to 12 mg) to terminate the arrhythmia. Similarly, if a patient has VT and is hemodynamically unstable, immediate synchronized DC cardioversion is recommended. In conscious patients requiring electrical cardioversion, regardless of the underlying arrhythmia, anesthesia (conscious sedation) should be initiated before electrical cardioversion except in life-threatening circumstances. In patients with either SVT or VT who are hemodynamically stable and minimally symptomatic, pharmacologic therapy can be initiated (see later). Electrical cardioversion is contraindicated in a symptomatic patient with sinus tachycardia and hypotension.

In patients who present with hemodynamically *stable* SVT, the initial drug of choice is adenosine, infused as a rapid intravenous push in a large proximally located vein, followed by a fluid bolus. Intravenous diltiazem or metoprolol may also be used. One should avoid using an intravenous calcium channel blocker in a patient who is currently taking a scheduled dose of an oral β -blocker, and vice versa. In patients with known WPW syndrome and SVT, adenosine is the drug of choice, and diltiazem and metoprolol should be used only for special indications.

In patients who present with hemodynamically *unstable* VT requiring urgent synchronized DC cardioversion, it is important to immediately follow restoration of normal sinus rhythm with institution of intravenous antiarrhythmic therapy. Amiodarone, β -blocker, and magnesium are most commonly used.

In patients presenting with a hemodynamically *stable* VT, one should consider treatment with intravenous β -blockers, amiodarone, magnesium, or a combination of these. If 1 hour elapses without termination to sinus rhythm, a synchronized DC shock should be performed.

VF requires an emergent asynchronous DC shock followed by infusion of intravenous amiodarone, β -blocker, and magnesium.

The acute management of *atrial flutter* and *atrial fibrillation* with rapid ventricular response depends on the clinical presentation, as with SVT and VT. Hemodynamically stable patients can be treated medically. Intravenous diltiazem or esmolol are the drugs of choice because they provide graded, dose-related control of the ventricular response. When not effective, it is often because an inadequate dose has been used. Slowing the ventricular response to less than 90 beats per minute increases the diastolic filling time and improves cardiac output. Patients with atrial flutter or atrial fibrillation with rapid ventricular response who are hemodynamically unstable should undergo immediate synchronous DC cardioversion.

In significant *bradycardia* due to sinus arrest or complete heart block, a temporary transvenous pacemaker should be placed in the right ventricle until the condition resolves or a permanent pacemaker is placed (Fig. 36-1). Patients who present with second-degree AV block Mobitz types I and II should be monitored closely. Temporary pacing is ordinarily only necessary if these rhythms result in hemodynamic instability or progress (Fig. 36-2).

Sinus tachycardia most often reflects an underlying condition. A careful history and physical examination should provide clues as to the etiology. These include, but are not limited to, dehydration, anemia, fever, pain, anxiety, medications including bronchodilators, vomiting, diarrhea, and illicit drug use. Pharmacologic or other therapy for sinus tachycardia (or multifocal atrial tachycardia, which usually occurs in the setting of respiratory distress) should focus on treating the underlying disease rather than the resulting tachycardia.

Long-term Management

Initial therapies for *recurrent SVT* may include β -blockers or calcium channel blockers (see Table 36-1). Initiation of these agents will depend on the frequency of the episodes and the presence of comorbid conditions. An electrophysiology study and radiofrequency ablation (RFA) should be considered for recurrent episodes, intolerance to medications, or women in childbearing years who wish to become pregnant. RFA successfully eliminates the SVT in 90% to 95% of patients with a 5% recurrence rate.

For those with *AVNRT*, the ablation target is the “slow pathway,” which is occasionally located in close proximity to the AV node. Ablation in this location is associated with a 1% to 2% risk for heart block, which may require pacemaker placement. Other complications related to this procedure are uncommon (occurring in about 1% of patients).

SVT in the presence of a *WPW* pattern is associated with a risk for sudden death (see Fig. 36-3), particularly in patients in whom atrial fibrillation develops with rapid antegrade conduction over the accessory pathway. Patients with WPW in whom atrial fibrillation develops can progress rapidly to VF. In these patients, who typically have a wide, rapid, irregular tachycardia, treatment options

Table 36-1 Acute and Long-term Management of Arrhythmias

Arrhythmia	Acute Care	Long-term Management
Sinus tachycardia (>100 beats/min)	Treat underlying cause	If inappropriate, β -blocker or calcium channel blocker. Consider POTS and midodrine or fludrocortisone, rehabilitation, rehabilitative aerobic training (e.g., swimming, walking)
Sinus bradycardia (<60 beats/min)	If asymptomatic, no intervention. If symptomatic and severe (rates <40 beats/min) with nonreversible cause, consider temporary pacing	If asymptomatic, no intervention. If symptomatic and severe (rates <40 beats/min) with nonreversible cause, consider permanent pacing
Premature atrial complexes	If asymptomatic, no intervention. Check potassium, magnesium	If asymptomatic, no intervention. Check potassium, magnesium. If symptomatic, consider β -blocker
Premature ventricular complexes	If asymptomatic, no intervention. Check potassium, magnesium	Echo to assess LV and RV function, and LV wall thickness. Normal echo: no intervention. β -Blocker for symptoms. Abnormal echo: evaluate etiology and add β -blocker. Consider PO magnesium PRN
Sinus node dysfunction	No intervention, unless unstable	Permanent pacemaker. Allows the use of β -blocker in patients with tachybrady syndrome
Prolonged PR interval	No intervention	No intervention unless symptomatic
Second degree AV block	No intervention, unless unstable	Symptomatic patient, consider permanent pacemaker
Mobitz type I (Wenckebach)	No intervention, unless unstable	Permanent pacemaker
Mobitz type II AV block	Possible temporary pacemaker	Permanent pacemaker
Complete heart block	Control SVT with adenosine	Consider EPS and RFA for recurrent episodes
Supraventricular tachycardia (SVT)	Control SVT with adenosine	WPW with SVT needs EPS and RFA, because of risk for sudden death
Wolff-Parkinson-White syndrome and concealed accessory pathway	Control SVT with adenosine, IV β -blocker, diltiazem	Consider EPS and RFA for recurrent episodes
AV nodal reentrant tachycardia	Control SVT with adenosine, IV β -blocker, diltiazem	Consider EPS and RFA for recurrent episodes
Atrial tachycardia	Heparin in all. Determine time of symptom onset. Duration <48 hours may cardiovert (DC or IV antiarrhythmic agents); >48 hours, either TEE, and if negative for thrombus, cardiovert; or warfarin with INR 2.0-3.0 for 3 weeks and then cardioversion	Warfarin with INR 2.0 to 3.0 in all at-risk patients. Consider pharmacologic treatment or elective DC cardioversion
Atrial fibrillation	Rate control	Soluble aspirin, 81-325 mg, for all other patients at low risk for stroke
anticoagulation	Rate control	Recurrent episodes need antiarrhythmic agent. Pulmonary vein isolation ablation for drug failures
Paroxysmal	Rate control	Cardioversion, addition of antiarrhythmic agent for recurrences. Pulmonary vein isolation ablation for drug failures
Persistent	Rate control	Rate control. If unsuccessful, consider pulmonary vein isolation or AV node ablation and permanent pacemaker
Permanent	Rate control	RFA for recurrent episodes
Atrial flutter	DC cardioversion if unstable or refractory to antiarrhythmic drugs	Echo to assess LV function. Ischemic evaluation +/- revascularization. EF <35% for ICD placement. Normal echo, consider RVOT or LV VT and ablation
Ventricular tachycardia	Emergent DC cardioversion	Rule out acute myocardial infarction. ICD placement in absence of acute myocardial infarction
Ventricular fibrillation	Rate control	Rule out RV and LV dysfunction; EF <35%, needs ICD. If normal β -blockers, possible ablation.
Nonsustained ventricular tachycardia (3-30 beats)	Primary prevention of sudden cardiac death	Previous myocardial infarction or dilated cardiomyopathy. LV EF <35%, require ICD placement
Left ventricular dysfunction	Treat as for arrhythmia	ICD for at-risk individuals
Hypertrophic cardiomyopathy	Resuscitate as for arrhythmia	β -blocker or permanent pacemaker at 85 beats/min/ICD
Long QT syndrome	Resuscitate as for arrhythmia	Symptomatic ICD placement. Asymptomatic and abnormal ECG, some favor EPS +/- ICD, but others favor observation
Brugada syndrome		

AV, atrioventricular; DC, direct current; EF, ejection fraction; EPS, electrophysiology study; ICD, implantable cardioverter-defibrillator; INR, international normalized ratio; LV, left ventricular; POTS, postural orthostatic tachycardia syndrome; RFA, radiofrequency ablation; RV, right ventricular; RVOT, right ventricular outflow tract; TEE, transesophageal echocardiography; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White syndrome.

Figure 36-1 Atrioventricular Conduction Variations I.

include intravenous procainamide or synchronized DC cardioversion. Blocking the AV node with agents such as verapamil and digoxin may accelerate the ventricular rate, and these drugs are contraindicated in WPW with atrial fibrillation and a rapid ventricular response.

Patients who present with WPW syndrome and SVT should undergo an RFA to reduce the risk for sudden death. In WPW syndrome, an accessory pathway allows antegrade (antidromic) and retrograde (orthodromic) conduction. Most SVTs associated with WPW syndrome are

orthodromic. Antidromic tachycardia presents with wide complexes that resemble VT and should be treated as such unless there is a clear history of WPW syndrome.

Patients who have WPW may also have a concealed accessory pathway detectable only during an electrophysiology study. In these individuals, the tachycardia usually conducts retrograde over the accessory pathway and antegrade through the AV node.

The evaluation of patients who present with WPW on resting ECG without SVT is best done by a physician with

Figure 36-2 Atrioventricular Conduction Variations II.

**G. No relationship between P waves and QRS complexes: QRS rate slower than P rate
Third-degree (complete) AV block**

1. Impulses originate at both SA node (P waves) and below site of block in AV node (junctional rhythm) conducting to ventricles

Atria and ventricles depolarize independently. QRS complexes less frequent; regular at 40 to 55/minute but normal in shape

2. Impulses originate at SA node (P waves) and also below site of block in ventricles (idioventricular rhythm)

Atria and ventricles depolarize independently. QRS complexes less frequent; regular at 20 to 40/minute but wide and abnormal in shape

Features of two types of atrioventricular block		
	“High”	“Low”
Site of block	Crest of AV node	Bundle of His, bilateral bundle branch, or trifascicular
Type of escape rhythm	Junctional escape rhythm Narrow QRS Adequate rate (40-55)	Ventricular escape rhythm Wide QRS Inadequate rate (20-40) Danger of asystole or ventricular tachycardia
Underlying pathology	Right coronary artery disease, diaphragmatic infarction, edema around AV node	Left anterior descending coronary artery disease, large anteroseptal infarction, or chronic degeneration of conduction system
Rhythm before complete block	Preceded by Mobitz I (Wenckebach) second-degree AV block	Preceded by Mobitz II second-degree AV block

H. No relationship between P waves and QRS complexes. QRS rate faster than P rate AV dissociation

P waves less frequent than QRS complexes and totally unrelated to them

F. Netter M.D.

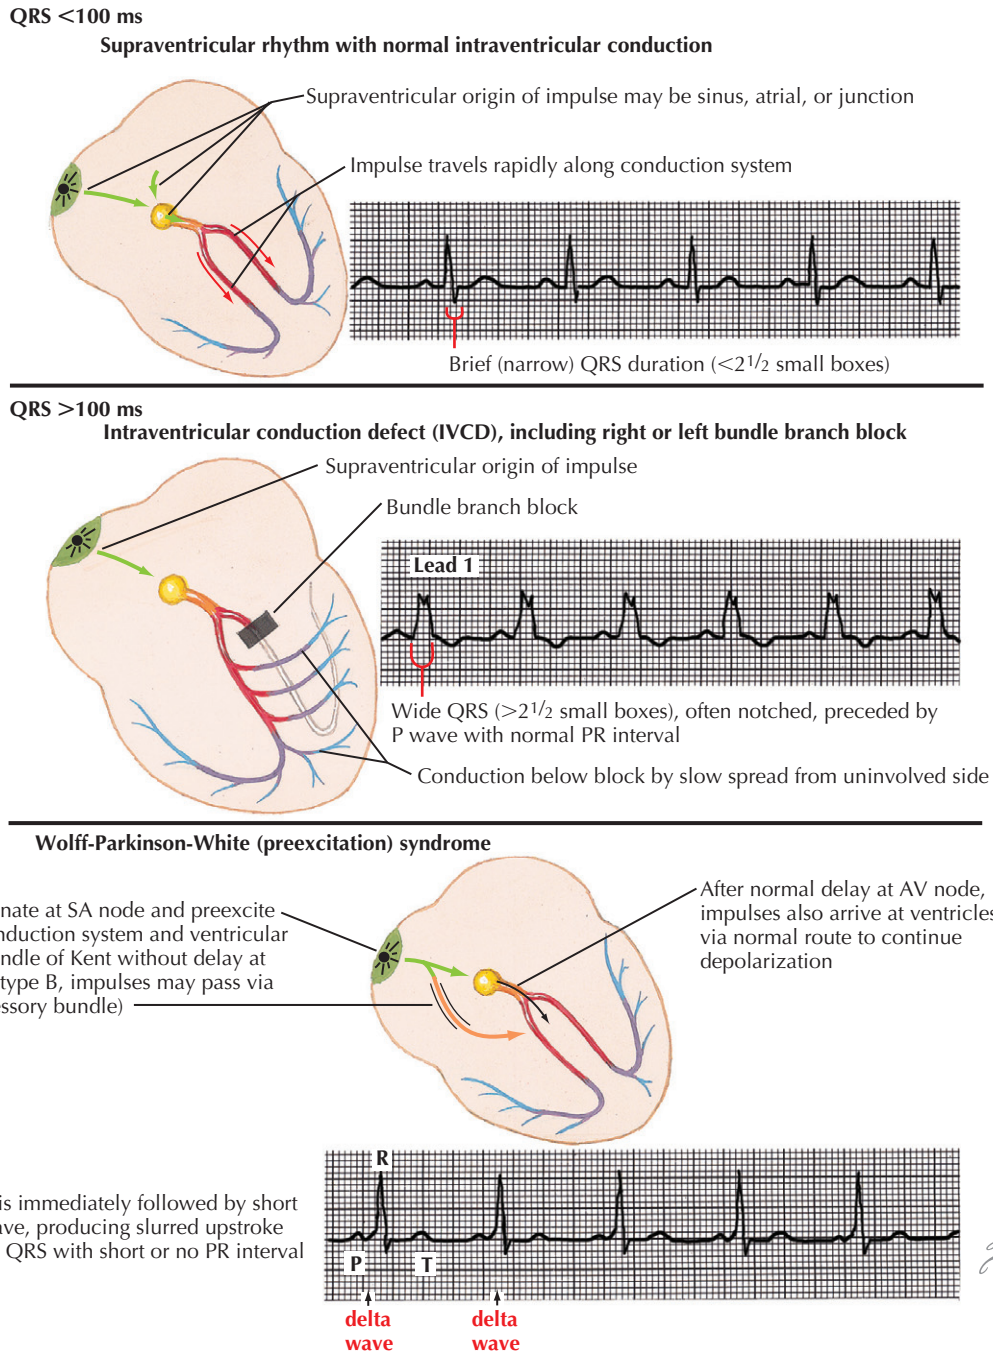

expertise in this area. Many of these patients are at low risk and do not require further therapy. However others, particularly with a high-risk family history and significant symptoms without prior documentation of SVT or atrial fibrillation, are best treated with RFA.

Atrial tachycardia occurs in about 10% of SVTs. Ablation has, historically, been more difficult in these individuals. However, the latest mapping technology allows for accurate and easier localization of the focus and facilitates ablation.

In *atrial flutter*, the atrial rate is usually 300 beats per minute, with conduction occurring over the AV node at a 2 : 1, 3 : 1, 4 : 1, or 5 : 1 ratio. After the ventricular response is controlled, it is important to restore sinus rhythm chemically or electrically. Antiarrhythmic agents may be used to treat recurrent episodes. Current techniques allow successful and curative ablation for patients with recurrent episodes of atrial flutter.

Atrial fibrillation is a lifelong condition involving recurrent episodes. Atrial fibrillation presents in several ways:

Figure 36-3 Ventricular Rhythms I.

paroxysmal (terminates spontaneously), persistent (needs cardioversion to terminate), or permanent (cannot be maintained in sinus rhythm, i.e., chronic). Patients with nonvalvular heart disease who have any one of several risk factors (older than 75 years, hypertension, diabetes, congestive heart failure, previous embolic episode) have a higher risk (>5% per year) for stroke and require chronic anticoagulation with an International Normalized Ratio (INR) between 2 and 3.

Antiarrhythmic agents are indicated to prevent recurrences of either paroxysmal or persistent atrial fibrillation. Therapeutic choices include amiodarone, sotalol, propafenone, flecainide, and dofetilide. The latter four drugs have proarrhythmic effects and require close monitoring. Digoxin, β-blockers (other than sotalol), and diltiazem do not convert atrial fibrillation to sinus rhythm, but conversion to normal sinus rhythm may occur with rate control. Pulmonary vein isolation is the ablation procedure of

choice for patients who have been unresponsive or intolerant of two or more antiarrhythmic agents. Premature atrial complexes originating from the atrial tissue in the pulmonary veins act as triggers for the initiation of atrial fibrillation, and occasionally as facilitators for the maintenance of atrial fibrillation. This procedure is associated with a greater than 70% freedom of atrial fibrillation at 1 year.

Permanent atrial fibrillation requires rate control using combinations of β -blockers, calcium channel blockers, and digoxin. Patients in whom intermittent bradycardia develops (tachy-brady syndrome) or who have a persistent tachycardia may require a permanent pacemaker with or without AV node ablation. If the ventricular response cannot be controlled or the medications cannot be tolerated, AV node ablation will prevent rapid ventricular response, and a permanent pacemaker will prevent bradycardia. After ablation and pacemaker placement, quality-of-life scores are greatly improved.

Patients who are active and have atrial fibrillation with a rapid ventricular response, and who get an inadequate therapeutic response to rate-control agents, should be considered for isolation and radiofrequency ablation of the pulmonary veins. For these patients with permanent atrial fibrillation, a more extensive procedure is required, which includes a left atrial roof ablation line, mitral annulus ablation line, coronary sinus isolation, tricuspid annulus ablation line, and isolation of the superior and inferior vena cava. Sinus rhythm can be restored in more than half of patients. Because atrial fibrillation can be due to numerous pathophysiologic factors and because multiple sites for initiation of atrial fibrillation often exist in a single individual, radiofrequency ablation has been challenging, as indicated by the success rates cited here. It is anticipated that with continued investigation and technologic advances, therapeutic outcomes in this area will continue to improve.

Inappropriate sinus tachycardia refers to sinus tachycardia occurring in the absence of provoking factors, including hyperthyroidism, fever, and systemic diseases. It is a frustrating and debilitating condition; patients complain of sudden rapid increases in heart rate with minimal or no physical activity. Initially, β -blocker or calcium channel blocker alone or in combination may be used. If symptoms persist despite use of maximally tolerated doses, an RFA of the superior portion of the sinus node may be considered.

In some individuals with inappropriate sinus tachycardia, head-up tilt testing will reveal a rapid increase in heart rate upon changing from a supine position to a 70-degree upright position. This condition is called *postural orthostatic tachycardia syndrome* (POTS). Ablation of the sinus node in the setting of POTS may worsen the condition. Preliminary studies suggest that an immunologic mechanism may be responsible for POTS.

The use of ICDs has significantly reduced arrhythmic death from VT. The largest potential target group includes patients with VT due to prior myocardial infarction. In the

recent past, guidelines limited ICD implantation in this group of patients and were stringent, requiring demonstration of nonsustained VT in the setting of left ventricular dysfunction due to a previous myocardial infarction and a positive electrophysiology study for inducible VT before ICD placement. As a result of recent studies, ICD placement is now recommended in a much larger group of at-risk patients. Primary prevention of sudden cardiac death has been confirmed with the publication of a number of randomized studies. ICD placement is now recommended in patients with either an ischemic cardiomyopathy or a dilated cardiomyopathy who have a left ventricular EF of less than 35%, as well as in those presenting with VT or resuscitated VF.

VT most commonly presents in patients with left ventricular dysfunction (Fig. 36-4), although there are less common types of VT that present with normal left ventricular function (see later). If an abnormal EF is documented, the patient should have a cardiac catheterization with calculation of cardiac output and coronary angiography. Revascularization should precede placement of an ICD. Despite the use of antiarrhythmic agents and an ICD, some patients may also require RFA of the VT circuit. Patients presenting with syncope in the presence of left ventricular dysfunction should be considered to have VT and have an ICD placed.

In patients with a normal echocardiogram, the VT may originate from a focus located in the right ventricular outflow tract or the left ventricle, and may be verapamil or adenosine sensitive. RFA is a curative option for these patients.

Patients with VF that occurs outside the setting of an acute myocardial infarction should receive an ICD (see Fig. 36-4).

In those patients who have an ICD indication and a QRS duration of more than 120 milliseconds and CHF, a biventricular ICD should be placed. This has been shown to significantly improve the quality of life and exercise duration and decreases rehospitalization and mortality.

Symptomatic patients with *complete heart block*, *second-degree Mobitz type II AV block*, and *sinus pauses* should receive a permanent pacemaker. Asymptomatic patients with prolonged PR intervals, sinus bradycardia, or second-degree Mobitz type I AV block (Wenckebach) should not receive a pacemaker (see Fig. 36-2). Also, a *bifascicular block* (bundle branch block in the context of left anterior fascicular block or left posterior fascicular block) in asymptomatic individuals should be observed, rather than referred for pacemaker implantation. However, patients with bifascicular block, who present with syncope in the absence of any identifying cause, should undergo pacemaker placement.

Premature ventricular complexes without left ventricular dysfunction should be managed conservatively, as should *premature atrial complexes*. Because caffeine, sleep deprivation, and alcohol can all increase the frequency of premature ventricular and atrial complexes, patients should be

Figure 36-4 Ventricular Rhythms II.

QRS >100 ms (continued)

No P waves (ventricular impulse origin)

Rate <40/minute: idioventricular rhythm

Rate 40 to 120/minute: accelerated idioventricular rhythm (AIVR)

Short bursts (usually <20 seconds) of AIVR, often a few days after myocardial infarction. Usually asymptomatic with no progression to ventricular tachycardia or ventricular fibrillation

Rate >120/minute: ventricular tachycardia

Rapid, bizarre, wide QRS complexes

Ventricular fibrillation

Coarse fibrillation

Fine fibrillation

Pacer rhythm

Transvenous pacemaker produces beat in right ventricle. Not supraventricular, and therefore wide QRS

Pacemaker spike (may be small; sometimes missed)

F. Netter M.D.

encouraged to cease or limit these. Regular exercise can reduce the frequency of premature ventricular and atrial complexes.

Congenital long QT syndrome is an inherited condition that presents with syncope or sudden death. Exercise-induced symptoms are a particular cause for concern. Frequently, a family history of similar episodes will be found. Management includes β -blockers, dual-chamber pacemaker with a lower rate at 85 beats per minute, or an ICD.

Patients with *Brugada syndrome* are at risk for sudden cardiac death. Symptomatic individuals should receive an ICD; asymptomatic individuals with an abnormal ECG pattern may undergo an electrophysiology study, and, if results are positive, may have an ICD placed.

More recently, the *short QT syndrome* and *catecholamine-induced polymorphic VT* have been recognized. These conditions are associated with sudden cardiac death and may need an ICD with or without an antiarrhythmic agent.

In all these instances, referral to a cardiac electrophysiologist is recommended for management.

Avoiding Treatment Errors

Many opportunities for error exist in the treatment of patients with symptomatic arrhythmias. In some circumstances, a failure to pursue adequate evaluation represents a preventable error. For instance, occasional patients with SVT are only diagnosed after years of being treated ineffectively for panic attacks. Similarly, it is important to recognize the increased risk for individuals with significant LV dysfunction and syncope. These individuals are best treated with ICD placement.

In elderly patients with atrial fibrillation, physicians may overestimate the relative risk of warfarin therapy versus its protective effect against thromboembolic events. In reality, although elderly individuals are indeed at increased risk for both falls (and if anticoagulated, bleeding due to their injury) and gastrointestinal bleeding, their risk for having a devastating life-altering stroke is much greater. Unless there is a history of falls or of gastrointestinal bleeding, most elderly patients with atrial fibrillation will benefit from anticoagulation with warfarin.

An INR below 2 is associated with an increased risk for stroke and is not associated with a decreased risk for hemorrhage. Once a decision is made to start anticoagulation for atrial fibrillation, an INR in the 2 to 3 range should be the goal for all patients. In patients at high risk for stroke, soluble aspirin and clopidogrel are not an acceptable alternative to therapeutic warfarin. Finally, in regard to rate control in atrial fibrillation, it is important to objectively assess the efficacy of the medical regimen being used.

Before the final decision-making analysis, whether for ICD placement, radiofrequency ablation, pharmacologic therapy, or warfarin therapy for atrial fibrillation in elderly patients, it is essential to define the patient's wishes and the family's preferences.

Future Directions

Further improvements in ablation technology for atrial fibrillation will greatly simplify the procedure and increase its safety and efficacy. ICD technology continues to evolve and improve the quality of life of patients who previously were at high risk for arrhythmic death. Cardiac resynchronization therapy with atrio-biventricular pacing in patients with CHF and prolonged intraventricular conduction (wide QRS complexes) is now a very effective therapy in this

group of severely impaired and debilitated patients. Current device studies are examining the role of biventricular device placement in the prevention of CHF progression in patients receiving an ICD who have wide QRS complexes (the REsynchronization reVErses Remodeling in Sytolic left vEntricular dysfunction (REVERSE) study).

Atrial Fibrillation

Introduction

Atrial fibrillation, the most common arrhythmia in adults and elderly people, occurs in response to a myriad of conditions. The irregular pulse found with mitral valve disease, described as *delirium cordis*, was once the most common manifestation of atrial fibrillation. With the decreasing prevalence of rheumatic fever, other causes of atrial fibrillation now far surpass mitral valve disease. Moreover, it is understood that patients with atrial fibrillation have substantially increased morbidity and mortality.

The prevalence of atrial fibrillation is increasing worldwide, particularly as populations age. Atrial fibrillation is uncommon in infants and children and becomes increasingly common with age. Of adults younger than 55 years, less than 0.1% have atrial fibrillation, whereas 4% of individuals older than 60 years and about 10% of those older than 80 years have atrial fibrillation. It is estimated that more than 2 million U.S. adults have atrial fibrillation; by the midpoint of the 21st century, that number may exceed 5.5 million, with more than 50% being older than 80 years. Patients with atrial fibrillation have a 1.5- to 2.0-fold increased mortality risk, compared with age- and disease-matched controls, and a markedly increased risk for embolic events and congestive heart failure (CHF), according to data from the Framingham Study.

Etiology and Pathogenesis

Many factors predispose the heart to atrial fibrillation (Box 37-1; Fig. 37-1), including structural abnormalities (such as valvular heart disease), systolic or diastolic dysfunction, CHF, hypertension, diabetes, and myocardial infarction. Other conditions associated with an increased prevalence of atrial fibrillation include acute or chronic alcohol ingestion, hyperthyroidism or hypothyroidism, and alterations in vagal or sympathetic tone. Of patients with atrial fibrillation, less than 10% are classified as having *lone atrial fibrillation*, that is, no clinical, electrocardiographic, or echocardiographic evidence of structural heart disease and none of the predisposing factors cited earlier.

No single electrical mechanism causes atrial fibrillation. Early investigators proposed multiple reentrant waves (or wavelets) to indicate that these small multiple waves initiate in the atrium, spreading and coalescing to form small circuits of reentrant electrical activity. The short and variable wavelengths of these activities preclude organized atrial electrical activity and result in atrial fibrillation. It has been found that rapid, repetitive impulse generation by atrial myocytes located near the orifice of the pulmonary veins stimulates atrial fibrillation. Moreover, atrial

fibrillation begets atrial fibrillation. Anatomic remodeling, disruption of electrical circuits, and cellular damage and fibrosis result from chronic atrial fibrillation, all decreasing the likelihood of a return to normal sinus rhythm.

More recently, triggers, which initiate, and rotors, which maintain atrial fibrillation, have been identified. Ganglionic plexuses, a complex and extensive neuronal network, have been demonstrated in atrial tissue. Electrical activity from these plexuses can result in abnormal (fractionated) electrograms that are important in continued atrial fibrillation. Ablation of these electrograms is often associated with successful termination of atrial fibrillation.

Clinical Presentation

The clinical presentation of patients with atrial fibrillation varies. Some patients are asymptomatic. The diagnosis of atrial fibrillation may be made on a regular annual examination or as an incidental finding during the evaluation of a patient being seen for a different (sometimes related) illness. Others patients with atrial fibrillation note sensations that reflect the irregularity of the rhythm, often indistinguishable from frequent ventricular or atrial pre-

mature contractions. These symptoms may range from noticeable but not bothersome to nerve-racking. Occasionally, a patient presents for evaluation of bradycardia diagnosed by the patient or someone who recorded a slow radial pulse rate (that underestimates the true heart rate). Still others present with symptoms reflecting decreased cardiac output, which occurs when atrial fibrillation replaces normal sinus rhythm; these symptoms range from fatigue to shortness of breath at rest or with activity, to chest pain. Severe symptoms and physical examination findings of CHF occasionally are found in patients with new-onset atrial fibrillation. Finally, the first manifestation of atrial fibrillation may be the devastating effects of a cerebrovascular accident/transient ischemic attack (CVA/TIA).

Diagnostic Approach

The history, physical examination, electrocardiogram, and a variety of laboratory and cardiovascular tests are commonly employed in the initial evaluation of atrial fibrillation. Upon presentation, most patients can be classified into one of four categories, as recommended by a joint task force of the American College of Cardiology, the American Heart Association, and the European Society of Cardiology: paroxysmal, persistent, permanent, or lone atrial fibrillation. Treatment differs among the four groups.

1. *Paroxysmal atrial fibrillation* is described as episodes of atrial fibrillation that last less than a week (and often less than 24 hours), self-terminate, and are usually recurrent.
2. *Persistent atrial fibrillation* lasts more than a week, does not self-terminate, and may recur after cardioversion.
3. *Permanent atrial fibrillation* is diagnosed if atrial fibrillation has lasted more than a year, has been refractory to cardioversion, or both.
4. *Lone atrial fibrillation* can be paroxysmal, persistent, or permanent atrial fibrillation in the absence of structural heart disease.

In addition to classifying the atrial fibrillation, the history and physical examination should focus on clues to the underlying cause. Symptoms and examination findings relevant to the conditions that predispose to atrial fibrillation (as listed previously) should be sought. It is important to seek evidence for complications of atrial fibrillation, including presyncopal symptoms (especially with initiation or termination of atrial fibrillation), decreased cardiac output, and thromboembolism (including transient ischemic attacks, evidence of peripheral embolization, or both). An ophthalmoscopic examination may reveal retinal artery embolism in some patients with atrial fibrillation. Patients at highest risk for atrial fibrillation with rapid ventricular response, including those with accessory pathways (Wolff-Parkinson-White syndrome) or dilated cardiomyopathy, can present with frank syncope or even sudden cardiac death.

The electrocardiogram can confirm atrial fibrillation, heart rate, and the presence of underlying structural heart disease, such as chamber enlargement or (hypertrophy), prior myocardial infarction, and conduction abnormalities. The transthoracic echocardiogram is an essential part of a complete evaluation, particularly in patients being considered for cardioversion. Underlying structural contributors to atrial fibrillation and left atrial size, a predictor of short- and long-term success in cardioversion, should be examined by echocardiography. Transesophageal echocardiography is indicated in some settings to document, before cardioversion, the presence or absence of thrombi in the left atrium or the left atrial appendage. Laboratory testing should be performed to evaluate thyroid status and screen for electrolyte abnormalities. Additional testing may include functional assessment for coronary heart disease (exercise or pharmacologic stress testing with or without imaging) and even coronary angiography. Electrophysiology studies are not indicated as part of the initial evaluation but are indicated when radiofrequency ablation of potential atrial fibrillation sites is being considered. An electrophysiology study may also be considered for younger patients with a history of supraventricular tachycardia and a regular rhythm, which has now become more irregular. In this setting, the supraventricular tachycardia may be the trigger for the initiation of atrial fibrillation. Although uncommon, this is an example of tachycardia-induced tachycardia. In this circumstance, radiofrequency ablation of the supraventricular tachycardia can prevent subsequent episodes of atrial fibrillation.

Figure 37-1 Atrial Fibrillation.

Management and Therapy

Treatment of atrial fibrillation largely depends on symptoms and the cause of the atrial fibrillation (Figs. 37-2 to 37-4). Are the symptoms related to atrial fibrillation tolerable or intolerable to the patient? Has atrial fibrillation resulted in an unfavorable hemodynamic picture that may have long-term consequences? Have embolic events occurred, and what is the long-term risk for thromboembolism? Consideration of important issues related to each of these areas can help guide treatment options.

Optimum Treatment

Acute Management of Atrial Fibrillation

Initial management of atrial fibrillation is dependent on ventricular response, blood pressure, evidence of ischemia,

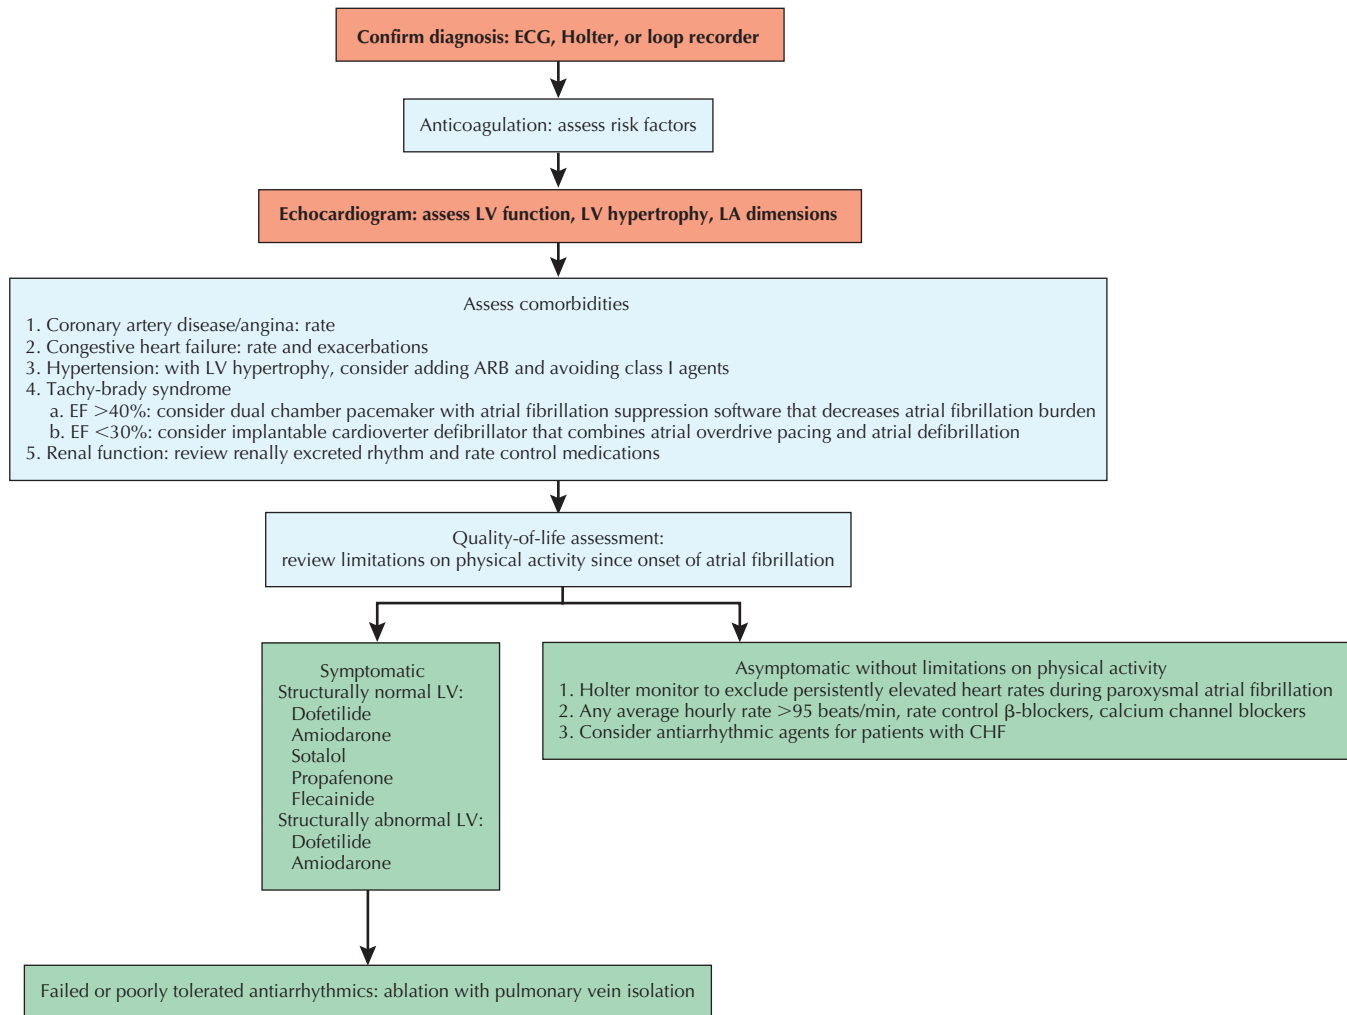

shortness of breath, and cardiogenic shock. Figure 37-2 provides a schematic to management. Once the patient has been stabilized, subsequent evaluation and management depend on age, heart rate, symptoms, etiologic considerations, hypertension, myocardial ischemia, diabetes mellitus, thyroid disease, cerebrovascular accidents, and pulmonary considerations (see Box 37-1 and Figs. 37-2 to 37-4).

Nonacute Management of Atrial Fibrillation

Four major issues must be considered in determining the treatment of atrial fibrillation: conversion from atrial fibrillation to normal sinus rhythm, maintenance of normal sinus rhythm, rate control in patients with chronic atrial

Figure 37-2 Long-term Management of Paroxysmal Atrial Fibrillation.

ARB, angiotensin receptor blocker; CHF, congestive heart failure; ECG, electrocardiogram; EF, ejection fraction; LA, left atrial; LV, left ventricular.

fibrillation, and prevention of thromboembolic complications (Fig. 37-5). These four issues are discussed with special emphasis on controversial factors.

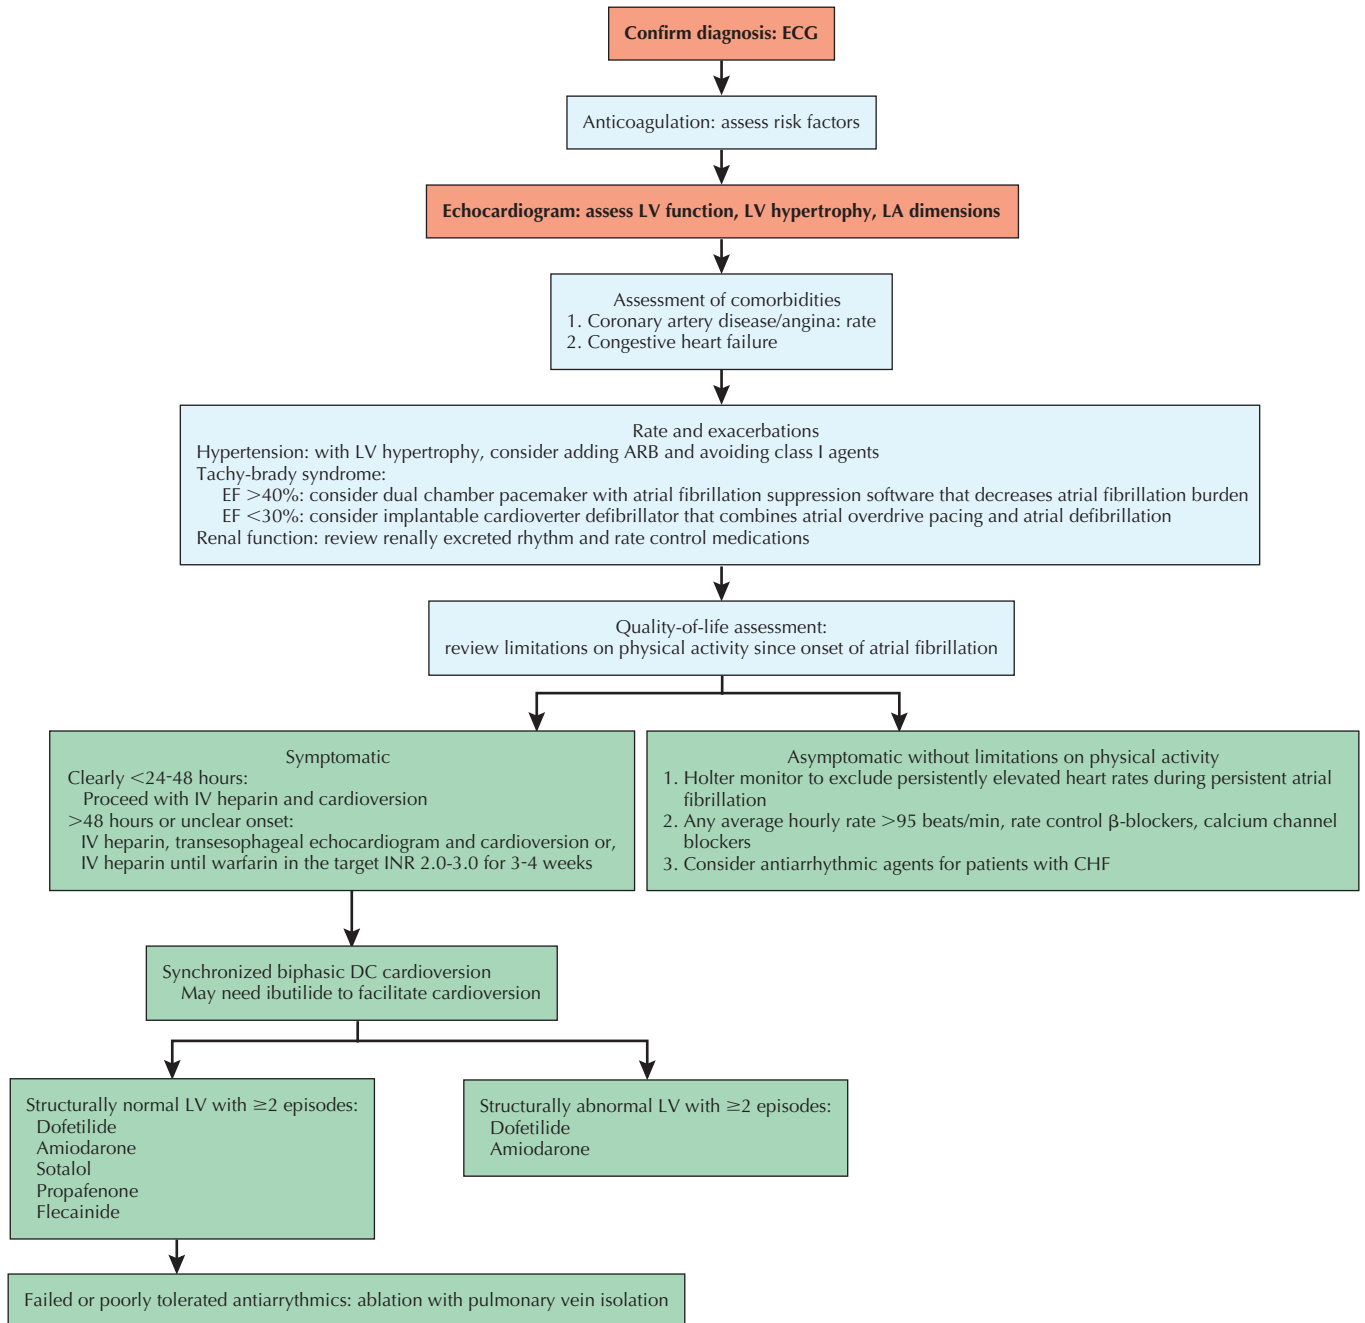

Cardioversion

Cardioversion for atrial fibrillation should be considered in two settings. In patients who present acutely with hemodynamically unstable atrial fibrillation, immediate cardioversion may be indicated. Remember the sinus tachycardia concept: atrial fibrillation with a rapid response may be triggered by an underlying cause. Initially, this cause should be sought and, if necessary, addressed. Other causes of hypotension and tachycardia should be excluded, including hypovolemia, septic shock, acute hemorrhage, profound anemia, and acute myocardial infarction leading to cardiogenic shock. Usually, patients who are hypotensive from atrial fibrillation with a rapid ventricular rate also have underlying cardiovascular disease. After reversible

factors have been addressed, these patients should undergo electrical cardioversion immediately. Rate control with intravenous short-acting β -blockers (esmolol) or calcium channel blockers (diltiazem) can be considered, but in the setting of marked hypotension, these should be cautiously initiated. However, because there is no atrial contraction in atrial fibrillation, the left ventricle (LV) fills passively. Therefore, in patients with a rapid ventricular response, slowing of the ventricular rate allows a more prolonged diastolic filling time and thus may improve cardiac output. In hemodynamically stable patients with myocardial ischemia, either intravenous β -blockers (including esmolol or metoprolol) or calcium channel blockers (diltiazem or verapamil) can be used safely before cardioversion. Neither β -blockers nor calcium channel blockers are effective agents for cardioversion, although spontaneous cardioversion may occur when the heart rate is slowed pharmacologically. There is a growing indication for certain type III

Figure 37-3 Long-term Management of Persistent Atrial Fibrillation.

antiarrhythmic drugs in the urgent treatment of atrial fibrillation. Intravenous ibutilide and amiodarone are safe in this setting, when used with proper monitoring. In some circumstances, class IA agents (intravenous procainamide principally) are recommended in the acute setting, but the advent of ibutilide and amiodarone have largely displaced their use.

The second setting in which cardioversion is considered for atrial fibrillation is in symptomatic (or sometimes even asymptomatic) but stable patients. In this setting, before cardioversion, it is essential to consider the need for anticoagulation (see “Anticoagulation in Atrial Fibrillation”). In general, in uncomplicated cases when the duration of atrial fibrillation is clearly less than 24 hours, anticoagula-

Figure 37-4 Long-term Management of Permanent Atrial Fibrillation.

ARB, angiotensin receptor blocker; ECG, electrocardiogram; LV, left ventricular; LA, left atrial; EF, ejection fraction.

tion is not required before cardioversion. When the duration of atrial fibrillation is more than 48 hours, it is generally recommended that the patient be started on intravenous heparin. Differences of opinion exist about whether to anticoagulate patients who have been in atrial fibrillation for 24 to 48 hours. The more conservative approach (which we adhere to) is to anticoagulate, the same as for patients in whom the duration of atrial fibrillation has been more than 48 hours. An alternative approach uses transesophageal echocardiography to screen for thrombi in the atria or the atrial appendages and proceed with cardioversion if no thrombi are present. In this case, anticoagulation with warfarin for 3 to 4 weeks (International Normalized Ratio [INR], 2.0 to 3.0) is initiated at the time of cardioversion and for at least 1 month afterward. These issues are discussed in the following subsections.

A trend in Europe, but less so in the U.S. is the so-called “pill in the box” strategy in patients at low risk for proarrhythmia is a safe and effective way of pharmacologic cardioversion. Patients who either are on telemetry in the

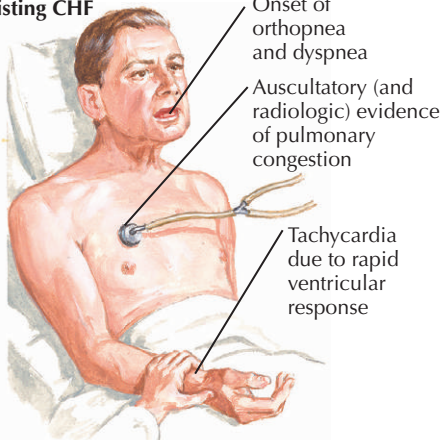

emergency department or in some cases have been shown to have no arrhythmias during prior hospitalizations may take a single dose of propafenone, 600 mg orally, or flecainide, 300 mg orally. Studies in Europe have suggested this approach is safe, but it is not yet endorsed in the United States.

Rhythm Control

The selection of electrical versus pharmacologic cardioversion is often an individualized decision based on the patient’s history and predisposing factors for atrial fibrillation. For instance, patients with paroxysmal or persistent atrial fibrillation are likely to require antifibrillatory medication to maintain sinus rhythm. Obviously, these patients need to be maintained on anticoagulants before chemical cardioversion. The pharmacologic choices for cardioversion are principally amiodarone, sotalolol, and dofetilide. All have advantages and disadvantages. For patients with paroxysmal atrial fibrillation, amiodarone can safely be initiated in the outpatient setting and is probably the most

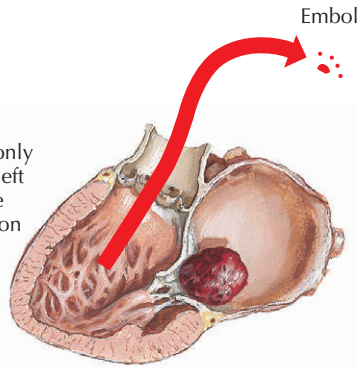

Figure 37-5 Complications of Atrial Fibrillation.

Hemodynamic deterioration in existing CHF

Patients with stable or asymptomatic congestive heart failure may show marked worsening if atrial fibrillation (AF) ensues. Loss of atrial contraction and rapid ventricular heart rate decreases cardiac output and increases congestive symptoms

effective antifibrillatory agent. Even at the low doses used for atrial fibrillation prophylaxis (about 200 mg/day), the side-effect profile of amiodarone requires annual or semi-annual screening for thyroid and hepatic dysfunction and for the rare occurrence of diminishing pulmonary function from early pulmonary fibrosis. Sotalol is also effective and can be particularly beneficial in patients who require β blockade for other reasons, but sotalol should be initiated in an inpatient setting because of unpredictable QT prolongation in some individuals. Dofetilide is a promising agent, but its use also requires 3 days of telemetry monitoring for QT prolongation and torsades de pointes. The initial dofetilide dosage is based on renal function. Subsequent doses are determined by QT response to the previous dose until a steady state is reached.

The decision to use medications in an effort to maintain normal sinus rhythm is common. Indeed, less than one third of patients who are successfully cardioverted maintain normal sinus rhythm for more than a year without antifibrillatory therapy. Many predictors of the potential need for antifibrillatory therapy are known. Sometimes the use of β -blockers can blunt adrenergic drive sufficiently to prevent recurrence of atrial fibrillation, although this is the exception. Many cardiologists favor an initial trial of electrical cardioversion alone in low-risk patients with atrial fibrillation, reasoning that the third of patients who do not require antifibrillatory therapy will be spared the expense and the associated risks. In patients who have an increased risk for recurrent atrial fibrillation, or who have had a second electrical cardioversion, use of the medications dis-

cussed previously (and in Figs. 37-2 and 37-3) is generally indicated for maintenance of normal sinus rhythm. However, this practice has come into question and is discussed later in the section, “Rate versus Rhythm Control.”

The issue of measuring quality of life (QOL) in patients with atrial fibrillation is fraught with methodologic difficulties. Using an intention to treat analysis does not adequately control for the rhythm at time the QOL questionnaire is completed. Likewise, using the rhythm at the time of the QOL questionnaire completion makes comparisons between different treatment strategies extremely difficult to interpret. Several studies have now shown that patients in sinus rhythm have improved QOL scores compared with patients in atrial fibrillation at the time of QOL questionnaire completion.

Rate Control

Many patients with chronic atrial fibrillation are not successfully treated with cardioversion or antiarrhythmic agents, are unwilling to undergo cardioversion, are unable to tolerate antiarrhythmic agents, or have factors that predict that treatment will fail and are minimally symptomatic except at rapid heart rates. For them (see Fig. 37-4), pharmacologic rate control should be considered. β -Blockers, calcium channel blockers, or both can often control rapid heart rates with or without digoxin. Digoxin is particularly useful in controlling atrioventricular (AV) conduction in patients who are minimally active or bedridden from comorbidities. However, because there is considerable overlap between atrial fibrillation and conduction abnormalities, including sinus node dysfunction (sick sinus syndrome), an appropriate balance between tachycardia and bradycardia may be difficult to obtain. These patients may require a permanent pacemaker to prevent bradycardic episodes while being treated with β -blockers, calcium channel blockers, or antifibrillatory medications for tachycardia. Although the initial promise of permanent dual-chamber pacing (or even atrial pacing alone) to prevent atrial fibrillation has not been fulfilled, in patients with episodic atrial fibrillation, dual-chamber pacing with an atrial fibrillation suppression algorithm should be considered when a pacemaker is indicated. Use of ventricular pacing is likely to convert episodic atrial fibrillation into chronic atrial fibrillation. Another special case, discussed later (see “Atrioventricular Node Ablation and Permanent Pacing”), is the patient whose rapid ventricular response is resistant to pharmacologic control or for whom the pharmacologic approach results in intolerable side effects.

Anticoagulation in Atrial Fibrillation

Anticoagulation considerations include anticoagulation during restoration of normal sinus rhythm, chronic anticoagulation, and cessation and restoration of anticoagulation for patients with atrial fibrillation who are undergoing surgical procedures. Consensus panels from the American

College of Cardiology, the American Heart Association, the European Society of Cardiology, and the American College of Chest Physicians have concurred on the use of anticoagulation therapy in the pericardioversion period. In patients with atrial fibrillation of unknown duration, valvular heart disease, evidence of LV dysfunction, or prior thromboembolism, or for whom cardioversion is entirely elective, therapeutic anticoagulation with warfarin (with an INR of 2.0 to 3.0) for 3 to 4 weeks before cardioversion is strongly recommended. Anticoagulation should be continued at the same level for at least 4 weeks after cardioversion. An alternative approach in low-risk patients (lacking any of the criteria listed here) is to assess for atrial or atrial appendage thrombi by transesophageal echocardiography. Lacking thrombi, or a low-flow state (also referred to as “smoke” or spontaneous echocardiographic contrast), the patient can be safely cardioverted without antecedent anticoagulation with warfarin, although many use heparin or low-molecular-weight heparin before cardioversion. These patients do require anticoagulation for 4 to 6 weeks after cardioversion.

Long-term anticoagulation with warfarin is advocated in patients in several settings. Irrespective of the type of atrial fibrillation (paroxysmal, persistent, or permanent), patients at high risk for stroke should be anticoagulated for life. Because many patients have recurrent atrial fibrillation, some episodes of which may not be recognized by the patient, anticoagulation is indicated. Other symptomatic patients may also experience asymptomatic episodes of atrial fibrillation that predispose to embolic events, even when they are in sinus rhythm. Finally, in patients with chronic atrial fibrillation, five large prospectively randomized studies demonstrated that warfarin reduced the risk for stroke by 45% to 82%. The use of aspirin remains controversial for patients at low risk for stroke (lone atrial fibrillation) or for patients with increased risk for bleeding in whom warfarin may be contraindicated.

Avoiding Treatment Errors

The three most common types of errors in treatment of patients with atrial fibrillation are (1) failure to recognize an underlying, potentially reversible cause of atrial fibrillation; (2) failure to consider potential drug interactions that could lead to bradycardia in patients with atrial fibrillation treated with AV node blocking drugs; and (3) failure to rigorously monitor and adjust anticoagulant therapy, leading to either excess bleeding or thrombus formation. Although these complications cannot be completely avoided, with careful and conscientious physician oversight, the risk for one of these complications can be minimized. All patients with atrial fibrillation should have a comprehensive evaluation before initiation of therapy. Upon initiation of therapy with AV node blocking drugs, all concurrent therapies should be reviewed, and patients should be followed closely. Finally, difficulty with antico-

agulant therapies can largely be avoided by using standardized protocols and, for difficult to control patients, referral to an anticoagulation clinic.

Special Issues

Because atrial fibrillation represents a diverse group of etiologies and risks, several special issues merit further discussion.

Lone Atrial Fibrillation

By definition, *lone atrial fibrillation* occurs in individuals younger than 60 years who lack evidence of other cardiovascular diseases, including structural heart disease, hypertension, or diabetes. This definition has been refined with the use of echocardiography to confirm the lack of structural heart disease, even including mild mitral valve regurgitation, left atrial enlargement, and LV hypertrophy. The general experience in patients with lone atrial fibrillation is that their risk for stroke is low, anticoagulation is unnecessary for stroke prophylaxis, and further treatment for atrial fibrillation is probably also not necessary. As lone atrial fibrillation has become more clearly defined, this trend holds. Questions that remain include: How often should individuals carrying the diagnosis of lone atrial fibrillation have echocardiography to be certain that structural abnormalities are still absent? Should patients with lone atrial fibrillation be given aspirin? There are no studies that answer these questions. In general, patients with lone atrial fibrillation should be seen at least annually to document that stroke risk factors, including hypertension and diabetes, are still absent, and echocardiography and Holter monitoring should be performed annually to ascertain that there is no evidence of tachycardia-induced cardiomyopathy. The results of studies are mixed on the role of aspirin in patients with lone atrial fibrillation, and there is no consensus for its use. However, given the epidemiologic data supporting the use of low-dose aspirin (81-325 mg per day, as tolerated) in lessening long term risk for stroke and myocardial infarction in patients from age 40 on, low-dose aspirin is often recommended in patients with lone atrial fibrillation.

Nonpharmacologic Approaches to Preventing Atrial Fibrillation

Surgical and percutaneous approaches exist for the treatment of atrial fibrillation (Fig. 37-6; and see Figs. 37-2 to 37-4). In the past, two landmark surgical approaches led the way for the current understanding of the critical role of the pulmonary veins in the initiation and maintenance of atrial fibrillation. The best-studied surgical approaches are the corridor and maze procedures. In the *corridor procedure*, a corridor of atrial tissue is surgically isolated between the sinus and the AV nodes from the rest of the atria, providing chronotropic rate control and demonstrat-

ing an increased ability to maintain normal sinus rhythm. In the *maze procedure*, small incisions are made to effectively interrupt reentrant atrial arrhythmias and prevent sustained atrial fibrillation, while providing one pathway from the sinus node to the AV node and simultaneously activating the right and left atria. The concept behind both of these procedures is maintenance of normal sinus rhythm and atrial systole. Although both procedures are effective, they both require open chest surgery, usually require continued anticoagulation, are complicated by the frequent need for permanent pacing, and, hence, are indicated only for a small portion of patients with atrial fibrillation, principally those with a planned cardiac surgical procedure for other reasons (coronary or valvular heart disease). Currently, a modified procedure is employed that isolates the pulmonary veins and adds an ablation line from the veins to the mitral valve annulus.

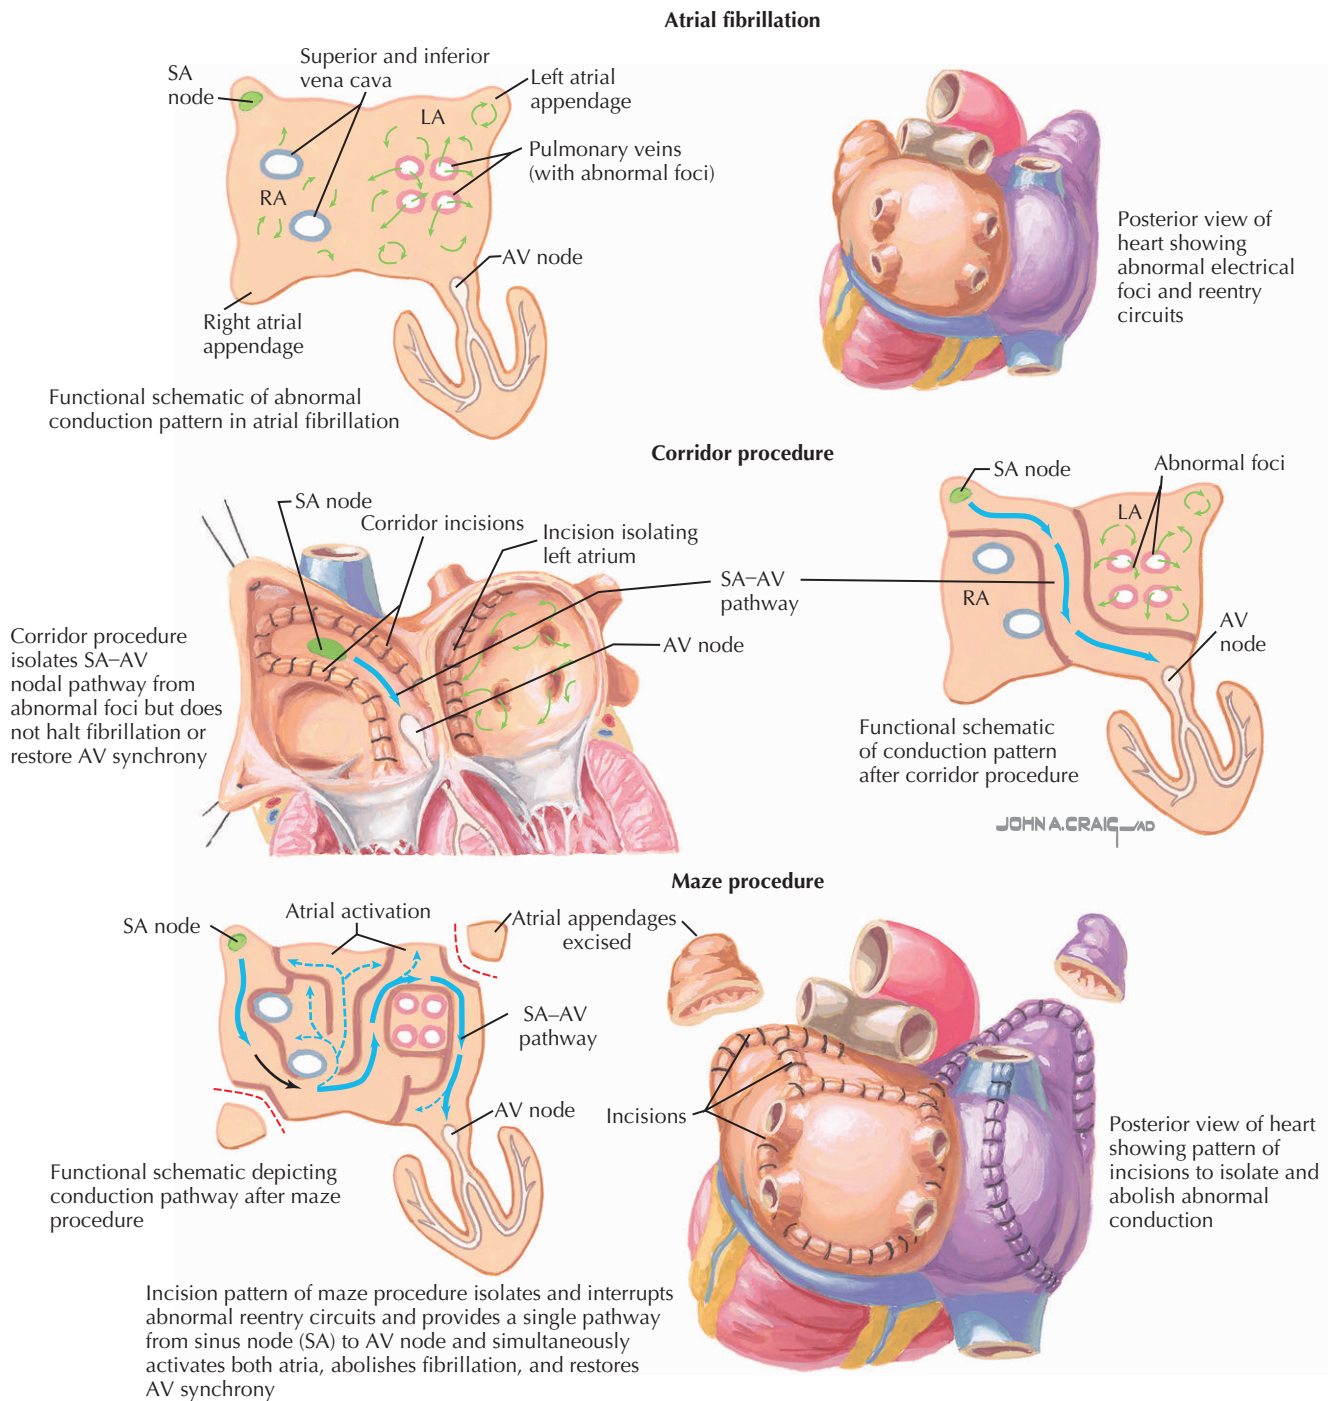

Radiofrequency catheter ablation of atrial fibrillation isolates foci of early depolarizing atrial cells in the cuffs of the pulmonary veins and has a success rate of 70% to 80% of individuals who are free of atrial fibrillation and off all antiarrhythmic agents. Recurrent atrial fibrillation, risk for thromboembolic episodes, cardiac tamponade, infrequent pulmonary vein stenosis, and rarely an atriopharyngeal fistula make the procedure technically challenging. The use of advanced mapping techniques has undoubtedly improved the efficacy of radiofrequency catheter ablation, which is recommended in cases in which pharmacotherapy has failed or is not tolerated and other approaches are unsuitable. Imaging of the left atrium using computed tomographic angiography or magnetic resonance angiography can now be merged with data obtained by electrophysiologic mapping to provide a three-dimensional view that improves the accuracy of ablation. Newer catheter technologies and a better understanding and identification of electrogram targets will allow for an easier and more reliable ablation procedure. In the future, stereotactic technology will likely make atrial fibrillation ablation procedures faster and more effective.

Frequently because of coexistent sinus node dysfunction, tachy-brady syndrome, or excessive bradycardia caused by medications, a permanent pacemaker is indicated. For patients with paroxysmal or persistent atrial fibrillation (see Figs. 37-2 and 37-3), a pacemaker that combines atrial suppression software should be considered. These pacemakers prevent atrial sensing by pacing at rates faster than the underlying atrial rhythm. In clinical trials, these pacemakers reduced atrial fibrillation burden by up to 25%. Dual-chamber pacemakers are superior to ventricular pacemakers in preventing the development of atrial fibrillation.

Rate versus Rhythm Control

On the basis of hemodynamic studies, it has been assumed that patients with normal sinus rhythm fare better than do

Figure 37-6 Surgical Management of Atrial Fibrillation.

those with atrial fibrillation but well-controlled ventricular rates. Two studies call into question this conventional wisdom. In both, rhythm control did not provide a survival advantage over rate control in terms of symptoms, risks for stroke, or other morbidities. The groups were highly selected and minimally symptomatic, and there was considerable crossover, such that a statistically significant portion of the rate control group was actually in normal

sinus rhythm at the conclusion of the study, creating a significant negative impact on the power of the study. In addition, patients at higher risk for hemodynamic compromise were largely excluded from these studies. Although we await a final answer to the debate on rate versus rhythm control, these studies clearly demonstrate that rhythm control is a more viable option than it was previously considered to be.

Atrioventricular Node Ablation and Permanent Pacing

Consistent with the idea that rhythm control is a useful approach, several studies demonstrated remarkable symptom reduction in patients with atrial fibrillation and refractory rapid ventricular response by making these patients pacemaker dependent. In essence, the patient undergoes radiofrequency catheter ablation of the AV node and implantation of a permanent pacemaker. Depending on the likelihood of restoring normal sinus rhythm, a dual-chamber pacemaker may be used, or in cases where that likelihood is low, a single-chamber ventricular pacemaker is implanted. Studies support the rationale that the rapid ventricular response resulting from atrial fibrillation can be effectively eliminated for selected patients. There may also be a reversal of tachycardia-induced cardiomyopathy, with improvement in LV ejection fraction. Uniformly for patients with permanent atrial fibrillation, QOL scores and exercise tolerance improve and rehospitalization and resource utilization decrease following AV node ablation and permanent pacemaker placement.

Currently, the procedure of “ablate and pace” is reserved for patients with permanent atrial fibrillation, who are not candidates or do not wish to have pulmonary vein isolation performed. Many will already have a single-lead ventricular (VVI) pacemaker. In patients undergoing a *de novo* procedure, a few small studies have shown that biventricular pacing is superior to right ventricular pacing only.

Congestive Heart Failure

Atrial fibrillation occurs in 15% to 30% of patients with CHF. In these patients, atrial fibrillation can lead to hemodynamic deterioration and rehospitalization, with worsening of symptoms in patients with existing heart failure. The rapid heart rate and loss of atrial contraction can precipitate an exacerbation of CHF in patients with asymptomatic stable LV dysfunction. These changes can be reversed with rate control or reversion to sinus rhythm. It appears that patients with more severe CHF (New York Heart Association class III and IV) and atrial fibrillation have higher all-cause mortality and pump failure deaths. In patients with milder forms of CHF (New York Heart Association class I and II), however, atrial fibrillation was not associated with an increase in mortality or rehospitalization. Class I antiarrhythmic agents are independently associated with an increased mortality in patients with CHF and atrial fibrillation and should be avoided. Amiodarone and dofetilide are safe for patients with CHF. Optimal pharmacologic therapy may play a favorable role in influencing the outcomes for these patients. Even in patients at highest risk with atrial fibrillation and severe CHF, it has not been shown that maintenance of sinus rhythm with antiarrhythmic agents improves survival. Since the emergence of isolation of the pulmonary veins even for patients with permanent atrial fibrillation of several years' duration, this

procedure has been shown to improve QOL, LV ejection fraction, and symptoms.

Implantable Atrial Defibrillation

Between 20% and 30% of patients have coexisting atrial fibrillation at the time of placement of an implantable cardioverter-defibrillator (ICD). Seventeen months after placement of an ICD, up to 45% of patients have atrial fibrillation. The latest ICDs also incorporate atrial conversion therapy, which includes atrial overdrive antitachycardia pacing, atrial high-frequency burst pacing, and atrial defibrillation. These devices are safe and efficacious. Therefore, an ICD with atrial therapies should be considered for patients with atrial fibrillation or the potential to develop atrial fibrillation.

Coronary Artery Bypass Surgery

Atrial fibrillation is frequently seen in patients after coronary artery bypass graft (CABG) surgery. Up to 40% of patients are estimated to develop atrial fibrillation, usually beginning after postoperative day 1 and lengthening the hospital stay. Older patients and those who have β -blockers withdrawn before surgery are more likely to develop atrial fibrillation. Use of β -blockers or amiodarone preoperatively decreases the frequency of postoperative atrial fibrillation. Interestingly, atrial fibrillation is a transient phenomenon; most patients are in sinus rhythm when discharged. Only a minority, less than 5%, are in atrial fibrillation 30 days after surgery.

Ablation has been performed during CABG in patients undergoing mitral valve surgery. The four pulmonary veins are isolated with either radiofrequency ablation or cryoablation. In some circumstances, the ablation line is extended to the mitral valve annulus, with reportedly fewer episodes of recurrence of atrial fibrillation. Early studies showing sinus rhythm maintenance have been encouraging, even in patients with permanent atrial fibrillation before surgery.

Postmortem studies have identified the left atrial appendage as the most likely source for the development of thrombus in patients with atrial fibrillation. This has been confirmed in a large series of patients who underwent transesophageal echocardiogram before cardioversion. Percutaneous approaches have been developed that aim to isolate the left atrial appendage from the left atrium in an attempt to prevent the development of thrombus in patients who cannot take warfarin. During CABG or valve surgery, many surgeons either remove the appendage or oversuture the orifice of the appendage, thereby preventing flow and stasis in the appendage.

Hypertension

Two recent antihypertensive studies, Losartan Intervention for End Point Reduction in Hypertension (LIFE) and

Valsartan Antihypertensive Long-term Use Evaluation (VALUE), have shown prospective observational data suggesting a significant decrease in the prevalence of atrial fibrillation in patients treated with the angiotensin receptor blockers (ARBs) losartan and valsartan. These agents were compared with atenolol in the LIFE study and amlodipine in the VALUE study. In both studies, there was either a similar or slightly better control of blood pressure with atenolol and amlodipine. However, despite adequate blood pressure control, significantly fewer patients taking ARBs developed atrial fibrillation. Several possible explanations may account for these observations. The antifibrotic and anti-inflammatory effects associated with ARBs, as well as a more favorable effect on LV remodeling, may facilitate a reverse remodeling of the left atrium, thereby decreasing the propensity to develop atrial fibrillation. This hypothesis is being tested prospectively in the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) irbesartan trial.

Future Directions

Advances in the treatment of atrial fibrillation hold promise. Newer antifibrillatory agents are in development, as are anticoagulants that will be easier to administer and safer than warfarin. Although the oral thrombin inhibitor ximelagatran was shown to be comparable to warfarin in anticoagulant efficacy, there was an unexplained and unexpected elevation in liver function tests. Newer oral thrombin inhibitors are currently being studied. Exciting nonpharmacologic therapies are undergoing testing and early clinical use, including implantable atrial defibrillators and pacemakers (with the rationale that early conversion of atrial fibrillation to normal sinus rhythm facilitates maintenance of normal sinus rhythm), newer mapping, and more sophisticated percutaneous approaches. Eventually, it may be possible to cure atrial fibrillation, much as radiofrequency catheter ablation can now cure supraventricular tachycardias in many and maintain normal sinus rhythm in most. Percutaneous left atrial appendage transcatheter occlusion devices, which are easier to implant, are being evaluated in clinical trials at present. This is an attractive strategy for patients who cannot or will not take warfarin or for patients who have embolic episodes while taking warfarin. Early clinical data suggest that patients with closure devices have lower than expected CVA/TIA rates based on their Congestive heart failure, Hypertension, Age, Diabetes (CHAD) score risk estimates. Randomized data comparing appendage closure devices with warfarin treatment with an INR of 2 to 3 in patients with a high risk for thromboembolism are awaited.

The Losartan Intervention for End Point Reduction in Hypertension (LIFE) study compared the effects of losartan and atenolol on new-onset AF. This study concluded that losartan-based antihypertensive therapy (as compared with atenolol-based antihypertensive therapy) significantly reduced new-onset AF and associated stroke.

6. Wyse DG, Waldo AL, DiMarco JP, et al: A comparison of rate control and rhythm control in patients with atrial fibrillation. *N Engl J Med* 347(23):1825-1833, 2002.

This study compared the two approaches, rate and rhythm control, in the management of AF. There was no significant difference in survival between the two therapies. Patients randomized to rate control did have a lower risk for adverse drug effects.

Atrial Fibrillation

Introduction

Atrial fibrillation, the most common arrhythmia in adults and elderly people, occurs in response to a myriad of conditions. The irregular pulse found with mitral valve disease, described as *delirium cordis*, was once the most common manifestation of atrial fibrillation. With the decreasing prevalence of rheumatic fever, other causes of atrial fibrillation now far surpass mitral valve disease. Moreover, it is understood that patients with atrial fibrillation have substantially increased morbidity and mortality.

The prevalence of atrial fibrillation is increasing worldwide, particularly as populations age. Atrial fibrillation is uncommon in infants and children and becomes increasingly common with age. Of adults younger than 55 years, less than 0.1% have atrial fibrillation, whereas 4% of individuals older than 60 years and about 10% of those older than 80 years have atrial fibrillation. It is estimated that more than 2 million U.S. adults have atrial fibrillation; by the midpoint of the 21st century, that number may exceed 5.5 million, with more than 50% being older than 80 years. Patients with atrial fibrillation have a 1.5- to 2.0-fold increased mortality risk, compared with age- and disease-matched controls, and a markedly increased risk for embolic events and congestive heart failure (CHF), according to data from the Framingham Study.

Etiology and Pathogenesis

Many factors predispose the heart to atrial fibrillation (Box 37-1; Fig. 37-1), including structural abnormalities (such as valvular heart disease), systolic or diastolic dysfunction, CHF, hypertension, diabetes, and myocardial infarction. Other conditions associated with an increased prevalence of atrial fibrillation include acute or chronic alcohol ingestion, hyperthyroidism or hypothyroidism, and alterations in vagal or sympathetic tone. Of patients with atrial fibrillation, less than 10% are classified as having *lone atrial fibrillation*, that is, no clinical, electrocardiographic, or echocardiographic evidence of structural heart disease and none of the predisposing factors cited earlier.

No single electrical mechanism causes atrial fibrillation. Early investigators proposed multiple reentrant waves (or wavelets) to indicate that these small multiple waves initiate in the atrium, spreading and coalescing to form small circuits of reentrant electrical activity. The short and variable wavelengths of these activities preclude organized atrial electrical activity and result in atrial fibrillation. It has been found that rapid, repetitive impulse generation by atrial myocytes located near the orifice of the pulmonary veins stimulates atrial fibrillation. Moreover, atrial

fibrillation begets atrial fibrillation. Anatomic remodeling, disruption of electrical circuits, and cellular damage and fibrosis result from chronic atrial fibrillation, all decreasing the likelihood of a return to normal sinus rhythm.

More recently, triggers, which initiate, and rotors, which maintain atrial fibrillation, have been identified. Ganglionic plexuses, a complex and extensive neuronal network, have been demonstrated in atrial tissue. Electrical activity from these plexuses can result in abnormal (fractionated) electrograms that are important in continued atrial fibrillation. Ablation of these electrograms is often associated with successful termination of atrial fibrillation.

Clinical Presentation

The clinical presentation of patients with atrial fibrillation varies. Some patients are asymptomatic. The diagnosis of atrial fibrillation may be made on a regular annual examination or as an incidental finding during the evaluation of a patient being seen for a different (sometimes related) illness. Others patients with atrial fibrillation note sensations that reflect the irregularity of the rhythm, often indistinguishable from frequent ventricular or atrial pre-

mature contractions. These symptoms may range from noticeable but not bothersome to nerve-racking. Occasionally, a patient presents for evaluation of bradycardia diagnosed by the patient or someone who recorded a slow radial pulse rate (that underestimates the true heart rate). Still others present with symptoms reflecting decreased cardiac output, which occurs when atrial fibrillation replaces normal sinus rhythm; these symptoms range from fatigue to shortness of breath at rest or with activity, to chest pain. Severe symptoms and physical examination findings of CHF occasionally are found in patients with new-onset atrial fibrillation. Finally, the first manifestation of atrial fibrillation may be the devastating effects of a cerebrovascular accident/transient ischemic attack (CVA/TIA).

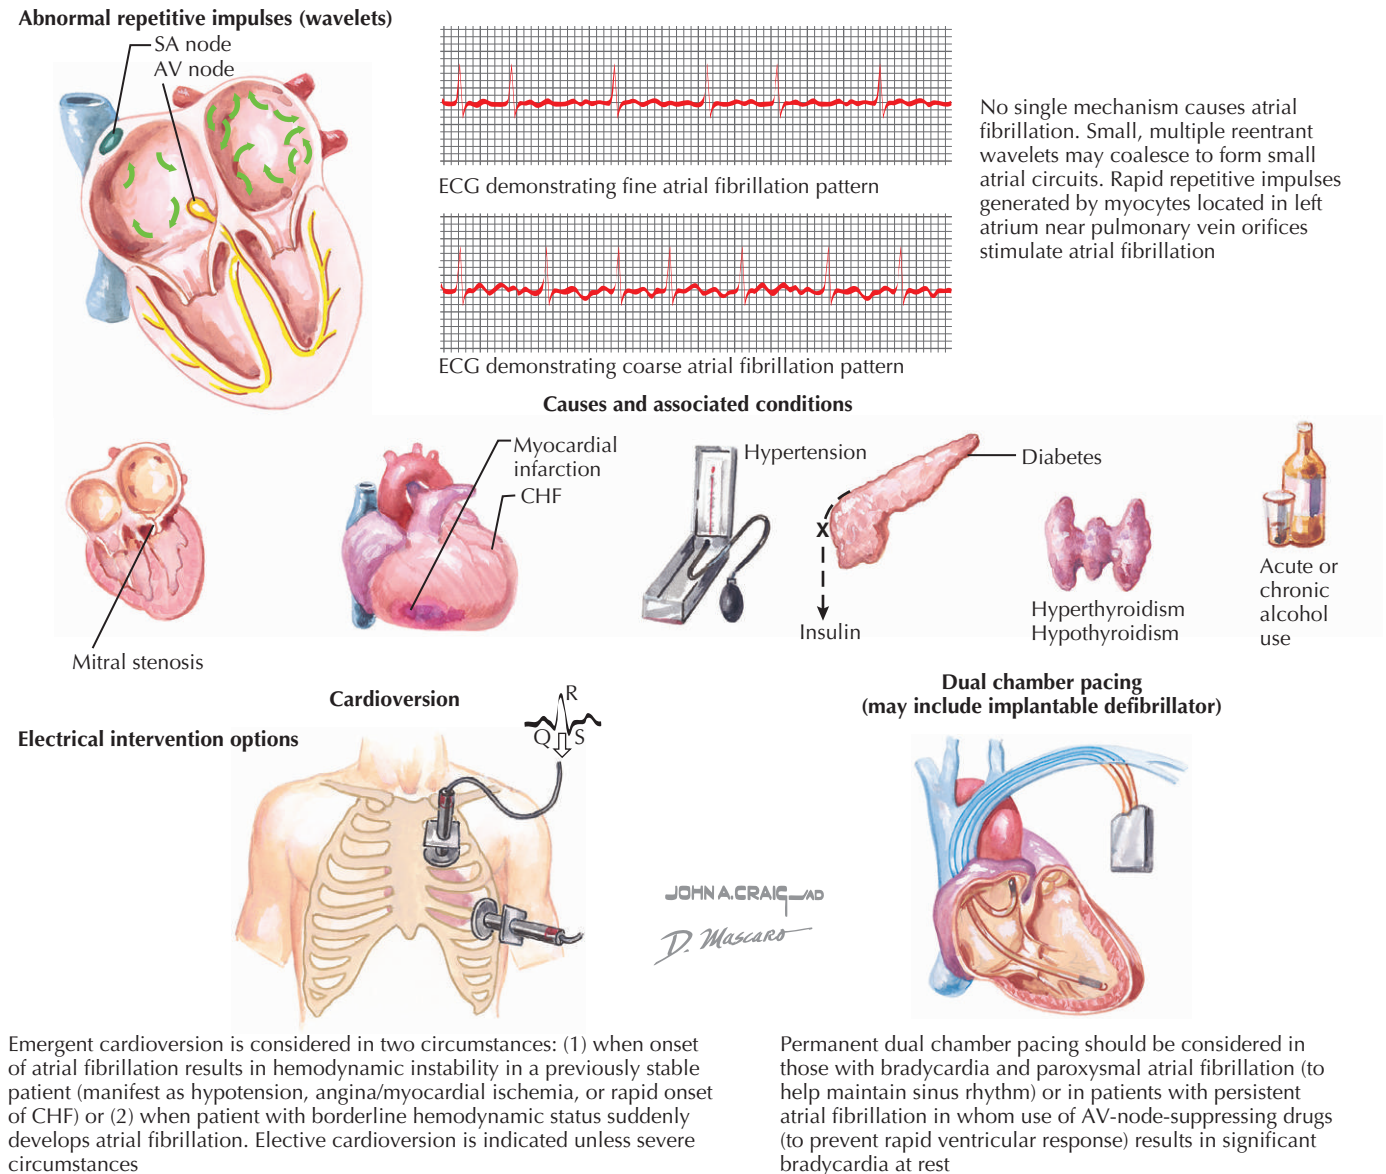

Diagnostic Approach

The history, physical examination, electrocardiogram, and a variety of laboratory and cardiovascular tests are commonly employed in the initial evaluation of atrial fibrillation. Upon presentation, most patients can be classified into one of four categories, as recommended by a joint task force of the American College of Cardiology, the American Heart Association, and the European Society of Cardiology: paroxysmal, persistent, permanent, or lone atrial fibrillation. Treatment differs among the four groups.

1. *Paroxysmal atrial fibrillation* is described as episodes of atrial fibrillation that last less than a week (and often less than 24 hours), self-terminate, and are usually recurrent.
2. *Persistent atrial fibrillation* lasts more than a week, does not self-terminate, and may recur after cardioversion.
3. *Permanent atrial fibrillation* is diagnosed if atrial fibrillation has lasted more than a year, has been refractory to cardioversion, or both.
4. *Lone atrial fibrillation* can be paroxysmal, persistent, or permanent atrial fibrillation in the absence of structural heart disease.

In addition to classifying the atrial fibrillation, the history and physical examination should focus on clues to the underlying cause. Symptoms and examination findings relevant to the conditions that predispose to atrial fibrillation (as listed previously) should be sought. It is important to seek evidence for complications of atrial fibrillation, including presyncopal symptoms (especially with initiation or termination of atrial fibrillation), decreased cardiac output, and thromboembolism (including transient ischemic attacks, evidence of peripheral embolization, or both). An ophthalmoscopic examination may reveal retinal artery embolism in some patients with atrial fibrillation. Patients at highest risk for atrial fibrillation with rapid ventricular response, including those with accessory pathways (Wolff-Parkinson-White syndrome) or dilated cardiomyopathy, can present with frank syncope or even sudden cardiac death.

The electrocardiogram can confirm atrial fibrillation, heart rate, and the presence of underlying structural heart disease, such as chamber enlargement or (hypertrophy), prior myocardial infarction, and conduction abnormalities. The transthoracic echocardiogram is an essential part of a complete evaluation, particularly in patients being considered for cardioversion. Underlying structural contributors to atrial fibrillation and left atrial size, a predictor of short- and long-term success in cardioversion, should be examined by echocardiography. Transesophageal echocardiography is indicated in some settings to document, before cardioversion, the presence or absence of thrombi in the left atrium or the left atrial appendage. Laboratory testing should be performed to evaluate thyroid status and screen for electrolyte abnormalities. Additional testing may include functional assessment for coronary heart disease (exercise or pharmacologic stress testing with or without imaging) and even coronary angiography. Electrophysiology studies are not indicated as part of the initial evaluation but are indicated when radiofrequency ablation of potential atrial fibrillation sites is being considered. An electrophysiology study may also be considered for younger patients with a history of supraventricular tachycardia and a regular rhythm, which has now become more irregular. In this setting, the supraventricular tachycardia may be the trigger for the initiation of atrial fibrillation. Although uncommon, this is an example of tachycardia-induced tachycardia. In this circumstance, radiofrequency ablation of the supraventricular tachycardia can prevent subsequent episodes of atrial fibrillation.

Figure 37-1 Atrial Fibrillation.

Management and Therapy

Treatment of atrial fibrillation largely depends on symptoms and the cause of the atrial fibrillation (Figs. 37-2 to 37-4). Are the symptoms related to atrial fibrillation tolerable or intolerable to the patient? Has atrial fibrillation resulted in an unfavorable hemodynamic picture that may have long-term consequences? Have embolic events occurred, and what is the long-term risk for thromboembolism? Consideration of important issues related to each of these areas can help guide treatment options.

Optimum Treatment

Acute Management of Atrial Fibrillation

Initial management of atrial fibrillation is dependent on ventricular response, blood pressure, evidence of ischemia,

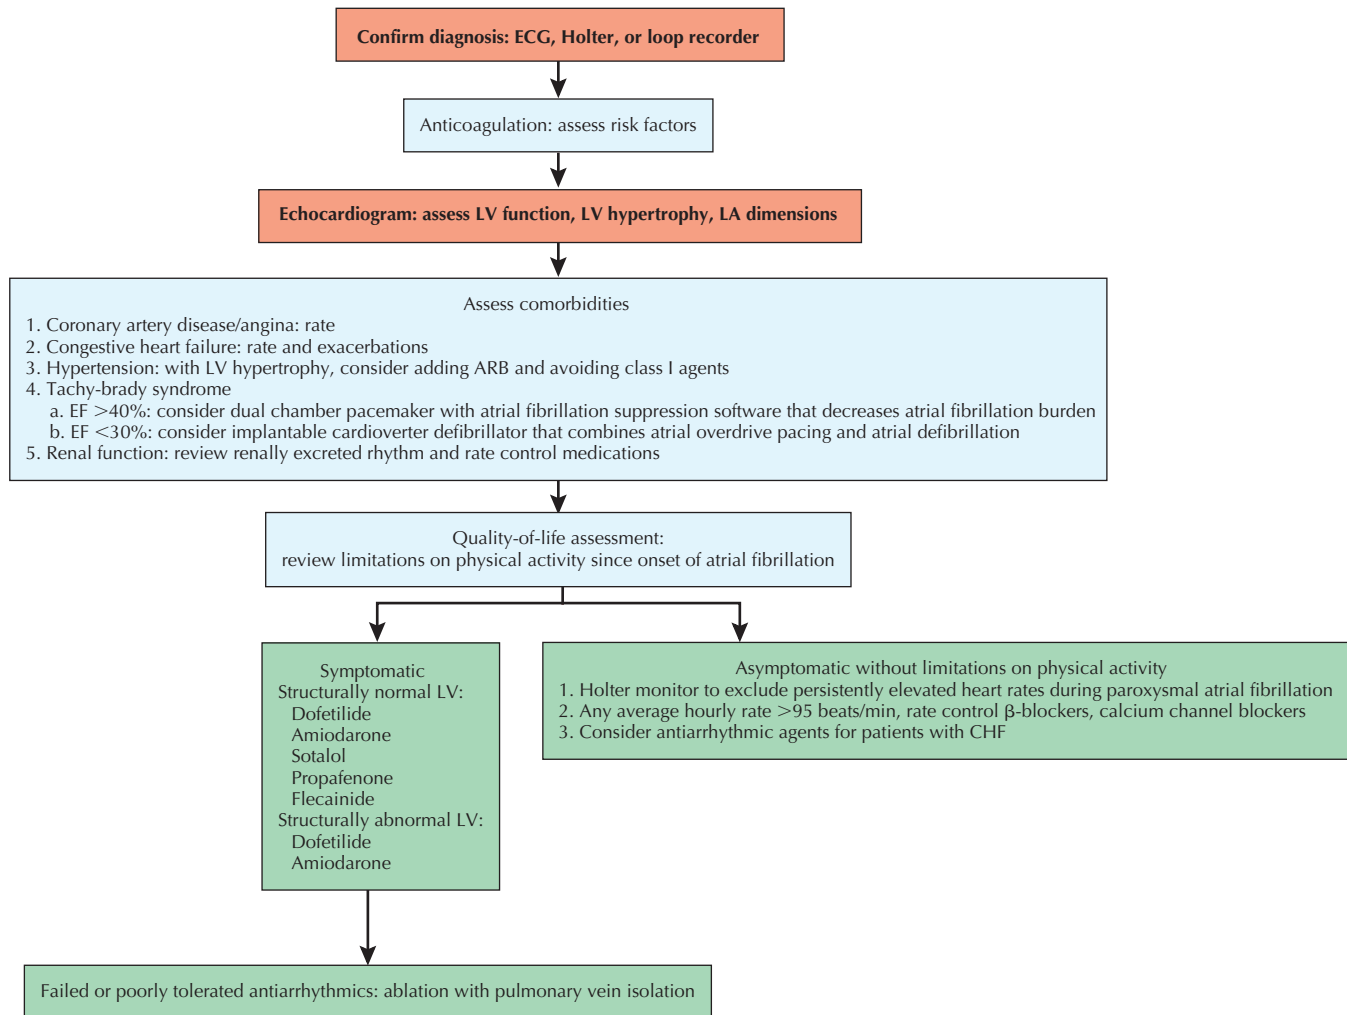

shortness of breath, and cardiogenic shock. Figure 37-2 provides a schematic to management. Once the patient has been stabilized, subsequent evaluation and management depend on age, heart rate, symptoms, etiologic considerations, hypertension, myocardial ischemia, diabetes mellitus, thyroid disease, cerebrovascular accidents, and pulmonary considerations (see Box 37-1 and Figs. 37-2 to 37-4).

Nonacute Management of Atrial Fibrillation

Four major issues must be considered in determining the treatment of atrial fibrillation: conversion from atrial fibrillation to normal sinus rhythm, maintenance of normal sinus rhythm, rate control in patients with chronic atrial

Figure 37-2 Long-term Management of Paroxysmal Atrial Fibrillation.

fibrillation, and prevention of thromboembolic complications (Fig. 37-5). These four issues are discussed with special emphasis on controversial factors.

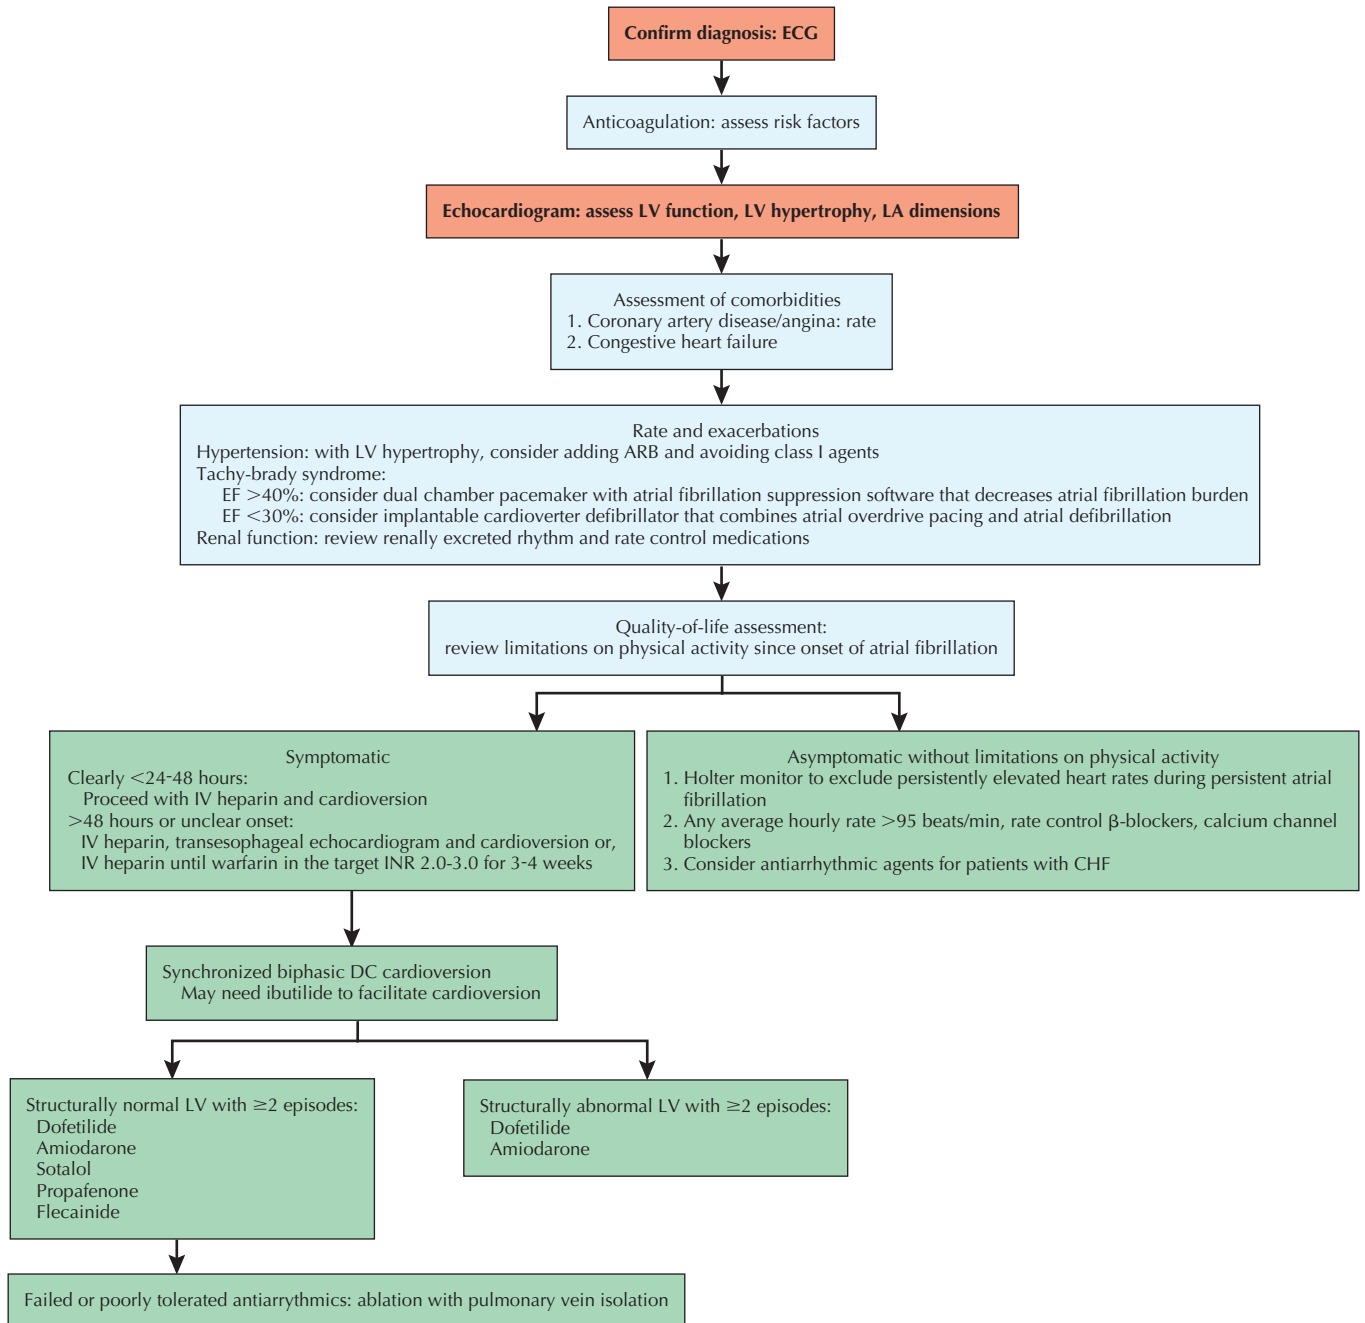

Cardioversion

Cardioversion for atrial fibrillation should be considered in two settings. In patients who present acutely with hemodynamically unstable atrial fibrillation, immediate cardioversion may be indicated. Remember the sinus tachycardia concept: atrial fibrillation with a rapid response may be triggered by an underlying cause. Initially, this cause should be sought and, if necessary, addressed. Other causes of hypotension and tachycardia should be excluded, including hypovolemia, septic shock, acute hemorrhage, profound anemia, and acute myocardial infarction leading to cardiogenic shock. Usually, patients who are hypotensive from atrial fibrillation with a rapid ventricular rate also have underlying cardiovascular disease. After reversible

factors have been addressed, these patients should undergo electrical cardioversion immediately. Rate control with intravenous short-acting β -blockers (esmolol) or calcium channel blockers (diltiazem) can be considered, but in the setting of marked hypotension, these should be cautiously initiated. However, because there is no atrial contraction in atrial fibrillation, the left ventricle (LV) fills passively. Therefore, in patients with a rapid ventricular response, slowing of the ventricular rate allows a more prolonged diastolic filling time and thus may improve cardiac output. In hemodynamically stable patients with myocardial ischemia, either intravenous β -blockers (including esmolol or metoprolol) or calcium channel blockers (diltiazem or verapamil) can be used safely before cardioversion. Neither β -blockers nor calcium channel blockers are effective agents for cardioversion, although spontaneous cardioversion may occur when the heart rate is slowed pharmacologically. There is a growing indication for certain type III

Figure 37-3 Long-term Management of Persistent Atrial Fibrillation.

antiarrhythmic drugs in the urgent treatment of atrial fibrillation. Intravenous ibutilide and amiodarone are safe in this setting, when used with proper monitoring. In some circumstances, class IA agents (intravenous procainamide principally) are recommended in the acute setting, but the advent of ibutilide and amiodarone have largely displaced their use.

The second setting in which cardioversion is considered for atrial fibrillation is in symptomatic (or sometimes even asymptomatic) but stable patients. In this setting, before cardioversion, it is essential to consider the need for anticoagulation (see “Anticoagulation in Atrial Fibrillation”). In general, in uncomplicated cases when the duration of atrial fibrillation is clearly less than 24 hours, anticoagula-

Figure 37-4 Long-term Management of Permanent Atrial Fibrillation.

ARB, angiotensin receptor blocker; ECG, electrocardiogram; LV, left ventricular; LA, left atrial; EF, ejection fraction.

tion is not required before cardioversion. When the duration of atrial fibrillation is more than 48 hours, it is generally recommended that the patient be started on intravenous heparin. Differences of opinion exist about whether to anticoagulate patients who have been in atrial fibrillation for 24 to 48 hours. The more conservative approach (which we adhere to) is to anticoagulate, the same as for patients in whom the duration of atrial fibrillation has been more than 48 hours. An alternative approach uses transesophageal echocardiography to screen for thrombi in the atria or the atrial appendages and proceed with cardioversion if no thrombi are present. In this case, anticoagulation with warfarin for 3 to 4 weeks (International Normalized Ratio [INR], 2.0 to 3.0) is initiated at the time of cardioversion and for at least 1 month afterward. These issues are discussed in the following subsections.

A trend in Europe, but less so in the U.S. is the so-called “pill in the box” strategy in patients at low risk for proarrhythmia is a safe and effective way of pharmacologic cardioversion. Patients who either are on telemetry in the

emergency department or in some cases have been shown to have no arrhythmias during prior hospitalizations may take a single dose of propafenone, 600 mg orally, or flecainide, 300 mg orally. Studies in Europe have suggested this approach is safe, but it is not yet endorsed in the United States.

Rhythm Control

The selection of electrical versus pharmacologic cardioversion is often an individualized decision based on the patient’s history and predisposing factors for atrial fibrillation. For instance, patients with paroxysmal or persistent atrial fibrillation are likely to require antifibrillatory medication to maintain sinus rhythm. Obviously, these patients need to be maintained on anticoagulants before chemical cardioversion. The pharmacologic choices for cardioversion are principally amiodarone, sotalol, and dofetilide. All have advantages and disadvantages. For patients with paroxysmal atrial fibrillation, amiodarone can safely be initiated in the outpatient setting and is probably the most

Figure 37-5 Complications of Atrial Fibrillation.

Hemodynamic deterioration in existing CHF

Patients with stable or asymptomatic congestive heart failure may show marked worsening if atrial fibrillation (AF) ensues. Loss of atrial contraction and rapid ventricular heart rate decreases cardiac output and increases congestive symptoms

effective antifibrillatory agent. Even at the low doses used for atrial fibrillation prophylaxis (about 200 mg/day), the side-effect profile of amiodarone requires annual or semi-annual screening for thyroid and hepatic dysfunction and for the rare occurrence of diminishing pulmonary function from early pulmonary fibrosis. Sotalol is also effective and can be particularly beneficial in patients who require β blockade for other reasons, but sotalol should be initiated in an inpatient setting because of unpredictable QT prolongation in some individuals. Dofetilide is a promising agent, but its use also requires 3 days of telemetry monitoring for QT prolongation and torsades de pointes. The initial dofetilide dosage is based on renal function. Subsequent doses are determined by QT response to the previous dose until a steady state is reached.

The decision to use medications in an effort to maintain normal sinus rhythm is common. Indeed, less than one third of patients who are successfully cardioverted maintain normal sinus rhythm for more than a year without antifibrillatory therapy. Many predictors of the potential need for antifibrillatory therapy are known. Sometimes the use of β -blockers can blunt adrenergic drive sufficiently to prevent recurrence of atrial fibrillation, although this is the exception. Many cardiologists favor an initial trial of electrical cardioversion alone in low-risk patients with atrial fibrillation, reasoning that the third of patients who do not require antifibrillatory therapy will be spared the expense and the associated risks. In patients who have an increased risk for recurrent atrial fibrillation, or who have had a second electrical cardioversion, use of the medications dis-

cussed previously (and in Figs. 37-2 and 37-3) is generally indicated for maintenance of normal sinus rhythm. However, this practice has come into question and is discussed later in the section, “Rate versus Rhythm Control.”

The issue of measuring quality of life (QOL) in patients with atrial fibrillation is fraught with methodologic difficulties. Using an intention to treat analysis does not adequately control for the rhythm at time the QOL questionnaire is completed. Likewise, using the rhythm at the time of the QOL questionnaire completion makes comparisons between different treatment strategies extremely difficult to interpret. Several studies have now shown that patients in sinus rhythm have improved QOL scores compared with patients in atrial fibrillation at the time of QOL questionnaire completion.

Rate Control

Many patients with chronic atrial fibrillation are not successfully treated with cardioversion or antiarrhythmic agents, are unwilling to undergo cardioversion, are unable to tolerate antiarrhythmic agents, or have factors that predict that treatment will fail and are minimally symptomatic except at rapid heart rates. For them (see Fig. 37-4), pharmacologic rate control should be considered. β -Blockers, calcium channel blockers, or both can often control rapid heart rates with or without digoxin. Digoxin is particularly useful in controlling atrioventricular (AV) conduction in patients who are minimally active or bedridden from comorbidities. However, because there is considerable overlap between atrial fibrillation and conduction abnormalities, including sinus node dysfunction (sick sinus syndrome), an appropriate balance between tachycardia and bradycardia may be difficult to obtain. These patients may require a permanent pacemaker to prevent bradycardic episodes while being treated with β -blockers, calcium channel blockers, or antifibrillatory medications for tachycardia. Although the initial promise of permanent dual-chamber pacing (or even atrial pacing alone) to prevent atrial fibrillation has not been fulfilled, in patients with episodic atrial fibrillation, dual-chamber pacing with an atrial fibrillation suppression algorithm should be considered when a pacemaker is indicated. Use of ventricular pacing is likely to convert episodic atrial fibrillation into chronic atrial fibrillation. Another special case, discussed later (see “Atrioventricular Node Ablation and Permanent Pacing”), is the patient whose rapid ventricular response is resistant to pharmacologic control or for whom the pharmacologic approach results in intolerable side effects.

Anticoagulation in Atrial Fibrillation

Anticoagulation considerations include anticoagulation during restoration of normal sinus rhythm, chronic anticoagulation, and cessation and restoration of anticoagulation for patients with atrial fibrillation who are undergoing surgical procedures. Consensus panels from the American

College of Cardiology, the American Heart Association, the European Society of Cardiology, and the American College of Chest Physicians have concurred on the use of anticoagulation therapy in the pericardioversion period. In patients with atrial fibrillation of unknown duration, valvular heart disease, evidence of LV dysfunction, or prior thromboembolism, or for whom cardioversion is entirely elective, therapeutic anticoagulation with warfarin (with an INR of 2.0 to 3.0) for 3 to 4 weeks before cardioversion is strongly recommended. Anticoagulation should be continued at the same level for at least 4 weeks after cardioversion. An alternative approach in low-risk patients (lacking any of the criteria listed here) is to assess for atrial or atrial appendage thrombi by transesophageal echocardiography. Lacking thrombi, or a low-flow state (also referred to as “smoke” or spontaneous echocardiographic contrast), the patient can be safely cardioverted without antecedent anticoagulation with warfarin, although many use heparin or low-molecular-weight heparin before cardioversion. These patients do require anticoagulation for 4 to 6 weeks after cardioversion.

Long-term anticoagulation with warfarin is advocated in patients in several settings. Irrespective of the type of atrial fibrillation (paroxysmal, persistent, or permanent), patients at high risk for stroke should be anticoagulated for life. Because many patients have recurrent atrial fibrillation, some episodes of which may not be recognized by the patient, anticoagulation is indicated. Other symptomatic patients may also experience asymptomatic episodes of atrial fibrillation that predispose to embolic events, even when they are in sinus rhythm. Finally, in patients with chronic atrial fibrillation, five large prospectively randomized studies demonstrated that warfarin reduced the risk for stroke by 45% to 82%. The use of aspirin remains controversial for patients at low risk for stroke (lone atrial fibrillation) or for patients with increased risk for bleeding in whom warfarin may be contraindicated.

Avoiding Treatment Errors

The three most common types of errors in treatment of patients with atrial fibrillation are (1) failure to recognize an underlying, potentially reversible cause of atrial fibrillation; (2) failure to consider potential drug interactions that could lead to bradycardia in patients with atrial fibrillation treated with AV node blocking drugs; and (3) failure to rigorously monitor and adjust anticoagulant therapy, leading to either excess bleeding or thrombus formation. Although these complications cannot be completely avoided, with careful and conscientious physician oversight, the risk for one of these complications can be minimized. All patients with atrial fibrillation should have a comprehensive evaluation before initiation of therapy. Upon initiation of therapy with AV node blocking drugs, all concurrent therapies should be reviewed, and patients should be followed closely. Finally, difficulty with antico-

agulant therapies can largely be avoided by using standardized protocols and, for difficult to control patients, referral to an anticoagulation clinic.

Special Issues

Because atrial fibrillation represents a diverse group of etiologies and risks, several special issues merit further discussion.

Lone Atrial Fibrillation

By definition, *lone atrial fibrillation* occurs in individuals younger than 60 years who lack evidence of other cardiovascular diseases, including structural heart disease, hypertension, or diabetes. This definition has been refined with the use of echocardiography to confirm the lack of structural heart disease, even including mild mitral valve regurgitation, left atrial enlargement, and LV hypertrophy. The general experience in patients with lone atrial fibrillation is that their risk for stroke is low, anticoagulation is unnecessary for stroke prophylaxis, and further treatment for atrial fibrillation is probably also not necessary. As lone atrial fibrillation has become more clearly defined, this trend holds. Questions that remain include: How often should individuals carrying the diagnosis of lone atrial fibrillation have echocardiography to be certain that structural abnormalities are still absent? Should patients with lone atrial fibrillation be given aspirin? There are no studies that answer these questions. In general, patients with lone atrial fibrillation should be seen at least annually to document that stroke risk factors, including hypertension and diabetes, are still absent, and echocardiography and Holter monitoring should be performed annually to ascertain that there is no evidence of tachycardia-induced cardiomyopathy. The results of studies are mixed on the role of aspirin in patients with lone atrial fibrillation, and there is no consensus for its use. However, given the epidemiologic data supporting the use of low-dose aspirin (81-325 mg per day, as tolerated) in lessening long term risk for stroke and myocardial infarction in patients from age 40 on, low-dose aspirin is often recommended in patients with lone atrial fibrillation.

Nonpharmacologic Approaches to Preventing Atrial Fibrillation

Surgical and percutaneous approaches exist for the treatment of atrial fibrillation (Fig. 37-6; and see Figs. 37-2 to 37-4). In the past, two landmark surgical approaches led the way for the current understanding of the critical role of the pulmonary veins in the initiation and maintenance of atrial fibrillation. The best-studied surgical approaches are the corridor and maze procedures. In the *corridor procedure*, a corridor of atrial tissue is surgically isolated between the sinus and the AV nodes from the rest of the atria, providing chronotropic rate control and demonstrat-

ing an increased ability to maintain normal sinus rhythm. In the *maze procedure*, small incisions are made to effectively interrupt reentrant atrial arrhythmias and prevent sustained atrial fibrillation, while providing one pathway from the sinus node to the AV node and simultaneously activating the right and left atria. The concept behind both of these procedures is maintenance of normal sinus rhythm and atrial systole. Although both procedures are effective, they both require open chest surgery, usually require continued anticoagulation, are complicated by the frequent need for permanent pacing, and, hence, are indicated only for a small portion of patients with atrial fibrillation, principally those with a planned cardiac surgical procedure for other reasons (coronary or valvular heart disease). Currently, a modified procedure is employed that isolates the pulmonary veins and adds an ablation line from the veins to the mitral valve annulus.

Radiofrequency catheter ablation of atrial fibrillation isolates foci of early depolarizing atrial cells in the cuffs of the pulmonary veins and has a success rate of 70% to 80% of individuals who are free of atrial fibrillation and off all antiarrhythmic agents. Recurrent atrial fibrillation, risk for thromboembolic episodes, cardiac tamponade, infrequent pulmonary vein stenosis, and rarely an atrioesophageal fistula make the procedure technically challenging. The use of advanced mapping techniques has undoubtedly improved the efficacy of radiofrequency catheter ablation, which is recommended in cases in which pharmacotherapy has failed or is not tolerated and other approaches are unsuitable. Imaging of the left atrium using computed tomographic angiography or magnetic resonance angiography can now be merged with data obtained by electrophysiologic mapping to provide a three-dimensional view that improves the accuracy of ablation. Newer catheter technologies and a better understanding and identification of electrogram targets will allow for an easier and more reliable ablation procedure. In the future, stereotactic technology will likely make atrial fibrillation ablation procedures faster and more effective.

Frequently because of coexistent sinus node dysfunction, tachy-brady syndrome, or excessive bradycardia caused by medications, a permanent pacemaker is indicated. For patients with paroxysmal or persistent atrial fibrillation (see Figs. 37-2 and 37-3), a pacemaker that combines atrial suppression software should be considered. These pacemakers prevent atrial sensing by pacing at rates faster than the underlying atrial rhythm. In clinical trials, these pacemakers reduced atrial fibrillation burden by up to 25%. Dual-chamber pacemakers are superior to ventricular pacemakers in preventing the development of atrial fibrillation.

Rate versus Rhythm Control

On the basis of hemodynamic studies, it has been assumed that patients with normal sinus rhythm fare better than do

Figure 37-6 Surgical Management of Atrial Fibrillation.

those with atrial fibrillation but well-controlled ventricular rates. Two studies call into question this conventional wisdom. In both, rhythm control did not provide a survival advantage over rate control in terms of symptoms, risks for stroke, or other morbidities. The groups were highly selected and minimally symptomatic, and there was considerable crossover, such that a statistically significant portion of the rate control group was actually in normal

sinus rhythm at the conclusion of the study, creating a significant negative impact on the power of the study. In addition, patients at higher risk for hemodynamic compromise were largely excluded from these studies. Although we await a final answer to the debate on rate versus rhythm control, these studies clearly demonstrate that rhythm control is a more viable option than it was previously considered to be.

Atrioventricular Node Ablation and Permanent Pacing

Consistent with the idea that rhythm control is a useful approach, several studies demonstrated remarkable symptom reduction in patients with atrial fibrillation and refractory rapid ventricular response by making these patients pacemaker dependent. In essence, the patient undergoes radiofrequency catheter ablation of the AV node and implantation of a permanent pacemaker. Depending on the likelihood of restoring normal sinus rhythm, a dual-chamber pacemaker may be used, or in cases where that likelihood is low, a single-chamber ventricular pacemaker is implanted. Studies support the rationale that the rapid ventricular response resulting from atrial fibrillation can be effectively eliminated for selected patients. There may also be a reversal of tachycardia-induced cardiomyopathy, with improvement in LV ejection fraction. Uniformly for patients with permanent atrial fibrillation, QOL scores and exercise tolerance improve and rehospitalization and resource utilization decrease following AV node ablation and permanent pacemaker placement.

Currently, the procedure of “ablate and pace” is reserved for patients with permanent atrial fibrillation, who are not candidates or do not wish to have pulmonary vein isolation performed. Many will already have a single-lead ventricular (VVI) pacemaker. In patients undergoing a *de novo* procedure, a few small studies have shown that biventricular pacing is superior to right ventricular pacing only.

Congestive Heart Failure

Atrial fibrillation occurs in 15% to 30% of patients with CHF. In these patients, atrial fibrillation can lead to hemodynamic deterioration and rehospitalization, with worsening of symptoms in patients with existing heart failure. The rapid heart rate and loss of atrial contraction can precipitate an exacerbation of CHF in patients with asymptomatic stable LV dysfunction. These changes can be reversed with rate control or reversion to sinus rhythm. It appears that patients with more severe CHF (New York Heart Association class III and IV) and atrial fibrillation have higher all-cause mortality and pump failure deaths. In patients with milder forms of CHF (New York Heart Association class I and II), however, atrial fibrillation was not associated with an increase in mortality or rehospitalization. Class I antiarrhythmic agents are independently associated with an increased mortality in patients with CHF and atrial fibrillation and should be avoided. Amiodarone and dofetilide are safe for patients with CHF. Optimal pharmacologic therapy may play a favorable role in influencing the outcomes for these patients. Even in patients at highest risk with atrial fibrillation and severe CHF, it has not been shown that maintenance of sinus rhythm with antiarrhythmic agents improves survival. Since the emergence of isolation of the pulmonary veins even for patients with permanent atrial fibrillation of several years' duration, this

procedure has been shown to improve QOL, LV ejection fraction, and symptoms.

Implantable Atrial Defibrillation

Between 20% and 30% of patients have coexisting atrial fibrillation at the time of placement of an implantable cardioverter-defibrillator (ICD). Seventeen months after placement of an ICD, up to 45% of patients have atrial fibrillation. The latest ICDs also incorporate atrial conversion therapy, which includes atrial overdrive antitachycardia pacing, atrial high-frequency burst pacing, and atrial defibrillation. These devices are safe and efficacious. Therefore, an ICD with atrial therapies should be considered for patients with atrial fibrillation or the potential to develop atrial fibrillation.

Coronary Artery Bypass Surgery

Atrial fibrillation is frequently seen in patients after coronary artery bypass graft (CABG) surgery. Up to 40% of patients are estimated to develop atrial fibrillation, usually beginning after postoperative day 1 and lengthening the hospital stay. Older patients and those who have β -blockers withdrawn before surgery are more likely to develop atrial fibrillation. Use of β -blockers or amiodarone preoperatively decreases the frequency of postoperative atrial fibrillation. Interestingly, atrial fibrillation is a transient phenomenon; most patients are in sinus rhythm when discharged. Only a minority, less than 5%, are in atrial fibrillation 30 days after surgery.

Ablation has been performed during CABG in patients undergoing mitral valve surgery. The four pulmonary veins are isolated with either radiofrequency ablation or cryoablation. In some circumstances, the ablation line is extended to the mitral valve annulus, with reportedly fewer episodes of recurrence of atrial fibrillation. Early studies showing sinus rhythm maintenance have been encouraging, even in patients with permanent atrial fibrillation before surgery.

Postmortem studies have identified the left atrial appendage as the most likely source for the development of thrombus in patients with atrial fibrillation. This has been confirmed in a large series of patients who underwent transesophageal echocardiogram before cardioversion. Percutaneous approaches have been developed that aim to isolate the left atrial appendage from the left atrium in an attempt to prevent the development of thrombus in patients who cannot take warfarin. During CABG or valve surgery, many surgeons either remove the appendage or oversuture the orifice of the appendage, thereby preventing flow and stasis in the appendage.

Hypertension

Two recent antihypertensive studies, Losartan Intervention for End Point Reduction in Hypertension (LIFE) and

Valsartan Antihypertensive Long-term Use Evaluation (VALUE), have shown prospective observational data suggesting a significant decrease in the prevalence of atrial fibrillation in patients treated with the angiotensin receptor blockers (ARBs) losartan and valsartan. These agents were compared with atenolol in the LIFE study and amlodipine in the VALUE study. In both studies, there was either a similar or slightly better control of blood pressure with atenolol and amlodipine. However, despite adequate blood pressure control, significantly fewer patients taking ARBs developed atrial fibrillation. Several possible explanations may account for these observations. The antifibrotic and anti-inflammatory effects associated with ARBs, as well as a more favorable effect on LV remodeling, may facilitate a reverse remodeling of the left atrium, thereby decreasing the propensity to develop atrial fibrillation. This hypothesis is being tested prospectively in the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE) irbesartan trial.

Future Directions

Advances in the treatment of atrial fibrillation hold promise. Newer antifibrillatory agents are in development, as are anticoagulants that will be easier to administer and safer than warfarin. Although the oral thrombin inhibitor ximelagatran was shown to be comparable to warfarin in anticoagulant efficacy, there was an unexplained and unexpected elevation in liver function tests. Newer oral thrombin inhibitors are currently being studied. Exciting nonpharmacologic therapies are undergoing testing and early clinical use, including implantable atrial defibrillators and pacemakers (with the rationale that early conversion of atrial fibrillation to normal sinus rhythm facilitates maintenance of normal sinus rhythm), newer mapping, and more sophisticated percutaneous approaches. Eventually, it may be possible to cure atrial fibrillation, much as radiofrequency catheter ablation can now cure supraventricular tachycardias in many and maintain normal sinus rhythm in most. Percutaneous left atrial appendage transcatheter occlusion devices, which are easier to implant, are being evaluated in clinical trials at present. This is an attractive strategy for patients who cannot or will not take warfarin or for patients who have embolic episodes while taking warfarin. Early clinical data suggest that patients with closure devices have lower than expected CVA/TIA rates based on their Congestive heart failure, Hypertension, Age, Diabetes (CHAD) score risk estimates. Randomized data comparing appendage closure devices with warfarin treatment with an INR of 2 to 3 in patients with a high risk for thromboembolism are awaited.

The Losartan Intervention for End Point Reduction in Hypertension (LIFE) study compared the effects of losartan and atenolol on new-onset AF. This study concluded that losartan-based antihypertensive therapy (as compared with atenolol-based antihypertensive therapy) significantly reduced new-onset AF and associated stroke.

6. Wyse DG, Waldo AL, DiMarco JP, et al: A comparison of rate control and rhythm control in patients with atrial fibrillation. *N Engl J Med* 347(23):1825-1833, 2002.

This study compared the two approaches, rate and rhythm control, in the management of AF. There was no significant difference in survival between the two therapies. Patients randomized to rate control did have a lower risk for adverse drug effects.

Diabetes and Prediabetes: Diagnosis and Treatment

Introduction

Diabetes mellitus (DM) affects about 21 million people in the United States and hundreds of millions of people worldwide. Prediabetes, abnormally high glucose levels that are insufficient to meet the diagnostic criteria of diabetes, affects more than 50 million people in the United States. Current estimates for those born in the year 2000 are that one in three will develop diabetes and more than one in two will have prediabetes in their lifetime. This epidemic of DM is driven by increasing obesity and progressively sedentary lifestyles.

DM is a major cause of morbidity and mortality. Premature vascular disease is the eventual cause of death in more than two thirds of people with DM, leading to a loss of more than 10 years of life in those diagnosed at age 40 years. The costs involved in the treatment of people with DM are staggering, accounting by some estimates for one sixth of all health care expenditures in the United States.

We are in the midst of multiple revolutions in DM management. Evidence that lifestyle interventions and patient self-management education are effective has driven improved third-party coverage for these services. Therapeutic targets have been established on the basis of outcomes trials not only for glycemia but also for common comorbidities—hypertension and dyslipidemia. There are new developments in glucose monitoring technology. Multiple new classes of pharmacologic agents are available to treat DM. Together, these advances create the possibility that the early death and disability associated with DM can be avoided.

Etiology and Pathogenesis

Type 1 DM (previously known as insulin-dependent DM) accounts for about 5% to 10% of all cases of diabetes. It can occur at any age but is more common among children and young adults. It is characterized by insulin deficiency generally resulting from autoimmune destruction of insulin-secreting β cells within the pancreatic islets of Langerhans. Other autoimmune endocrine diseases, such as hypothyroidism, ovarian failure, adrenal insufficiency, pernicious anemia, autoimmune hepatitis, and vitiligo, often coexist in patients with type 1 DM. Although classically considered a disease of children, adolescents, and young adults, it is estimated that up to 10% of adults with new-onset DM have a slowly evolving form of type 1 DM. Clinically, these adult-onset patients with type 1 diabetes are essentially indistinguishable from patients with type 2 diabetes except that they tend to be less overweight, to

present with weight loss, and to respond poorly to oral antihyperglycemic agents.

The risk for DM is genetically determined and involves several genetic loci, the most important of these being genes within the human leukocyte antigen (HLA) system. However, only 10% of people with type 1 DM exhibit a family history. The risk for future DM in the first-degree relative of a patient with type 1 DM is 2% to 5%. Islet cell antibodies, antibodies to glutamic acid decarboxylase (GAD), antibodies to insulin, and other autoantibodies are often present at diagnosis. There are likely environmental triggers to the development of this autoimmune process, although these are poorly understood.

Type 2 DM (previously known as noninsulin-dependent DM) generally occurs in adulthood, although it can develop at any age. Currently, almost half of children with new-onset diabetes now have type 2 diabetes. Most patients with type 2 DM have a first-degree relative with DM, and

most are overweight, generally with a central pattern of obesity. Type 2 DM is more common in all other ethnic groups than in whites of European extraction and tends to occur at an earlier age in these high-risk populations as well as in women. From recent prospective studies, we understand that type 2 DM develops as the result of progressive loss of insulin secretory capacity on the background of insulin resistance. Insulin resistance is defined as an inadequate response of metabolic processes to physiologic insulin concentrations.

A number of clinical phenotypes are associated with insulin resistance and are sometimes discussed together as the metabolic (or dysmetabolic) syndrome. These features include obesity with a central pattern of weight distribution, dyslipidemia, hyperglycemia, hypertension, hypercoagulability, endothelial dysfunction, and accelerated atherosclerosis. The dyslipidemia is characterized by increased triglycerides and decreased high-density lipoprotein (HDL) cholesterol. Although the absolute concentration of low-density lipoprotein (LDL) cholesterol is the same as the population average, the LDL particles are generally small, dense, more numerous, and thus more atherogenic. The pathophysiology of these associations is unknown. Nevertheless, a substantial portion of the increased cardiovascular morbidity in the setting of type 2 DM is likely related to this syndrome and its associated features.

Clinical Presentation

In type 1 DM, clinical deterioration can be quite rapid, and patients can transition from being completely asymptomatic to having rampant polyuria, polydipsia, and polyphagia with weight loss and blurred vision over a matter of days to weeks. Affected individuals generally have fairly widely fluctuating blood sugars. Diabetic ketoacidosis can occur when one or more insulin doses are missed or with physiologic stress. Hypoglycemia is quite common as a complication of insulin therapy in type 1 diabetes.

In type 2 DM, patients may be completely asymptomatic for years. Some present with classic symptoms of microvascular or macrovascular complications. More often, subtle symptoms may be present for years, including fatigue, recurrent cutaneous infections, and intermittent nocturia. If hyperglycemia is allowed to progress unchecked, life-threatening problems, such as diabetic ketoacidosis or hyperosmolar states, can develop.

Differential Diagnosis

Generally, DM is a primary disorder; however, it is worth noting the much less common secondary causes. Among these, pancreatic disorders are the most common, including chronic pancreatitis, cystic fibrosis, and pancreatic cancer. Although for years it was considered that these disorders were the result of destruction of most functioning β cells, the pathophysiology of DM in these cases is

more complex, probably involving ill-defined humoral factors. There are iatrogenic causes such as steroid therapy and syndromes associated with hormonal overproduction of glucocorticoids, growth hormone, glucagon, and catecholamines.

Diagnostic Approach

About one third of cases of DM in the United States are undiagnosed. In some studies, 20% to 50% of people with DM have one or more complications of the disease at the time that a diagnosis is made. Estimates suggest that the diagnosis of DM could be made 7 to 12 years earlier with screening than by waiting for symptoms to develop.

Current recommendations suggest screening for DM by measuring a fasting plasma glucose (FPG) starting at age 45 years, with repeat screening every 3 years. Screening should start at an earlier age and be repeated at shorter intervals, particularly in people who are overweight (body mass index [BMI] ≥ 25 kg/m²) with one or more risk factors (beyond age and weight as above):

- A family history of DM in a first-degree relative
- Belonging to a high-risk ethnic group (essentially all ethnicities except whites of western European extraction)
- Hypertension
- Dyslipidemia (high triglycerides or low HDL)
- Women with a history of gestational diabetes, birth of a child greater than 9 pounds, or ovarian hyperandrogenism
- Prior abnormal fasting glucose or glucose tolerance test
- Acanthosis nigricans
- Known vascular disease

Fasting for the purpose of diabetes screening is defined as nothing by mouth except water for at least 8 hours.

Glucose tolerance testing provides greater sensitivity than FPG but at the expense of greater burden and somewhat less reproducibility. To properly perform an oral glucose tolerance test (OGTT), the patient should be in generally good health without acute or uncontrolled chronic illness and should consume a high-carbohydrate diet (at least 200 g daily) for at least 3 days. The test should be performed in the morning and fasting. Nonpregnant adults should drink an oral solution containing 75 g of dextrose over no more than 3 minutes and should remain seated without smoking for 2 hours. Nausea is a fairly common complication of the OGTT. A single plasma glucose sample is drawn at the 2-hour time point.

Normal levels of glucose are defined as follows:

- Fasting: <100 mg/dL
- 2-hour OGTT: <140 mg/dL

The following levels of glucose are suggestive of diabetes but require confirmation for diagnosis:

- Fasting: ≥ 126 mg/dL, and/or
- 2-hour OGTT: ≥ 200 mg/dL
- In patients with symptoms of diabetes (polyuria, polydipsia, weight loss), random glucose measurements: ≥ 200 mg/dL

Generally, to make the diagnosis, measurements should be made on 2 separate days either repeating the same test or performing another.

Prediabetes is a state of abnormal glucose regulation associated with about twice the risk for developing diabetes and modestly increased risk for developing cardiovascular disease. The diagnosis of prediabetes is suggested by glucose levels as follows:

- Fasting: 100 to 125 mg/dL (i.e., impaired fasting glucose [IFG])
- 2-hr OGTT: 140 to 199 mg/dL (i.e., impaired glucose tolerance [IGT])

Management and Therapy

Optimum Treatment

The American Diabetes Association has recently developed consensus recommendations regarding the management of prediabetes and diabetes, which are summarized in Figure 39-1.

In patients with prediabetes, the development of DM can be prevented or delayed with diet and exercise programs aimed at producing a 5% to 10% loss of body weight, including at least 30 minutes of moderately vigorous physical activity at least 5 days per week.

Because lifestyle therapy is generally well tolerated and associated with broad-based benefits, it is recommended as treatment for both prediabetes and diabetes. To be effective, lifestyle (medical nutrition therapy and physical activity) interventions must be delivered flexibly in a patient-centered approach that both cajoles and seduces patients into a more healthful lifestyle through small steps and frequent follow-up, preferably with the help of a dietitian, diabetes educator, or other qualified lifestyle coach (Fig. 39-2). The major tenets of lifestyle management are to promote consistent moderate carbohydrate intake with an emphasis on whole grains, vegetables, and fruit combined with low saturated and polyunsaturated fat intake and regular aerobic exercise.

Pharmacologic intervention in the setting of prediabetes should be reserved for those at highest risk for developing diabetes and with the best predicted response to therapy: people with both IFG *and* IGT as well as at least one other high-risk feature:

- Age < 60 years
- BMI ≥ 35 kg/m²
- Family history of diabetes in first-degree relatives
- Elevated triglycerides
- Reduced HDL cholesterol

- Hypertension
- Hemoglobin A1C $> 6.0\%$

Based on expense, tolerability, and safety, metformin is the only currently recommended therapy for diabetes prevention. There is evidence that acarbose, orlistat, and rosiglitazone can be effective in preventing or delaying the development of diabetes, but each of these therapies is more expensive and associated with specific adverse effects that make the risk-benefit balance uncertain.

Glycemic control is a central issue for both patients and providers in the management of both type 1 and type 2 DM (see Fig. 39-2); the control of other cardiovascular risk factors is equally important. There are adequate prospective randomized clinical trial data documenting that treatment policies associated with more stringent glycemic targets are associated with decreased rates of retinopathy, nephropathy, and neuropathy. Epidemiologic studies support the potential of intensive glycemic control to reduce cardiovascular risk. For most patients, the following glycemic targets would be associated with a low risk for complications:

- Premeal plasma glucose between 70 and 130 mg/dL
- One- to 2-hour peak postprandial glucose levels less than 180 mg/dL
- Hemoglobin A1C levels below 7%

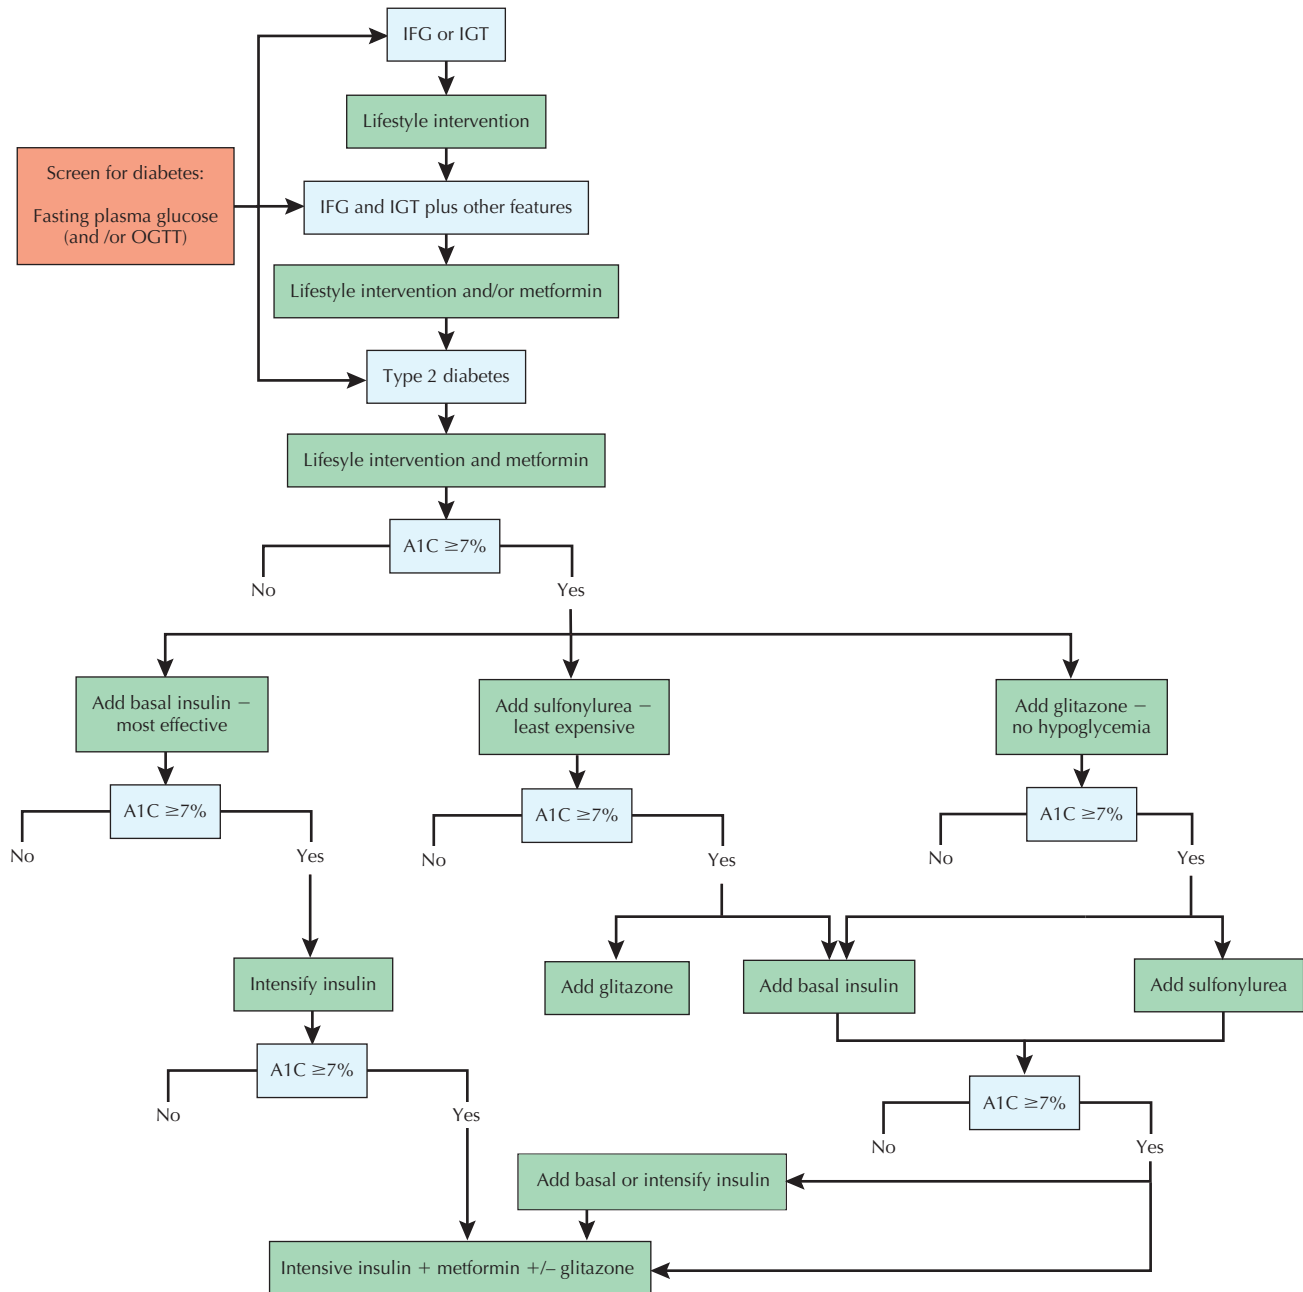

More stringent control (A1C $< 6\%$) is appropriate if the patient tolerates the therapy required. Less stringent treatment goals may be appropriate for patients with limited life expectancies (< 6 years). There are no adequately powered clinical trial data available to document the benefit of glycemic control in the setting of advanced complications, in elderly patients (> 65 years), and in young children (< 13 years). Severe or frequent hypoglycemia is an indication for modification of treatment regimens, including higher premeal and postprandial targets. Self-monitoring of blood glucose, lifestyle modification, and self-management education are integral parts of intensive glucose management strategies associated with a lower risk for complications.

There are inadequate clinical trial data to support dogmatic statements regarding optimal approaches to the management of type 2 DM. Eleven classes of treatments for diabetes are currently available (Table 39-1). In general, long-term clinical trials with metformin, pioglitazone, insulin, and sulfonylureas demonstrate at least trends toward reduction in cardiovascular outcomes. Current recommendations suggest that lifestyle intervention combined with metformin therapy should be initiated at the diagnosis of diabetes. Metformin monotherapy is relatively inexpensive and is not associated with hypoglycemia or weight gain. However, there are a number of contraindications to its use that must be carefully considered.

In patients who do not reach an A1C of less than 7% with lifestyle therapy plus metformin, and particularly in patients with premeal glucose levels of more than 250 mg/

Figure 39-1 Algorithm for Care of People with Prediabetes and Diabetes.

IFG, impaired fasting glucose; IGT, impaired glucose tolerance; OGTT, oral glucose tolerance test. Adapted from Nathan DM, Buse JB, Davidson MB, et al: *Management of hyperglycemia in type 2 diabetes mellitus: A consensus algorithm for the initiation and adjustment of therapy. Diabetes Care* 29(8):1963-1972, 2006; and Nathan DM, Davidson MB, DeFronzo RA, et al: *Impaired fasting glucose and impaired glucose tolerance. Diabetes Care* 30(3):753-759, 2007.

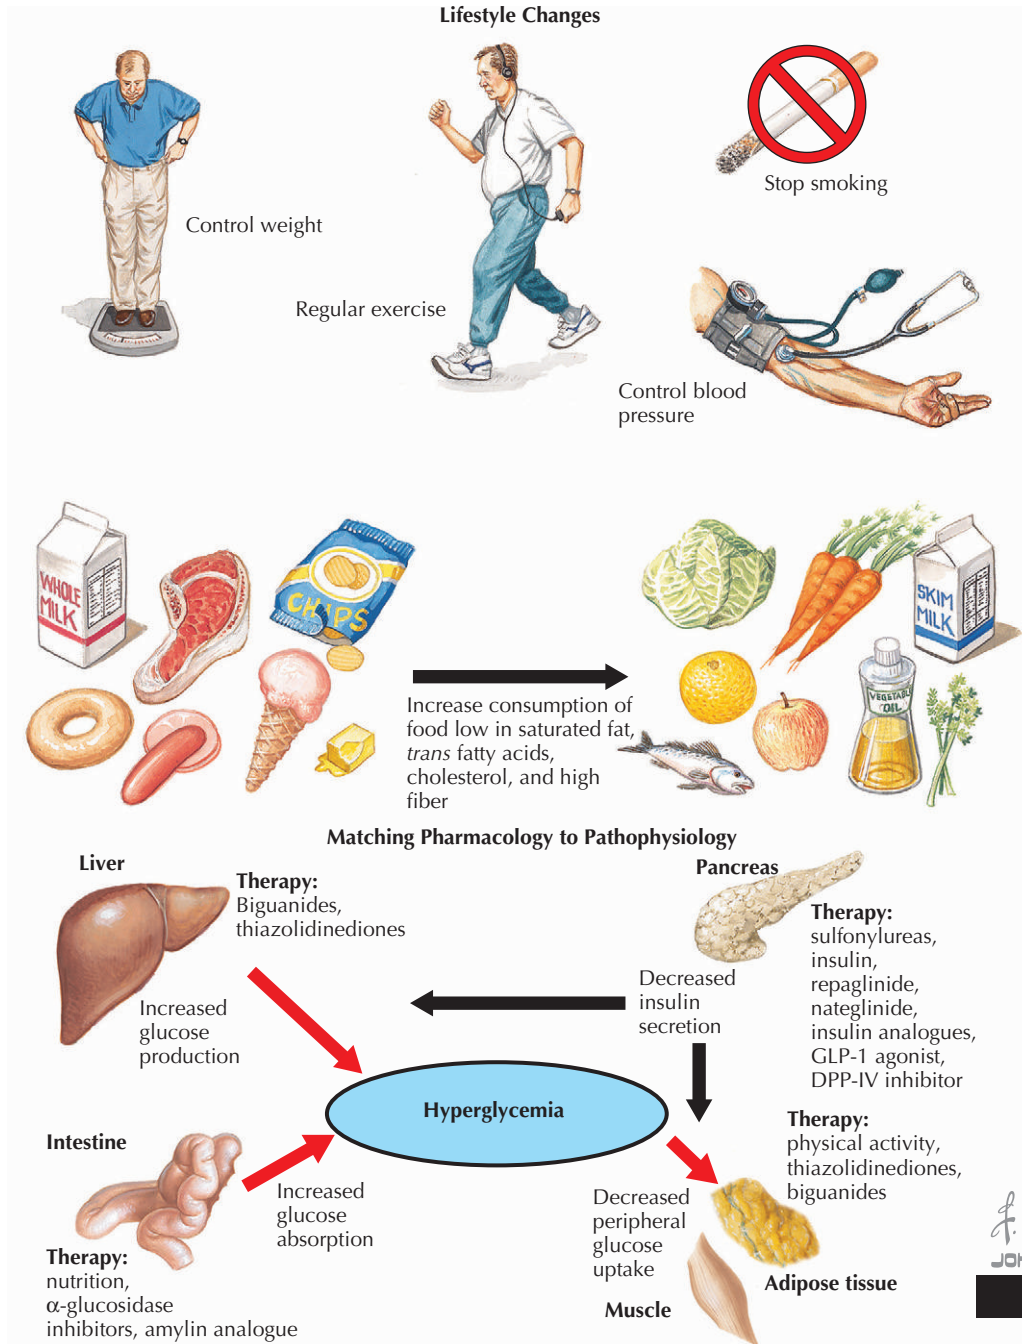

dL, early insulin therapy warrants consideration because it is the most effective antihyperglycemic therapy. Evening doses of long-acting insulin, specifically NPH (neutral protamine Hagedorn) insulin, glargine, or detemir, are highly effective in lowering A1C, although at times doses in excess of 1 U/kg per day are required. Alternative additional therapies in the algorithm include sulfonylureas, which are the least expensive antihyperglycemic treatment,

and thiazolidinediones (rosiglitazone and pioglitazone), which are associated with a low risk for hypoglycemia and progression of β -cell dysfunction. If lifestyle therapy combined with metformin and an additional agent is inadequate to achieve fasting and premeal glucose targets, additional agents should be added sequentially.

There are six additional classes of antihyperglycemic agents that are not included in the algorithm, predomi-

Figure 39-2 Nonpharmacologic Therapy.

nantly because long-term safety and efficacy studies with these agents have not been completed. The α -glucosidase inhibitors (acarbose and miglitol) lower postprandial glucose by reducing the rate of carbohydrate absorption from the intestinal tract. The major barrier to their use is abdominal complaints. Repaglinide and nateglinide (often lumped together as *glinides*, although technically belonging to two distinct classes of medications) are not sulfonylureas, but their action is mediated through the sulfonylurea receptor; they provide for moderately less risk for hypoglycemia

and some greater postprandial effect than glyburide. Exenatide is a glucagon-like peptide-I (GLP-1) agonist associated with predominantly postprandial glucose lowering, moderate weight loss, and no intrinsic risk for hypoglycemia. Sitagliptin is the first dipeptidyl peptidase (DPP)-IV inhibitor, an oral agent that increases GLP-1 levels modestly, producing glucose lowering without weight gain or hypoglycemia. Pramlintide is an amylin-mimetic approved for use in insulin-treated patients with type 2 diabetes; it reduces postprandial glucose and promotes weight loss.

Table 39-1 Antihyperglycemic Agents in Type 2 Diabetes and Their Characteristics

Class	A1C Reduction	Fasting vs. PPG	Hypoglycemia	Weight Change	Dosing (times/day)
Metformin	1.5	Fasting	No	Neutral	2
Insulin, long acting	1.5-2.5	Fasting	Yes	Gain	1, injected
Insulin, rapid acting	1.5-2.5	PPG	Yes	Gain	1 to 4, injected
Sulfonylureas	1.5	Fasting	Yes	Gain	1
Glitazones	0.5-1.4	Fasting	No	Gain	1
Repaglinide	1-1.5	Both	Yes	Gain	3
Nateglinide	0.5-0.8	PPG	Rare	Gain	3
α -Glucosidase inhibitors	0.5-0.8	PPG	No	Neutral	3
Amylin-mimetics (pramlintide)	0.5-1.0	PPG	No	Loss	3, injected
Incretin agonists (exenatide)	0.5-1.0	PPG	No	Loss	2, injected
DPP-IV inhibitors	0.6-0.8	Both	No	Neutral	1

DPP-IV, dipeptidyl peptidase-IV; PPG, postprandial glucose.

Adapted from Nathan DM, Buse JB, Davidson MB, et al: *Management of hyperglycemia in type 2 diabetes mellitus: A consensus algorithm for the initiation and adjustment of therapy. Diabetes Care* 29(8):1963-1972, 2006.

Most patients can achieve recommended glucose targets using combinations of agents that improve insulin sensitivity (metformin and thiazolidinediones) with agents that increase insulin levels (sulfonylureas, repaglinide, nateglinide, exenatide, sitagliptin, and insulin) as well as combinations of agents that primarily decrease fasting and premeal glucose levels (metformin, glitazones, sulfonylureas, and long-acting insulins) with agents that decrease postprandial glucose (α -glucosidase inhibitors, repaglinide, nateglinide, rapid-acting insulin, exenatide, sitagliptin, pramlintide). It is even now possible to use combinations of agents that promote weight loss (metformin, exenatide, pramlintide) or are not associated with hypoglycemia (metformin, glitazone, α -glucosidase inhibitor, exenatide, pramlintide, sitagliptin).

Management of type 1 DM requires replacement of insulin in a physiologic fashion. Novel insulin analogues allow this to be achieved to a greater extent than older insulin preparations. In general, most patients with type 1 DM require a multiple daily injection regimen in which they administer a long-acting insulin (i.e., glargine, detemir, NPH human insulin) to control fasting glucose and prevent the rise in glucose between meals. A fast-acting insulin analogue (lispro, aspart, or glulisine) or regular human insulin is administered with each meal in proportion to carbohydrate intake, taking into account planned activity and current levels of glucose. Using this regimen or a continuous subcutaneous insulin infusion (insulin pump) minimizes glycemic excursions. Such intensive regimens generally require substantial commitment on the part of the patient as well as a team of health care providers, including DM educators, dietitians, and physicians, to be effectively implemented. Frequent glucose monitoring (3 to 8 or more times a day) or the use of continuous glucose sensors is necessary to avoid severe hypoglycemia and allow

for rapid adjustments for changes in control. Pramlintide, as an adjunct to rapid-acting insulin, can be used to help lower A1C, postprandial glucose, and weight in the setting of type 1 or type 2 diabetes.

Hypoglycemia is the most common complication of diabetes and the major limitation to tight glycemic control. Particularly in type 1 diabetes, it can be severe, requiring the assistance of another person and even resulting in death, usually as a consequence of trauma. Patients should be asked about hypoglycemia at each encounter—what symptoms they experience and at what level of glucose. Early recognition and treatment of hypoglycemia will prevent more advanced symptoms and may over a period of years delay the development of hypoglycemic unawareness. Occasional glucose levels under 70 mg/dL should not cause great concern unless they occur unexpectedly or without accompanying symptoms. Expectant adjustments in medication, diet, and exercise prescriptions to avoid hypoglycemia are critical. Screening for nocturnal hypoglycemia by home blood glucose monitoring between 1 AM and 4 AM is essential. Temporary but complete avoidance of hypoglycemia (for 3 to 6 months) by raising glycemic goals can reverse hypoglycemic unawareness in many cases. Treatment of hypoglycemia should be measured (15 g carbohydrate, e.g., 4 oz. juice or caloric soda, 3 to 4 glucose tablets), with repeat blood glucose testing after 10 to 15 minutes and additional therapy as necessary. In the case of presumed severe hypoglycemia, intramuscular glucagon can be administered in the field by lay people while awaiting emergency-trained professionals. Certified diabetes educators should always participate in patient education, particularly in regard to hypoglycemia and other complications.

Because more than two thirds of patients with DM die from cardiovascular disease, aggressive management of

other cardiovascular risk factors is at least as important as glucose management. Current recommendations suggest that most patients with DM should do the following:

- Take aspirin, 81 mg/d (if older than 40 years or older than 30 years with additional CVD risk factors)
- Reduce blood pressure to less than 130/80 mm Hg with an antihypertensive regimen that generally includes an angiotensin-converting enzyme inhibitor or angiotensin receptor blocker
- Take a statin at a dose adequate to reduce LDL cholesterol by 30% to 40% and to reduce LDL to less than 100 mg/dL (<70 mg/dL in the setting of CVD)
- Reduce triglycerides to less than 150 mg/dL
- Increase HDL cholesterol to more than 40 mg/dL (perhaps 50 mg/dL in women)
- Stop smoking or don't start.

Finally, there are patients who, despite seemingly best efforts, have difficulty achieving adequate control of hyperglycemia and associated cardiovascular risk factors. In those individuals, there is a higher prevalence of depression and other psychological syndromes, sleep-disordered breathing, substance abuse, and physical or emotional abuse that should be screened for and treated if identified.

Avoiding Treatment Errors

The medical regimens required for treatment of diabetes and its comorbidities generally involve several to many pharmacologic agents and are often comanaged by primary care providers, consultants, and diabetes educators. Complicating this situation further is the fact that pharmacy benefit managers often request changes in medications that are not adequately communicated to all providers involved. Patients and providers should take great care in maintaining up-to-date lists of both over-the-counter and prescribed medications. Patients need to have a plan for sick days when oral intake is compromised; generally, they should take their medications as prescribed and monitor glucose more frequently, specifically in the setting of type 1 diabetes. Patients must understand that frequent or severe hypoglycemia is a potentially life-threatening complication of diabetes that must be brought to the attention of health care providers immediately to allow adjustment in therapy.

Future Directions

There is a huge pipeline of drugs in development, including numerous agents that promote weight loss. An exciting possibility for the future is that new islet growth can be fostered. Better glucose monitoring and insulin delivery

devices are under development, including approaches that combine these two techniques to create a closed loop or artificial β cell capable of administering insulin based on continuous monitoring of plasma glucose. A number of trials are underway to explore tighter glycemic, blood pressure, and lipid targets and establish their risks and benefits. Increasing efforts are going to focus on diabetes prevention; studies are underway to demonstrate the effectiveness of such approaches to improve outcomes. A broad-based public health approach to deal with the epidemic of obesity and DM is necessary to avoid the almost unimaginable morbidity and expense in managing the metabolic consequences of overnutrition and underactivity.

Prevention and Treatment of Complications of Diabetes

Introduction

Coupled with the current epidemic of diabetes mellitus (DM) is an increasing burden of death and disability. DM is the sixth leading cause of death as reported on death certificates, contributing to more than 200,000 deaths annually. This is likely a gross underestimate of its true burden because only one third of death certificates of those dying with diabetes list diabetes as a contributor despite the fact that more than two thirds succumb to cardiovascular diseases (CVDs) in which diabetes is a clear contributor. DM or prediabetes is present in about two out of three patients with clinical CVD, about two thirds of them are unaware of their diagnosis. The underlying metabolic syndrome of diabetes is clearly a major contributor to CVD, the leading cause of mortality in the Western world.

Microvascular complications of diabetes, namely eye, kidney, and nerve diseases, result in much of the disability associated with diabetes. Diabetes is the leading cause of new cases of blindness among adults with diabetic retinopathy contributing to about 20,000 new cases of blindness each year.

Diabetes is the leading cause of end-stage renal disease, accounting for almost 50% of new cases in the United States. Each year, more than 40,000 people with diabetes begin treatment for end-stage renal disease, and more than 150,000 are maintained on chronic dialysis or with kidney transplantation.

At least 60% of people with diabetes have one or more forms of diabetic neuropathy associated with a wide range of symptoms. Severe peripheral neuropathy is the major contributor to diabetic foot ulcers and amputations. More than 80,000 lower-limb amputations are performed annually among people with diabetes; this is about 60% of nontraumatic amputations in the United States.

Other complications of diabetes are legion. Poor control before conception and during the first trimester of pregnancy causes major birth defects in 5% to 10% of pregnancies and spontaneous abortions in 15% to 20%. Later in pregnancy, poor glycemic control is associated with substantial complications during delivery for both mother and child. Almost one third of people with diabetes have severe periodontal diseases. Musculoskeletal disorders associated with pain and decreased mobility are more common than in the general population. Diabetes is associated with an increased risk for many forms of cancer as well as overall cancer mortality. Particularly in the setting of poorly controlled diabetes, issues such as hypercoagulability and poor immunologic defenses contribute to excess morbidity and mortality across the entire spectrum of human maladies from influenza infections to recovery from surgery.

The costs of diabetes are staggering. In 2002, direct medical costs related to the disease were estimated to be \$92 billion, with an additional \$40 billion in indirect costs due to disability, work loss, and premature mortality. This estimated \$132 billion price tag is an underestimate because it omits costs incurred in the undiagnosed, the cost of care provided by family members and friends, and areas of health care spending unaccounted for in which people with diabetes consume services at higher rates than the general population, including care by optometrists and dentists. Overall health care costs in individuals with diabetes are more than double those in people without diabetes.

Put another way, in the United States, every hour among diagnosed patients with diabetes, the following occur:

- More than \$15 million is spent on health care
- Two patients go blind
- Five patients start dialysis
- Six patients suffer stroke
- Nine patients undergo amputation
- Ten patients have a heart attack
- Twenty-six patients die

Etiology and Pathogenesis

Glucose-dependent mechanisms for the development of complications have been described, including the intracellular accumulation of sorbitol, overactivity of protein kinase C, and the development of advanced glycosylation end products. How important these glucose-specific mechanisms are in the generation of complications is unclear. With respect to both CVD and microvascular complications, the contribution of hyperglycemia, increased blood pressure, lipid disorders, hypercoagulability, and smoking is absolutely clear. Finally, as one might expect, patients with any one complication are more likely to suffer others. Primary prevention, screening for early markers of complications, and intensive secondary intervention are critical to provide for optimal outcomes.

Clinical Presentation

With regard to macrovascular disease, the classic presentations of angina, myocardial infarction, stroke, transient ischemic attacks, and claudication are quite common (Figs. 40-1 and 40-2). As is true in nondiabetic individuals, many afflicted with life-threatening vascular disease are asymptomatic. A recent study documented that among patients with type 2 diabetes between the ages of 50 and 75 years who had no history of ischemic heart disease, a normal electrocardiogram, and negative screening questionnaire for anginal symptoms, 22% had silent ischemia by electrocardiograph (ECG)-gated adenosine-stress single-photon emission computed tomography.

Diabetic retinopathy is generally asymptomatic, although, as late manifestations, patients may note a change in their visual field with retinal detachments or may experience blurred vision in the setting of intraocular hemorrhage or macular edema (see Fig. 40-1).

Diabetic nephropathy is also generally asymptomatic until the late stages when patients present with fatigue, edema, symptoms of fluid overload, or a hypertensive crisis (see Fig. 40-1).

Diabetic neuropathy has multiple manifestations as a result of involvement of peripheral motor and sensory nerves, cranial nerves, and the autonomic nervous system. The most common of these is peripheral neuropathy, which can present with numbness or dysesthesias, including burning or tingling (Fig. 40-3; see Fig. 40-2). In general,

these symptoms proceed from distal sites proximally and can be associated with motor dysfunction. Mononeuropathies may develop in motor, sensory, or cranial nerves and present with dysfunction of a single nerve. Entrapment neuropathies such as carpal tunnel syndrome are quite common. Autonomic dysfunction can lead to disabling symptoms, including decreased night vision, facial sweating with meals, postprandial bloating, nausea, vomiting, diarrhea, constipation, orthostasis, dyshidrotic skin, urinary retention, and sexual dysfunction (see Fig. 40-2).

Differential Diagnosis

Diabetic retinopathy is pathognomonic of DM, although the retinopathy associated with acromegaly can present in a similar fashion.

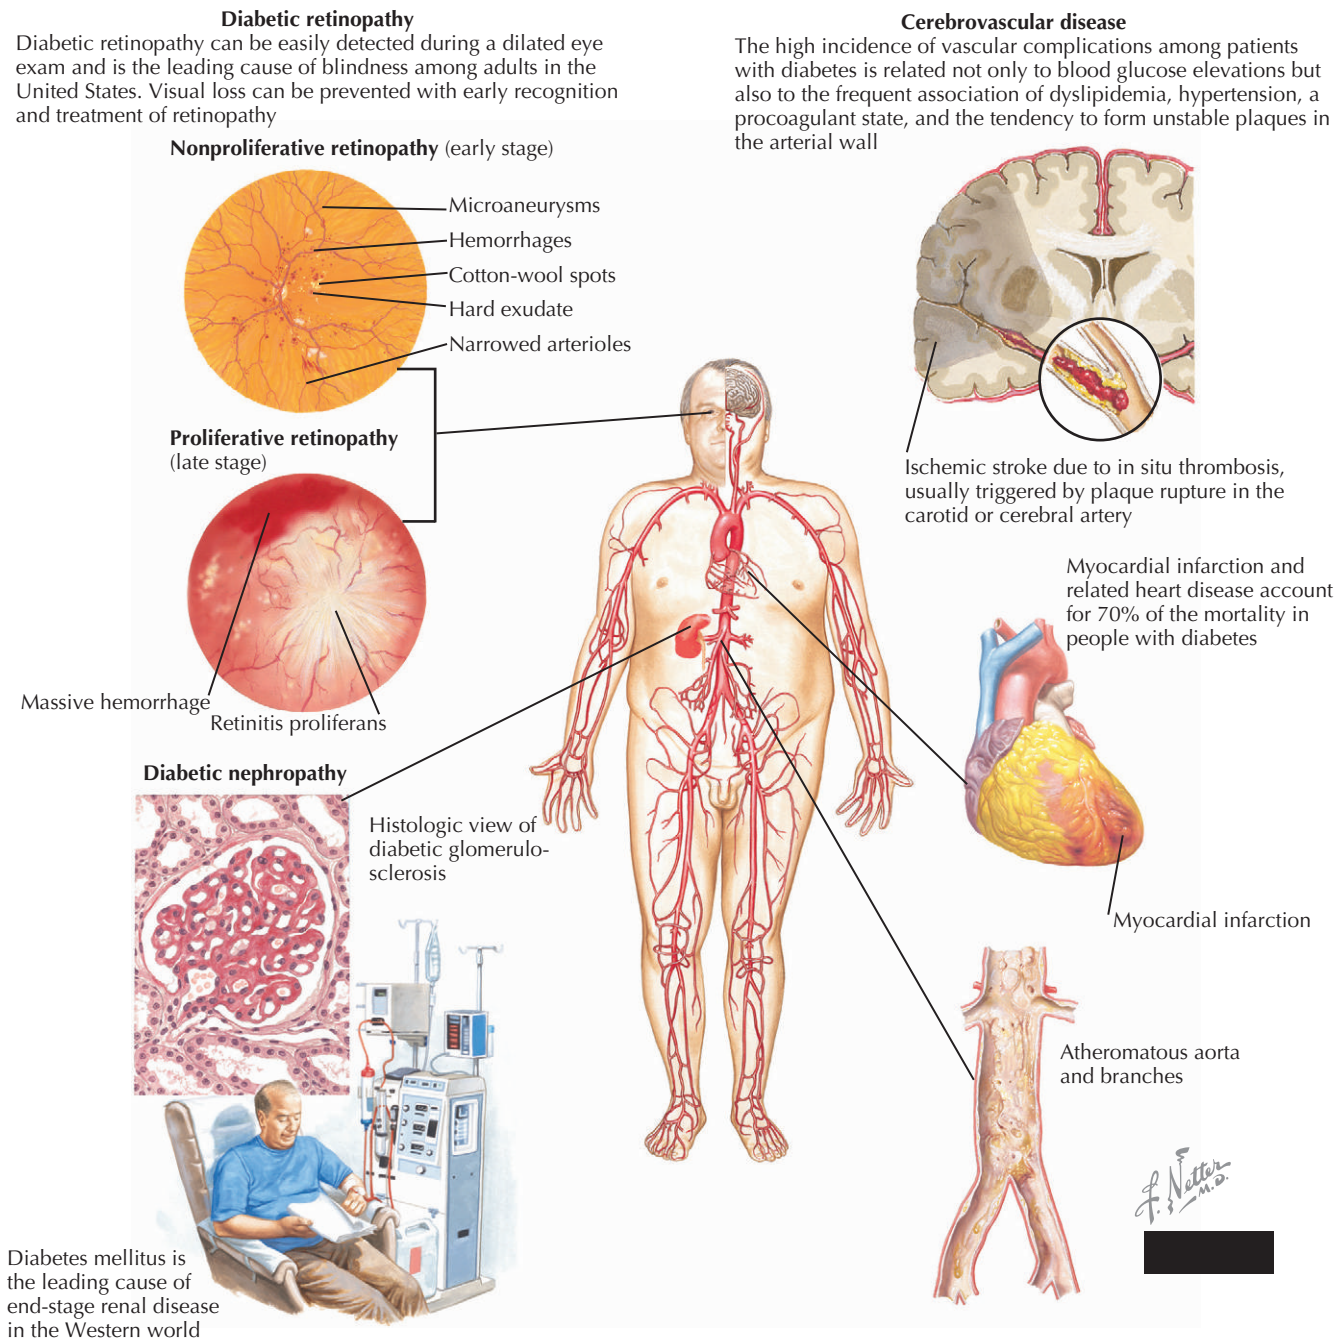

Diabetic nephropathy characteristically is associated with increased protein excretion, initially only detected with a very sensitive assay for microalbuminuria, then progressing to the full-blown nephrotic syndrome. In a patient with proteinuria and evidence of retinopathy, the renal disease is most often related to DM. In the absence of retinopathy or significant proteinuria, renal insufficiency is often secondary to other forms of kidney disease, particularly that caused by hypertension.

There is a substantial differential diagnosis for each of the peripheral and autonomic neuropathies. It is prudent to exclude reversible causes, such as vitamin B₁₂ deficiency, tertiary syphilis, hypothyroidism, heavy-metal intoxication, and monoclonal gammopathies, by utilizing the history, physical examination, and selected laboratory tests. If physical examination findings are asymmetrical or associated with back pain or other neurologic findings, consideration of spinal or central nervous system pathology is essential. Characteristically, the pain of diabetic neuropathy is worst at rest. Subcritical peripheral vascular disease warrants consideration because it is common and, like neuropathy, is often associated with worse symptoms in the supine position.

Diagnostic Approach

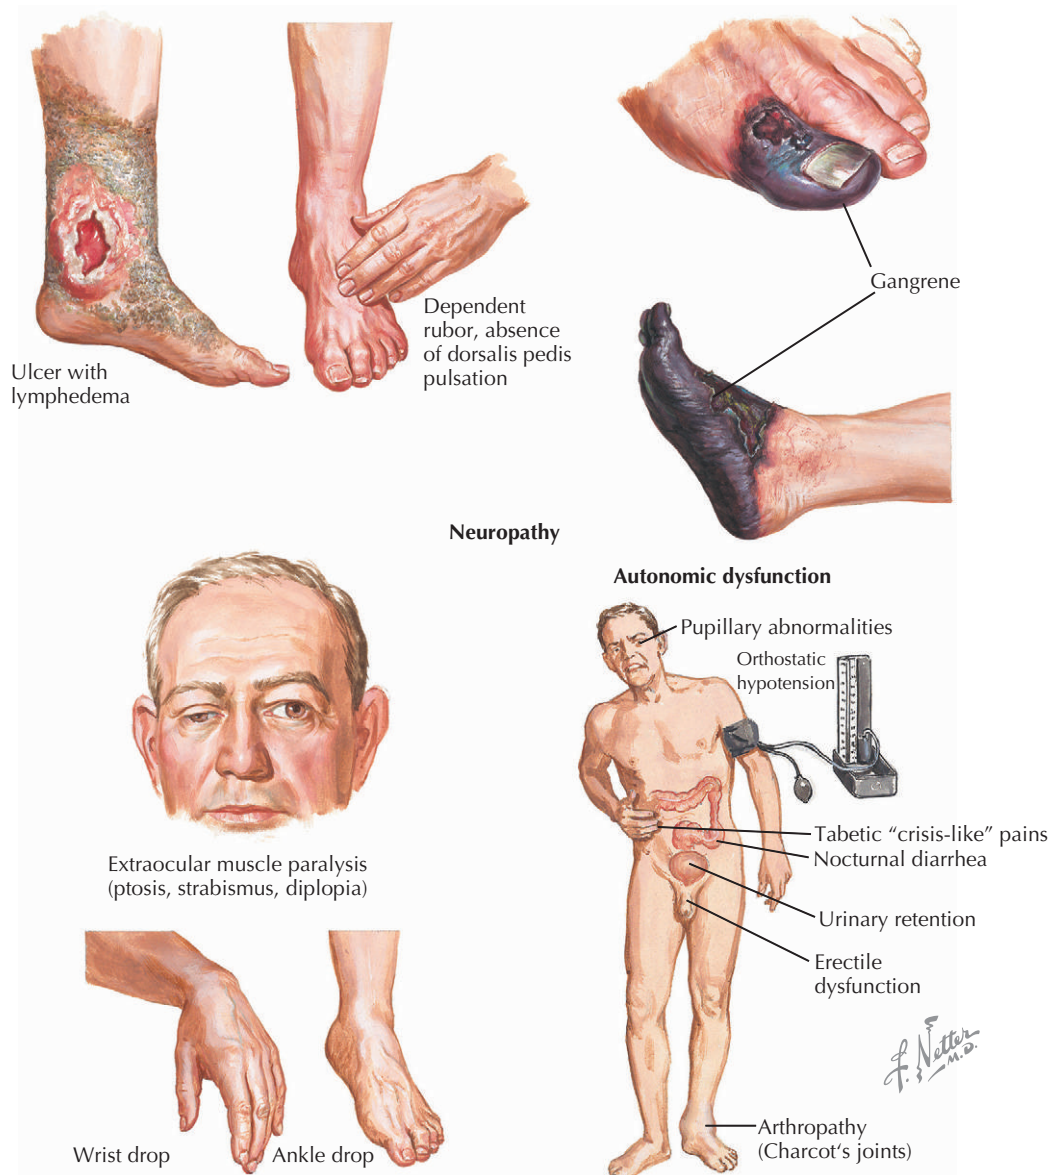

The key to management of the complications of diabetes is screening to detect early manifestations. For CVD, relevant recommendations include the following:

Figure 40-1 Microvascular and Macrovascular Complications.

- Blood pressure should be measured at every visit. If the blood pressure is 130 mm Hg or greater systolic, or 80 mm Hg or greater diastolic, the elevation should be confirmed on a separate day.
- A fasting lipid panel should be performed annually. If the patient is not available for testing in the fasting state, a nonfasting non-high-density lipoprotein (non-HDL) cholesterol is a reasonable surrogate for low-density lipoprotein (LDL) cholesterol but may miss even severe disorders of HDL or triglyceride metabolism. If the full

- fasting lipid panel is normal, testing may be deferred to every 2 years.
- Patients should be asked about tobacco use at every visit.
- Diagnostic stress testing with imaging procedures should be considered in those with ECG abnormalities, typical or atypical cardiac symptoms, known vascular disease or sedentary lifestyle older than 35 years who are planning to start a vigorous exercise program. Routine stress testing will identify many patients with disease, but it

Figure 40-2 Peripheral Vascular Disease.

remains unclear whether invasive management is associated with improved outcomes in the setting of asymptomatic CVD in diabetes.

To detect other early complications, the following are recommended annually beginning at diagnosis in the setting of type 2 diabetes and within 3 to 5 years in type 1 diabetes:

- Dilated and comprehensive eye exams by an eye care professional
- Spot urine sample for a microalbumin-to-creatinine ratio
 - An albumin excretion ratio of at least 30 μg albumin per mg creatinine suggests diabetic kidney disease.
 - Two out of three measures over a 6-month period are required for diagnosis of albuminuria.
- Serum creatinine for the estimation of glomerular filtration rate (GFR)
- Screen for distal symmetrical polyneuropathy, using simple clinical tests such as vibration perception with a 128-Hz tuning fork and pressure sensation using a 10-g monofilament at the distal plantar aspect of both great toes; electrophysiologic testing is rarely needed.
- Screen for autonomic neuropathy by a general review of systems.
- Identify high-risk foot-related conditions in addition to distal symmetrical polyneuropathy by visual inspection and palpation to identify altered biomechanics, evidence of increased pressure, peripheral vascular disease, or severe nail pathology.
- Semiannual exam and tooth cleaning by oral health professional

Figure 40-3 Neuropathy and Fungal Infection.

Fungal Infection

Fungal infections of the nails and skin are common in patients with diabetes. With foot involvement, accompanying minor skin lesions can be the portal of infection and can result in chronic wounds and even amputations. Excellent foot care and antifungal therapy are important preventative measures in the setting of advanced diabetic neuropathy

Management and Therapy

Optimum Treatment

Because more than two thirds of patients with DM die from CVD, aggressive management of other cardiovascular risk factors is at least as important as glucose management. Current recommendations suggest that most patients with DM should do the following:

- Take aspirin, 81 mg/d (if older than 40 years or older than 30 years with additional CVD risk factors).

- Reduce blood pressure to less than 130/80 mm Hg with a blood pressure regimen that generally includes an angiotensin-converting enzyme (ACE) inhibitor or angiotensin receptor blocker (ARB).
- Take a statin at a dose adequate to reduce LDL cholesterol by 30% to 40% and to reduce LDL to less than 100 mg/dL (<70 mg/dL in the setting of CVD).
- Reduce triglycerides to less than 150 mg/dL.
- Increase HDL cholesterol to more than 40 mg/dL (perhaps 50 mg/dL in women).
- Stop smoking or don't start.

In addition to glucose management as described in Chapter 39 and control of CVD risk factors as described earlier, there are a number of interventions that have been demonstrated to reduce the risk for developing clinical microvascular complications.

To slow the progression of diabetic kidney disease:

- Blood pressure targets less than 130/80 mm Hg can be considered.
- Prescribe an ACE inhibitor or ARB.
- Reduce dietary protein intake to 0.8 to 1.0 g per kg body weight per day.
- Refer to a physician experienced in the care of diabetic kidney disease when estimated GFR has fallen to less than 60 mL/min per 1.73 m².

To minimize the risk for visual loss, refer all patients with macular edema, proliferative retinopathy, or severe nonproliferative diabetic retinopathy to an ophthalmologist expert in the management of diabetic retinopathy.

To minimize the risk for amputation in patients with severe distal symmetrical polyneuropathy or other high-risk foot conditions, provide comprehensive foot self-care education, including the need for daily inspection, nail and skin care, and appropriate footwear. Also consider referral to a foot care specialty center for ongoing preventive care and surveillance.

Only recently have U.S. Food and Drug Administration–approved products for the treatment of painful distal symmetrical polyneuropathy become available: duloxetine and pregabalin. There are a large number of moderately effective therapies for distal polyneuropathy and autonomic neuropathies that can improve symptoms but do not alter the underlying pathophysiology or natural histories of these disorders. Medical providers should discontinue these therapies if relief of symptoms does not occur after titration to an adequate dose.

Avoiding Treatment Errors

The most common errors in the management of diabetic complications are failure to make a timely diagnosis and nonadherence to treatment guidelines once a diagnosis is made, often as a result of oversight. The health care team (both patients and providers) should keep a checklist to ensure that all the listed screening tests are performed at least annually and recommended preventative therapies continued. Nonjudgmental consistent collaboration among the team is the best guarantee that recommendations are adhered to by both patients and providers. In diabetes care, disability results from failure of the team more often than failure of the treatment.

Future Directions

There are a wide variety of treatments that target specific glucose-mediated mechanisms in the development of complications, which although promising, have been somewhat disappointing to date. We have the technology to prevent the development of most complications with glucose control, cardiovascular risk factor management, and screening with referral for specialty care in patients who have early complications. Historically, there has been widespread failure of health care teams to achieve the recommended targets or conduct the recommended screening tests. Recent changes in patient and physician awareness, coupled with potential changes in health care financing, raise the hope that complications of diabetes could be dramatically reduced in the next few decades.

Hypothyroidism

Introduction

Hypothyroidism is a common condition that occurs when the thyroid is unable to produce enough thyroid hormone to meet the body's needs. Onset can occur at any age and is more common in women, with a prevalence of about 2% in some age groups (compared with 0.1% in men). Congenital hypothyroidism is one of the most common endocrine abnormalities present at birth (about 1 in 5000 births).

Etiology and Pathogenesis

Thyroid-stimulating hormone (TSH, or thyrotropin), a glycoprotein produced by pituitary thyrotrophs, stimulates the synthesis and secretion of thyroid hormones by the thyroid. TSH binds to a plasma membrane receptor on thyroid follicular cells and activates adenylate cyclase. It stimulates every facet of thyroid iodine metabolism and promotes thyroid growth. TSH biosynthesis and secretion is inhibited by triiodothyronine (T_3) and thyroxine (T_4), forming a sensitive feedback loop to keep free thyroid hormone concentrations constant. Thyrotropin-releasing hormone (TRH) is a hypothalamic tripeptide that stimulates TSH release. TRH appears to set the level by which the negative feedback loop maintains thyroid hormone levels. Disturbances in the TRH-TSH-thyroid axis can lead to hypothyroidism.

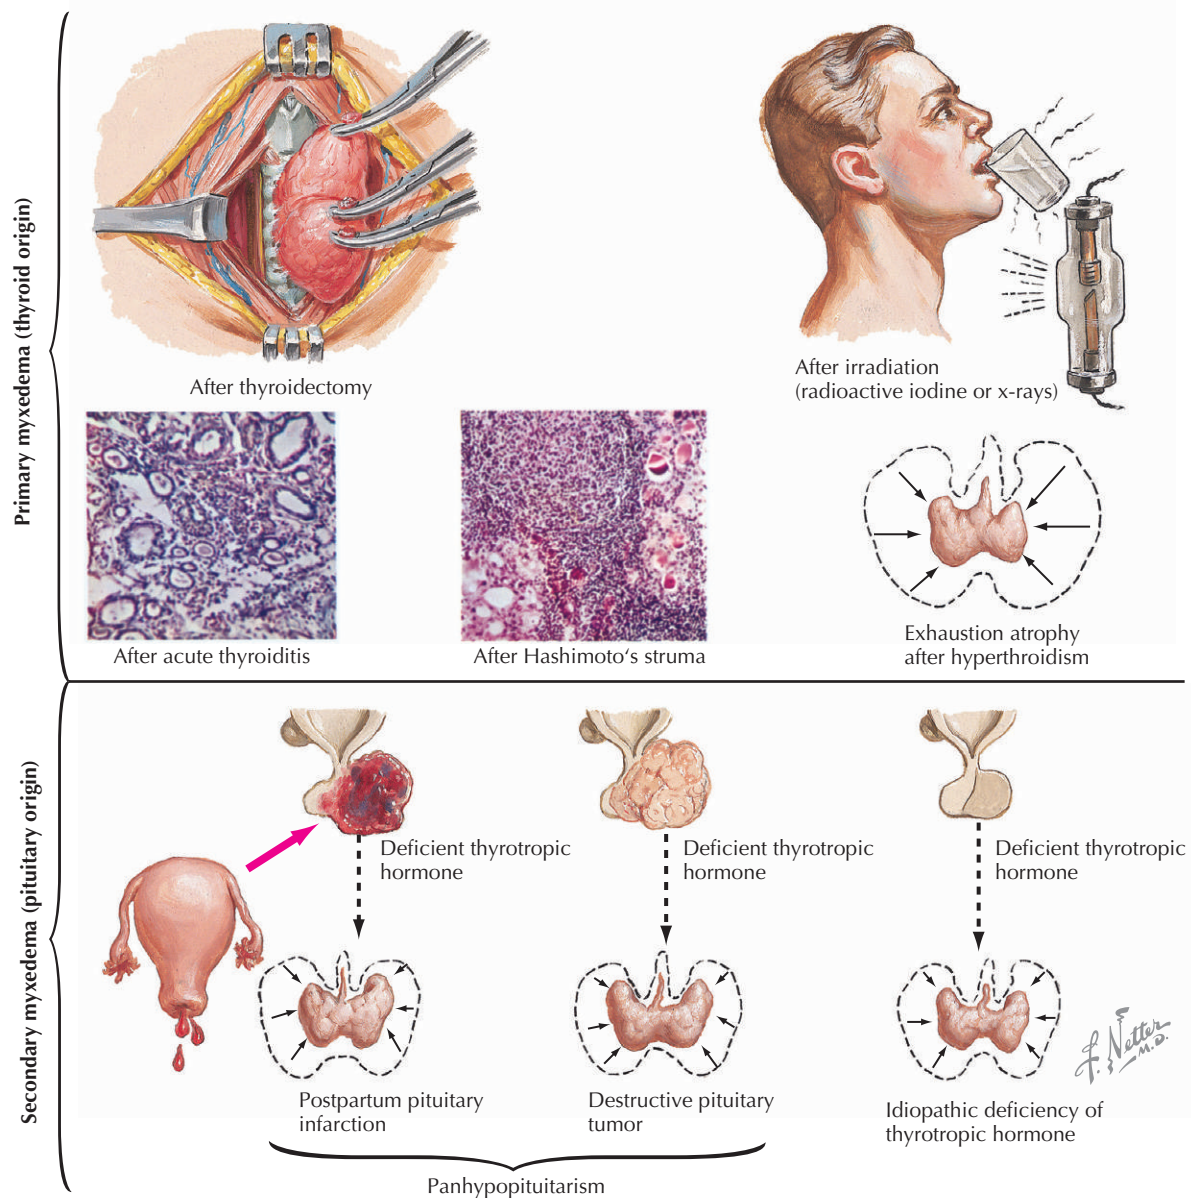

Primary hypothyroidism, the most common cause of thyroid failure, results in low serum thyroid hormone with elevated TSH levels. Loss of functional thyroid tissue and interference of thyroid hormone production are the major causes of primary hypothyroidism (Fig. 41-1).

Loss of functional thyroid tissue is usually due to autoimmune thyroid dysfunction (e.g., Hashimoto's or chronic lymphocytic thyroiditis; see Fig. 41-1). It is sometimes associated with polyglandular autoimmune syndromes and a family history of thyroid dysfunction. High titers of anti-thyroid antibodies (antithyroid peroxidase and antithyroglobulin antibodies) are common, although titers are sometimes low, particularly in elderly patients. Cell-mediated (T-lymphocyte) destruction of the thyroid probably plays a more significant role in thyroid damage than thyroid antibodies. Pathologic study shows lymphocytic

infiltration and fibrosis with destruction of follicles resulting in an atrophic thyroid gland or a firm, nontender diffuse goiter. Gradually, T_4 and T_3 synthesis is impaired, prompting a compensatory rise in TSH and a "subclinical" phase that may precede the onset of frank hypothyroidism. Usually, hypothyroidism is chronic, but transient hypothyroidism as well as hyperthyroidism can occur. Silent ("painless") thyroiditis is a common cause of transient hyperthyroidism, hypothyroidism, or both in the postpartum period (about 5% prevalence). Procedures that remove or destroy functional thyroid tissue, such as surgery or radioactive iodine, can render a person permanently hypothyroid. Finally, congenital agenesis or dysgenesis of the thyroid gland can occur.

Interference with thyroid hormone production is often drug induced. Iodine and lithium inhibit thyroid hormone secretion, particularly in patients with mild autoimmune thyroiditis. Endemic iodine deficiency can lead to goiter, cretinism, and hypothyroidism. Overtreatment with thionamides used for hyperthyroidism can also produce hypothyroidism. Amiodarone, an antiarrhythmic drug containing iodine, can block production of thyroid hormone. Rarely, congenital defects in T_4 biosynthesis or maternal treatment with antithyroid drugs or iodine causes congenital hypothyroidism and goiter.

Secondary hypothyroidism (low TSH or inappropriately normal TSH with low thyroid hormone levels) is usually the result of hypothalamic or pituitary dysfunction due to tumors, trauma, surgery, or irradiation (see Fig. 41-1). TSH deficiency occurs when the anterior pituitary thyrotropes are unable to secrete adequate amounts of TSH to regulate thyroid hormone production. Hypothalamic defects lead to TRH deficiency.

Figure 41-1 Adult Myxedema: Clinical Manifestations and Etiology.

Rare familial syndromes exist in which clinical hypothyroidism occurs despite elevated levels of T_4 and T_3 and sometimes an elevated level of TSH. Resistance to thyroid hormone can be due to a mutation in one of the thyroid hormone receptors that binds T_3 , rendering the receptor unable to activate target DNA sequences, or the pituitary gland resistant to feedback inhibition of thyroid hormone.

Clinical Presentation

The clinical spectrum of hypothyroidism is broad, ranging from subclinical, with few or no manifestations, to myxedema coma (Fig. 41-2). The onset of symptoms can be

insidious and is often overlooked, especially in elderly patients. Cold intolerance is the most specific symptom, and delayed relaxation of deep tendon reflexes is the most specific sign. Some clinical findings are explained by known thyroid hormone effects. Decreased metabolic rates lead to cold intolerance and a tendency to increased weight. The failure to metabolize glycosaminoglycans results in their accumulation in subcutaneous tissue, causing non-pitting edema (myxedema) (Fig. 41-3). A goiter can develop in Hashimoto's thyroiditis or in iodine deficiency, whereas the thyroid gland may be normal size, small, or absent in postprocedural hypothyroidism, congenital thyroid agenesis, or dysgenesis. Mild pituitary gland enlargement occurs in some cases. Laboratory abnormalities often include

Figure 41-2 Hypothyroidism.

hypertriglyceridemia, which responds to adequate thyroid hormone replacement (Box 41-1).

Differential Diagnosis

Hypothyroidism is accurately and easily diagnosed with thyroid function tests; however, these tests can be abnormal in sick but apparently euthyroid patients (“nonthyroidal illness” or “euthyroid sick syndrome”). These changes are not believed to indicate abnormal thyroid function because TSH levels are usually normal and other thyroid test abnormalities typically return to normal after the underlying illness resolves. The biologic importance of the euthyroid sick syndromes is not understood, and they may represent an adaptive stress response. The existence of these syndromes emphasizes the importance of exercising sound clinical judgment before ordering diagnostic tests. There are three major patterns of abnormalities in patients with nonthyroidal illness:

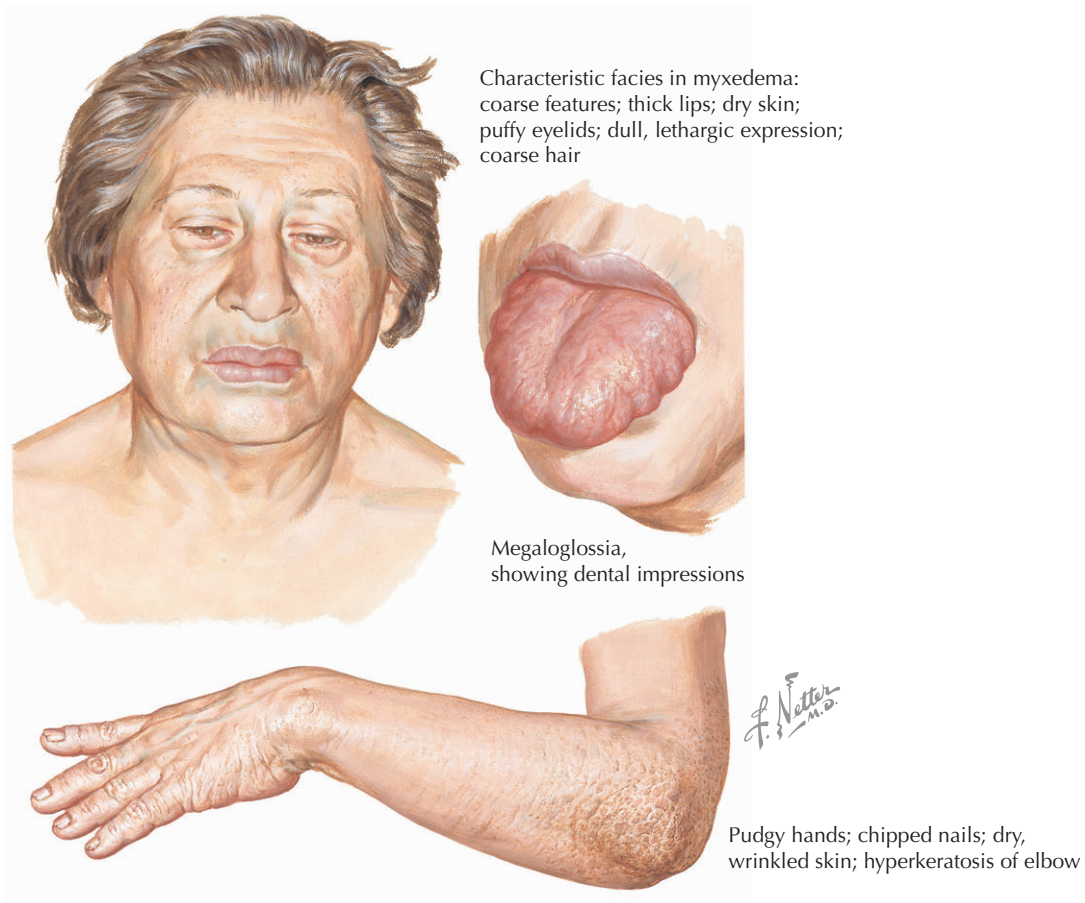

1. Low T_3 syndrome with impaired T_4 -to- T_3 conversion is seen in most acute and chronic diseases, trauma, surgery, and starvation. T_3 levels are decreased, and reverse T_3 levels are increased, whereas T_4 and TSH concentrations are normal. Although common, this

syndrome is seldom a diagnostic problem because T_3 levels are not routinely measured.

2. Low (total) T_4 syndromes, also seen in severe illnesses, often are due to very low levels of plasma-binding proteins. The T_4 index is often low as well, but free T_4 measured by equilibrium dialysis is normal. Normal TSH levels are seen in most patients and provide the best evidence against hypothyroidism.
3. High T_4 syndromes are seen occasionally and may be due to increased plasma-binding proteins. These are usually transient, and normal TSH levels indicate that these patients do not have hypothyroidism.

Diagnostic Approach

An elevated TSH level confirms the diagnosis of primary hypothyroidism. The T_4 level will be low and can be measured directly with a free T_4 assay or estimated by a free thyroxine index (FTI). A decreased serum free T_4 (by equilibrium dialysis) verifies true T_4 deficiency even in the presence of binding protein changes or severe illness and for this reason is generally preferred over the FTI. If the

Figure 41-3 Adult Myxedema: Clinical Manifestations and Etiology.**Box 41-1** Major Clinical Findings of Hypothyroidism

- **Constitutional:** Malaise, cold intolerance, lethargy, fatigue, hoarseness
- **Skin:** Thickened, coarse, dry, cool, nonpitting edema (myxedema), hair loss, decreased sweating
- **Cardiovascular:** Decreased cardiac contractility and rate, cardiac dilation, pericardial and pleural effusions, increased peripheral resistance
- **Gastrointestinal:** Decreased appetite, constipation, mild weight gain
- **Musculoskeletal:** Myalgias, arthralgias
- **Hematologic:** Mild anemia (usually children)
- **Neurologic:** Delayed relaxation phase of deep tendon reflexes, slowing of physical or mental activity, poor memory, somnolence, rarely dementia or anxiety
- **Thyroid gland:** May be large, "normal," or absent
- **Suggestive laboratory abnormalities:** Hypercholesterolemia, increased creatine kinase, hyponatremia, hyperprolactinemia, electrocardiographic changes (prolonged PR interval, low voltage), normochromic anemia, with or without mild increase in mean corpuscular volume
- **Neonatal and pediatric hypothyroidism:** Delayed growth and development, umbilical hernia, prolonged neonatal jaundice, protruding tongue, poor feeding, delayed bone age

FTI is measured, however, it is useful to be aware of a couple of scenarios:

- If the total T_4 is decreased and T_3 uptake is increased, the patient has decreased plasma-binding proteins, not hypothyroidism. The FTI is usually normal, and a normal TSH level confirms that the patient is euthyroid.
- If the total T_4 and the FTI are decreased, but TSH is not elevated, the patient may have secondary hypothyroidism, and evidence of other pituitary hormone deficits should be sought. In most cases, this combination of laboratory findings is due to abnormal plasma hormone binding or the effects of nonthyroidal illness on thyroid tests.

Diagnosis of the distinct cause of hypothyroidism is usually not necessary because most cases are either iatrogenic or due to autoimmune thyroiditis. Antithyroid antibodies, thyroid scans, and uptake measurements are rarely necessary because they do not change the management of the hypothyroidism. If secondary hypothyroidism is suspected, it is more important to assess the function of other pituitary hormones and obtain a magnetic resonance image of the pituitary gland and hypothalamus, than it is to perform a TRH stimulation test.

Management and Therapy

Optimum Therapy

Levothyroxine (L-T₄) is the drug of choice. It has sup-plantated desiccated thyroid extract, which has variable potency and purity. L-T₄ is deiodinated and peripherally converted to T₃, producing normal plasma levels of both T₄ and T₃. Therapy begins with average replacement doses of 100 to 125 mg per day (about 1.6 mg/kg/day) and varies depending on age. In elderly patients or those with cardiac disease, therapy should be initiated with smaller doses (25 to 50 mg/day) and increased gradually to avoid precipitating myocardial ischemia or heart failure due to increased metabolic rate and cardiac output. Infants can be treated immediately with full doses (25 to 50 mg/day). The half-life of T₄ is about 7 days, so most symptoms gradually resolve within several days to weeks of initiating therapy.

T₃ is used infrequently for replacement because of its short half-life and slightly higher cost. Similarly, combination L-T₄/T₃ preparations offer no pharmacologic advantage because T₄ naturally undergoes deiodination in peripheral tissues once absorbed. The role for low supplements of T₃ in patients with persistent fatigue, depression, or cognitive problems despite normalization of thyroid function tests is unclear. A recent systematic review did not find evidence supporting its use.

Parenteral L-T₄ is indicated for myxedema (see Fig. 41-3) coma or severe life-threatening hypothyroidism, which is rare and occurs most often after an intervening illness. Glucocorticoids are also given in suspected cases because adrenal insufficiency commonly coexists with severe hypothyroidism.

In pregnancy, maternal thyroid requirements increase about 25%, and the increase in total T₄ is accompanied by rising levels of thyroid-binding globulin (an effect of increased estrogen). Placental transfer of thyroid hormones is limited, and TSH does not cross the placenta. However, iodine and maternal antibodies readily cross the placenta. Recent studies suggest that maintaining euthyroidism in pregnancy is important for producing a normal intelligence quotient in offspring. Antithyroid drugs cross the placenta in limited amounts but usually do not cause fetal hypothyroidism or goiter unless taken in large doses.

Subclinical hypothyroidism (an increased TSH level with normal T₄ levels) is common, occurring in about 7.5% of women and about 3% of men. Treatment is controversial and usually not indicated because of lack of data on relevant clinical outcomes. A recent U.S. Preventive Services Task Force concluded that it is uncertain whether treatment will improve quality of life. A scientific review by Surks and colleagues concluded there was little evidence to support the routine treatment of patients with TSH values between 4.5 and 10.0 mIU/L. However, in individual patients, low doses of thyroid hormone can be given to normalize thyroid function tests and ascertain whether there is an improvement in symptoms.

Avoiding Treatment Errors

The maintenance dose of L-T₄ should be adjusted in primary hypothyroidism to normalize the TSH level. Because of the long half-life of T₄ and the delayed decrease of chronically elevated TSH levels, dose adjustments are made no more often than every 5 to 6 weeks. It is important to avoid over-treatment because it is associated with accelerated loss of bone mass and a higher prevalence of arrhythmias.

In patients with secondary hypothyroidism, TSH is not regulated normally and cannot be used to adjust the dose. T₄ or free T₄ levels should be maintained within the normal range. If adrenal insufficiency is present, glucocorticoids should be administered before replacing thyroid hormone to avoid precipitating symptomatic adrenal crisis.

Future Directions

Studies are also underway regarding the long-term outcome and appropriate treatment of patients with subclinical hypothyroidism. Prenatal screening of hypothyroidism will receive more attention given recent evidence of loss of cognitive ability in offspring of untreated mothers.

Thyrotoxicosis

Introduction

Thyrotoxicosis is the constellation of clinical findings that arise when the peripheral tissues are presented with and respond to an excess of thyroid hormone—free thyroxine (T_4) and free triiodothyronine (T_3). Hyperthyroidism refers to sustained increases in thyroid hormone synthesis and secretion by the thyroid gland. The prevalence of hyperthyroidism is estimated at 2% for women and 0.2% for men. About 15% of cases occur in patients older than 60 years.

The most common causes of thyrotoxicosis in Western society are Graves' disease, autonomous single nodules (also known as *toxic hot nodules*), multiple functioning nodules (also called *toxic multinodular goiter*), and thyroiditis. The pathogenesis in each of these conditions is different (Table 42-1). However, the initial therapy is similar and focuses on blocking the peripheral effects of thyroid hormone excess and reducing thyroid hormone overproduction where present.

Etiology and Pathogenesis

Graves' disease is the most common cause of hyperthyroidism in patients younger than 40 years (Fig. 42-1). The pathophysiology represents one of the classic receptor antibody disease states due to thyroid-stimulating hormone (TSH) receptor autoantibodies that continuously stimulate the thyroid gland as TSH agonists. Intrathyroidal lymphocytic infiltrate is the initial abnormality (Fig. 42-2). As in other autoimmune disease states, females are more commonly affected than males. Autonomously functioning thyroid nodules are discrete and function independently of the pituitary-thyroid negative feedback loop. Thyroiditis is characterized by inflammation, with thyroidal damage leading to release of T_4 and T_3 without active formation of T_4 and T_3 . Transient hypothyroidism typically follows, with the rare development of permanent hypothyroidism. Other rare causes of hyperthyroidism include (1) TSH-secreting pituitary tumors, (2) struma ovarii, (3) iodine-induced hyperthyroidism (Jod-Basedow), (4) hyperthyroidism mediated by human chorionic gonadotropin, (5) metastatic follicular thyroid cancer, and (6) factitious thyrotoxicosis caused by surreptitious thyroid hormone ingestion.

Clinical Presentation

Common symptoms of thyrotoxicosis include nervousness, emotional lability, fatigability, heat intolerance, weight change (usually weight loss), appetite change (usually increased), myopathic symptoms, increased frequency of bowel movements, sweating, menstrual irregularities (usually oligomenorrhea), and central nervous system disturbance. Common signs include hyperactivity; tachycardia or atrial arrhythmias; systolic hypertension; warm, moist, smooth skin; stare and eyelid retraction; tremor; hyperreflexia; and muscle weakness. Palpitations are a prominent symptom in elderly patients, as is cardiac failure. Generally, elderly patients present with less florid features of thyrotoxicosis and commonly exhibit cardiac symptoms or dementia.

Graves' Disease

A triad of manifestations define the disease: (1) hyperthyroidism and goiter; (2) ophthalmopathy, clinically evident in 10% to 25% of patients, with a higher prevalence in men and in those who smoke; and (3) dermopathy in the form of localized myxedema, which is a skin thickening typically limited to the pretibial area. About 4% of patients

Table 42-1 Disorders Associated with Thyrotoxicosis

Disorder	Pathogenic Mechanism

T₄, thyroxine; TSH, thyroid-stimulating hormone.

Figure 42-1 Hyperthyroidism with Diffuse Goiter (Graves' Disease).

with clinically evident ophthalmopathy have thyroid dermopathy.

The onset of the disease is usually insidious. Some patients may notice the gradual development of goiter and its associated symptoms, including difficulty in fastening the collar button, fullness in the neck, or a choking sensa-

tion. Slightly more than one half of the patients experience symptoms of ophthalmopathy (i.e., grittiness and tearing of the eyes, retro-ocular pressure, photophobia, a staring appearance, and the development of diplopia (Fig. 42-3)). The thyroid gland is diffusely enlarged and may be firmer, and an audible bruit may be auscultated. Radioactive iodine

Figure 42-2 Thyroid Pathology in Hyperthyroidism with Diffuse Goiter (Graves' Disease).

imaging reveals diffuse radioiodine uptake, although this test is not essential to make the diagnosis.

Toxic Multinodular Goiter and Toxic Hot Nodule

Thyroid nodules are the most common cause of thyrotoxicosis in elderly patients. The disease onset is also insidious, and the thyrotoxicosis is usually mild. The goiter may have been diagnosed many years previously. Because these disorders more commonly present in elderly patients, cardiac manifestations, such as tachycardia, atrial fibrillation, precipitation of angina, or cardiac failure, tend to predomi-

nate. On physical exam, toxic solitary nodule presents as a unilateral thyroid mass, and toxic multinodular goiter presents with multiple nodules often not as easily palpated. The nodules appear hyperfunctioning (hot) on radionuclide imaging, concentrating the radioiodide to a greater extent than the surrounding atrophic thyroid tissue (Fig. 42-4).

Thyroiditis

Subacute Thyroiditis

Subacute thyroiditis is also referred to as granulomatous, giant cell, or de Quervain's thyroiditis. Patients present

Figure 42-3 Ophthalmopathy of Graves' Disease.

with transient symptoms of thyrotoxicosis. Usually, thyroiditis follows a viral-like illness and presents as a tender, enlarged thyroid gland. The pain radiates to the jaw, ears, and occipital area. Episodes are usually self-limiting, although temporary or permanent hypothyroidism can occur. Relapses are common. Because of the lack of active formation of T_3 and T_4 , radioiodine thyroid imaging reveals a low thyroid uptake.

Silent Thyroiditis

Silent thyroiditis is thought to be a variant of Hashimoto's thyroiditis with circulating autoantibodies present and lymphocytic infiltration noted in the thyroid gland. The duration of hyperthyroid symptoms is short and has a self-limited course of a few weeks to months, and transient hypothyroidism occurs during recovery. One half of patients have persistent autoantibodies, goiter, and hypothyroidism. Postpartum

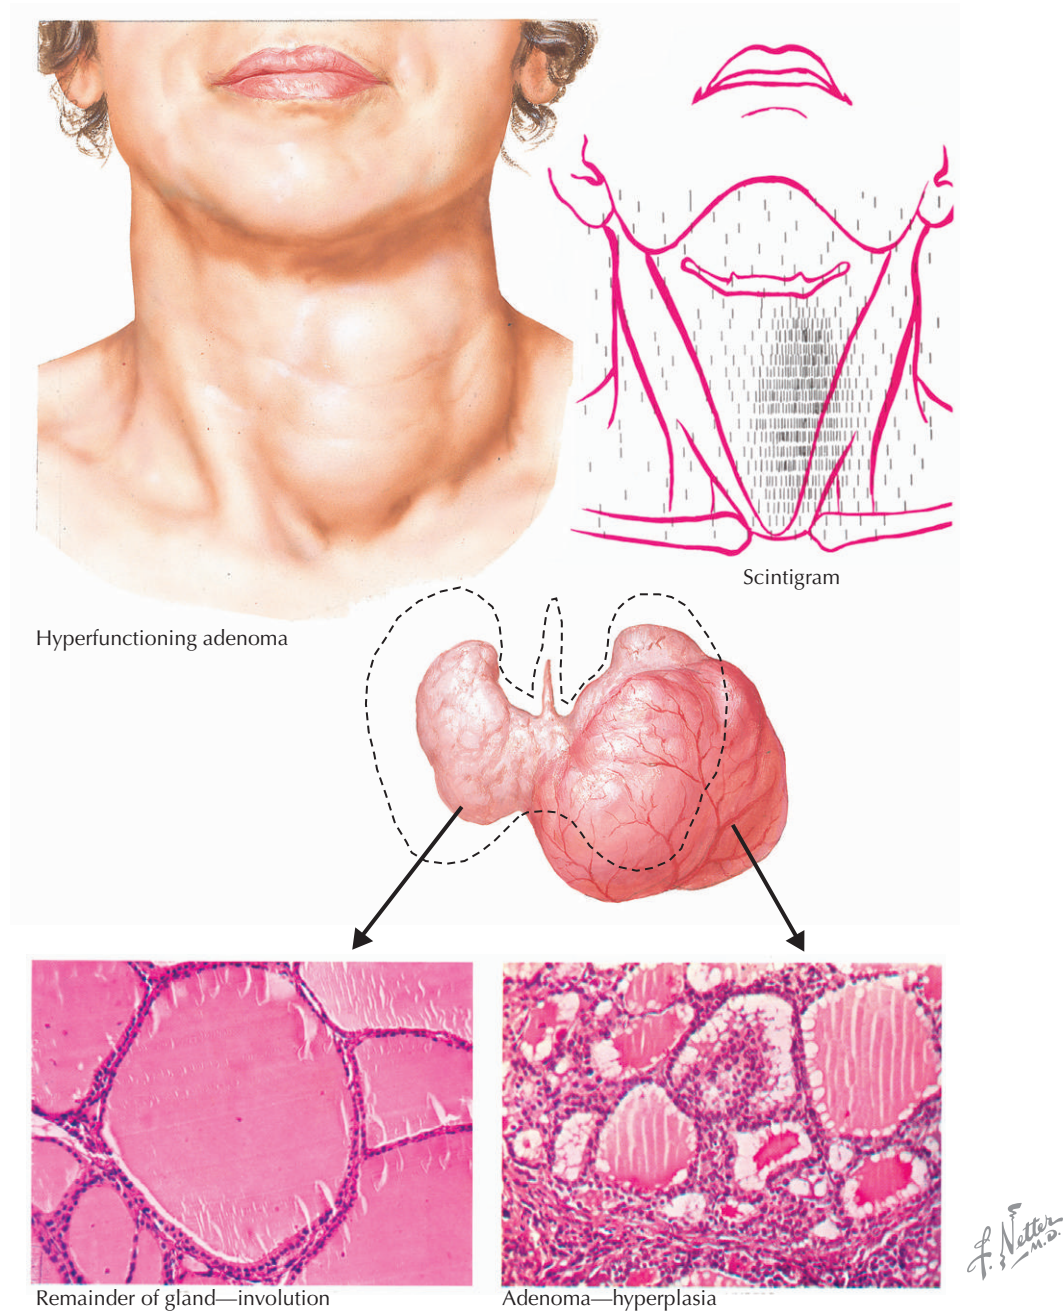

thyroiditis is considered a variant of silent thyroiditis, occurring in 5% of postpartum women.

Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism can occur after excess iodine in the diet, exposure to radiographic contrast media, or medications such as amiodarone.

Differential Diagnosis

The differential diagnosis of hyperthyroidism can be categorized by the underlying pathophysiology and broadly divided by radioactive iodine uptake findings. Thyroid disorders that cause excess production and release of thyroid hormone result in increased thyroid radioiodine uptake on thyroid scan and uptake. Autonomous thyroid hormone production characterizes toxic multinodular goiter and

Figure 42-4 Pathophysiology of Hyperfunctioning Thyroid Adenoma.

toxic hot nodule. Increased stimulation of the thyroid gland by autoantibodies, iodine, and TSH hypersecretion are the cause of Graves' disease, iodine-induced hyperthyroidism, and thyrotroph adenoma, respectively. Human chorionic gonadotropin stimulates the TSH receptor in hyperemesis gravidarum and trophoblastic tumor.

Thyroid disorders that cause release of stored thyroid hormone but no excess production result in low thyroid radioiodine uptake, which is seen in thyroiditis. Excess thyroid hormone not produced by the thyroid gland (thyrotoxicosis factitia, struma ovarii) will also result in a low thyroid radioiodine uptake (see Table 42-1).

Diagnostic Approach

The diagnosis of thyrotoxicosis is established by demonstrating an elevated free thyroxine (FT_4) level accompanied by a suppressed serum TSH level. All patients with thyrotoxicosis have a low or undetectable TSH level ($<0.1 \mu IU/mL$), except for TSH-induced thyrotoxicosis. FT_4 levels have generally replaced total T_4 levels, T_3 resin uptake, and corrected measures of FT_4 (e.g., FT_4 index) as the tests for thyrotoxicosis. FT_3 levels are elevated in all patients and are used to monitor response to therapy or in mild states of hyperthyroidism (T_3 toxicosis) where serum FT_4 levels

are normal. In Graves' disease and toxic multinodular goiter, T_3 levels typically are higher than T_4 levels (T_3 [ng/dL]/ T_4 [μ g/dL] ratio >20).

Thyroid Antibody Testing

Antithyroglobulin and antimicrosomal antibodies are directed toward the detection of cytoplasmic antibodies. These antibodies are usually present in patients with autoimmune thyroid disease, Graves' disease, and Hashimoto's thyroiditis. They are rarely present in patients with other types of thyroiditis. The TSH receptor-binding inhibitory immunoglobulins radioreceptor assay and thyroid-stimulating immunoglobulins bioassay detect antibodies to the TSH receptor, which, if present, are indicative of Graves' thyrotoxicosis.

Imaging

In general, radioisotope imaging of the thyroid is not necessary in all patients with thyrotoxicosis. Scanning may be useful to assess the function of a single nodule in the presence of biochemical evidence of hyperthyroidism, to evaluate the function of nodules in toxic multinodular goiter, to diagnose subacute thyroiditis when other clinical features are absent (i.e., absent uptake in the presence of hyperthyroidism), to confirm the diagnosis of thyrotoxicosis factitia, and to differentiate between silent or postpartum thyroiditis and Graves' disease in the postpartum patient (see Table 42-1).

Management and Therapy

Optimum Treatment

Graves' Disease

Graves' disease is an autoimmune disorder characterized by spontaneous remission and relapse. The three options for managing Graves' disease are antithyroid drugs, radioactive iodine ablation, and surgery. All three options have been shown to be effective, and treatment preferences vary globally. Within the United States, radioiodine ablation is generally preferred as optimal treatment, whereas antithyroid drugs are more popular in Europe and Japan. Antithyroid drugs (e.g., thiourea and β blockers) are the recommended treatment for pregnant women, children, and adolescents and for initial treatment of clinically significant hyperthyroidism. The thionamide antithyroid drugs propylthiouracil (PTU) and methimazole act as competitive inhibitors of thyroid peroxidase to effectively reduce thyroid hormone production. PTU in higher doses may also have the advantage of inhibiting peripheral conversion of T_4 to T_3 . These agents may also possess inherent immune-modulating effects that modify the disease pathophysiology. The usual starting doses are PTU, 100 mg every 8 hours, or methimazole, 10 to 30 mg once

daily. For compliance reasons, evidence of increased potency, and lower complication rates, methimazole is preferred. Major side effects develop within the first 3 months of therapy and include agranulocytosis; hepatic dysfunction; a lupus-like syndrome; vasculitis; and, more commonly, skin rash, fever, urticaria, and arthralgia. Patients should be warned about symptoms of fever and sore throat, which are typically seen with agranulocytosis. Follow-up every 4 to 6 weeks is recommended to assess clinical status and thyroid function tests (TSH, T_3 and T_4). The length of treatment is variable, but treatment for about 18 months results in long-term remission in 30% to 40% of cases. Patients with milder disease and small goiters are more likely to fully respond to a course of antithyroid medications and remain in disease remission. Therapy may be discontinued if the patient has been euthyroid for 18 months and the serum TSH is not suppressed. Most relapses occur within the first 6 months. A high dose of thiourea agents plus T_4 replacement technique may result in a higher rate of sustained remission.

For symptomatic relief of hyperthyroidism, β -adrenoceptor antagonists block the peripheral effects of thyroid hormone excess and the peripheral conversion of T_4 to T_3 . They are contraindicated in patients with asthma or chronic lung disease. Cardiac failure secondary to thyrotoxicosis is a relative contraindication. The most experience is with propranolol, 40 mg every 8 hours. These agents are given in conjunction with thiourea agents as first-line therapy to provide symptomatic relief of tremor, palpitations, anxiety, and heat intolerance.

For patients with more significant hyperthyroidism and larger goiters, radioactive iodine therapy or surgery is considered (usually subtotal thyroidectomy); radioactive iodine therapy is the preferred treatment in the United States. The decision to proceed to more definitive therapy is governed by the preference of the patient and the treating clinician. Radioactive iodine will provide an effective cure after a single dose of therapy in 70% to 90% of patients. Most centers give a moderate dose of iodine (15 mCi) to ensure adequate ablation of the thyroid gland. The patient is instructed to cease antithyroid therapy 4 to 7 days before the dose of radioactive iodine and then to recommence therapy 2 days after the therapy. Most patients may experience a dry mouth and transient pain in the thyroid and salivary glands during therapy and for a short time afterward and may be rendered hypothyroid 4 to 12 weeks after therapy. The patients must understand that they will become permanently hypothyroid and will require lifelong thyroid hormone replacement. Radioactive iodine is not contraindicated in younger patients or women of childbearing age unless they are pregnant. A pregnancy test is required in women of childbearing age before the administration of therapy.

The effectiveness of radioactive iodine and antithyroid agents has diminished the role of surgery. Thyroidectomy

is considered in special circumstances such as patient preference, poor response to antithyroid drugs, nodular or very large goiters, or coexistence of a potentially malignant thyroid nodule.

Second-line agents to treat hyperthyroidism include iodide, iodinated contrast agents, and lithium carbonate.

Autonomous Functioning Nodules

Radioactive iodine is the therapy of choice with a toxic multinodular goiter. Higher doses (in the order of 30 mCi) are usually used to achieve euthyroidism. Radioactive iodine therapy is also successful in patients with a single hot nodule, but repeated doses are often required. An antithyroid drug may be considered to reduce the risk for treatment-induced thyrotoxicosis and to attain euthyroidism faster. Near-total thyroidectomy is also an option. In Europe, percutaneous injection of nodules with ethanol is gaining popularity, but this is rarely used in the United States.

Thyroiditis

Thyroiditis is a self-limited disease in which the hyperthyroidism results from the release of stored thyroid hormone into the circulation. Pain associated with subacute thyroiditis is treated with aspirin or nonsteroidal anti-inflammatory drugs, if mild, or with steroids (prednisone, 30 mg daily, rapidly tapered over a few days) if severe. The hyperthyroidism is treated with β blockers if necessary. Treatment of subsequent hypothyroidism is usually unnecessary, although up to half of patients with silent thyroiditis eventually develop permanent hypothyroidism.

Iodine-Induced Hyperthyroidism

Iodine-induced hyperthyroidism is an extremely difficult condition to treat. Higher doses of thiourea agents are needed to control the hyperthyroidism. If possible, iodine consumption should be reduced, and perchlorate may in addition be useful to block iodine uptake into the gland. Steroid therapy may be useful in amiodarone-induced thyrotoxicosis. Radioactive iodine uptake assessments are useful to determine the degree of uptake before initiation of radioactive iodine (^{131}I) therapy. Early surgery should be considered if no other option is available and the patient is not responding to other therapeutic approaches.

Avoiding Treatment Errors

When following patients on antithyroid drugs, it is recommended to check thyroid function tests (i.e., TSH, T_3 , T_4) every 4 to 6 weeks initially until thyroid function is stable. Because thyrotropin levels remain suppressed for weeks to months, it is recommended to follow T_3 and T_4 levels. T_4 levels may normalize more rapidly than T_3 levels, so it is important to follow the T_3 levels to adjust the medication dosage. It is recommended to check the complete blood

count before initiation of antithyroid drugs because of the risk for agranulocytosis.

Future Directions

Ongoing research is focused on finding causes of autoimmune hyperthyroidism through genetic and molecular techniques to develop more effective treatments. For example, the molecular diagnosis of hereditary nonautoimmune hyperthyroidism has led to consideration of genetic counseling and primary thyroid ablation in individuals found to have the activated TSH receptor germline mutation.

Hyperparathyroidism

Introduction

Hyperparathyroidism is characterized by an elevation in serum parathyroid hormone (PTH) levels. The parathyroid glands synthesize and secrete PTH, which elevates calcium levels to maintain ionized calcium within a narrow physiologic range. PTH stimulates renal conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (calcitriol), which increases intestinal calcium absorption. PTH also acts to stimulate bone turnover, thereby releasing calcium and phosphorus from the bone matrix (Fig. 43-1). Appropriate homeostatic increases in PTH can occur from secondary causes; however, this chapter focuses on the inappropriate PTH levels that occur in primary hyperparathyroidism.

Etiology and Pathogenesis

Primary hyperparathyroidism results when the parathyroid glands hypertrophy and secrete excess PTH. Most individuals have four parathyroid glands, located in proximity to the thyroid gland. However, a wide range of variation exists in number and location. Two to eight glands may be found throughout the neck or mediastinum in normal individuals. Most individuals with primary hyperparathyroidism have a solitary parathyroid adenoma (80% to 85%). The remainder have diffuse hyperplasia (12% to 15%), double or triple adenomas (2%), or rarely, parathyroid carcinoma (<1%).

Although most cases are sporadic, there are familial forms of hyperparathyroidism that occur as part of the multiple endocrine neoplasia (MEN) syndromes. About 95% of individuals with MEN 1 have primary hyperparathyroidism along with pituitary and pancreatic tumors. Hyperparathyroidism occurs to a lesser extent in MEN 2a (20% to 30%) in conjunction with pheochromocytomas and medullary thyroid cancer. MEN 2b, which includes neuromas, does not generally have primary hyperparathyroidism as a feature. These familial forms have four-gland hyperplasia and require bilateral neck dissection for therapy.

Clinical Presentation

Primary hyperparathyroidism is usually asymptomatic (75% to 80%) and diagnosed when biochemical screening

reveals hypercalcemia. Symptoms vary depending on the level and duration of hypercalcemia (Fig. 43-2). Common symptoms include fatigue, constipation, polyuria, polydipsia, bone pain, and nausea. Neuropsychiatric symptoms (depression, memory loss, headaches) are reported frequently, but their relation to hypercalcemia is less clear because they do not always reverse with its correction. Nephrolithiasis is the most frequent overt complication, occurring in 15% to 20% of individuals. Nephrocalcinosis occurs infrequently. Bone disease is a prominent feature, with osteopenia or osteoporosis and, rarely, osteitis fibrosa cystica. Cortical bone (e.g., the distal radius) is affected more often than cancellous or trabecular bone (e.g., the vertebral column). Thus, bone loss is greater at the distal radius than in the spine. The hip is a mixture of both types of bone and is intermediate in its bone density. Despite decreased bone density, the fracture risk has not been adequately characterized. Cardiovascular manifestations may include hypertension, left ventricular hypertrophy, and myocardial and valvular calcifications. Neuromuscular symptoms occur but are less prominent, and proximal muscle weakness with type II muscle cell atrophy is quite rare. Occasionally, pancreatitis or peptic ulcer disease complicates the clinical course, as do gout and pseudogout.

Differential Diagnosis

The diagnosis is usually made after hypercalcemia is identified. Primary hyperparathyroidism and malignancies

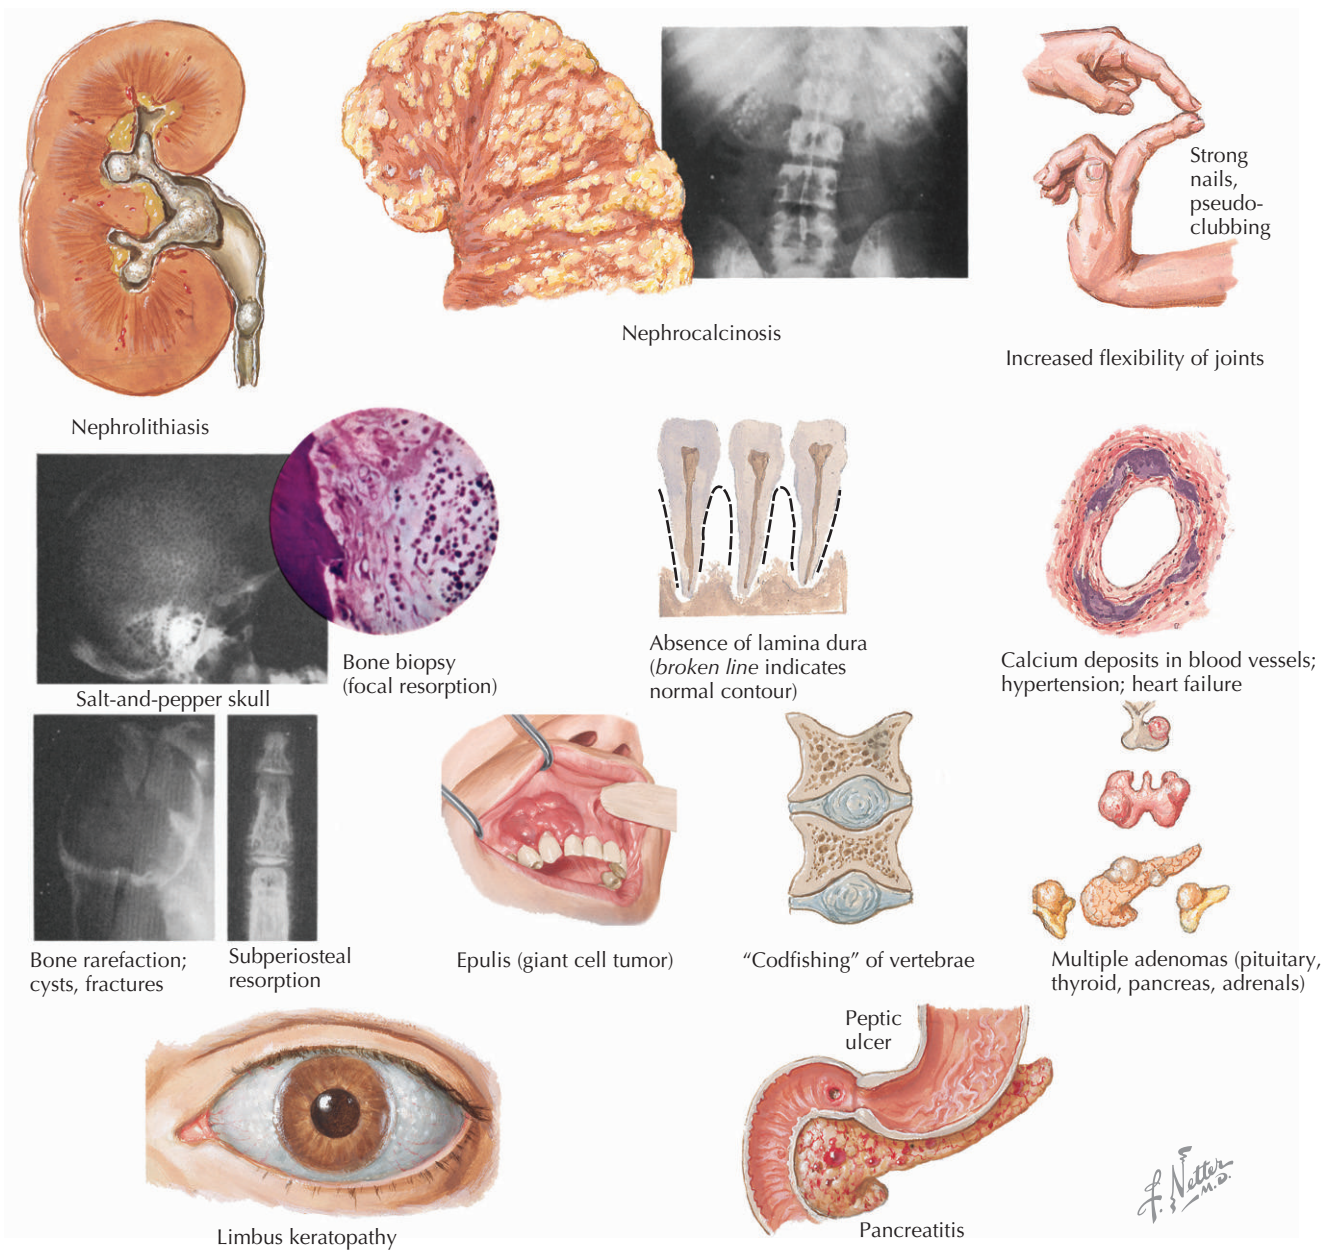

Figure 43-1 Physiology of the Parathyroid Glands.

account for about 90% of cases of hypercalcemia. Malignancies include multiple myeloma, lymphomas, and prostate, breast, and squamous cell lung carcinomas. Malignant tumors rarely secrete PTH, more often secreting PTH-related peptide, which does not cross-react on the current intact PTH assays. Certain medications cause hypercalcemia and may unmask underlying primary hyperparathyroidism. Thiazide diuretics decrease urinary calcium excretion and may affect the responsiveness of target cells to PTH. Lithium also increases urinary calcium retention

and may directly promote secretion of PTH. Additional causes include other endocrine disorders (hyperthyroidism, primary adrenal insufficiency, and less commonly, hypothyroidism and pheochromocytoma), milk alkali syndrome, excessive vitamin A or D intake, granulomatous disorders (sarcoidosis, tuberculosis), and immobilization. Generally, these conditions have suppressed PTH levels and can be readily distinguished from primary hyperparathyroidism. Benign familial hypocalciuric hypercalcemia is an autosomal dominant condition that causes asymptom-

Figure 43-2 Pathology and Clinical Manifestations of Hyperparathyroidism.

atic hypercalcemia with low urinary calcium excretion (<100 mg/day) and usually normal PTH levels. An inactivating mutation of the calcium receptor gene is the common primary underlying abnormality that should be suspected in individuals with a strong family history of hypercalcemia. It is important to diagnose this condition with a 24-hour urinary calcium measurement because these individuals do not require any surgical therapy.

Secondary hyperparathyroidism occurs commonly but is characterized by low or normal serum calcium levels. The elevated PTH often occurs as a physiologic response to conditions that cause hypocalcemia, such as vitamin D deficiency and acute hyperphosphatemia (tumor lysis syn-

drome, acute renal failure, and rhabdomyolysis). It is seen most commonly in renal insufficiency, particularly when renal 1,25-dihydroxyvitamin D production is impaired, with subsequent decreased intestinal calcium absorption. In long-standing renal failure, the parathyroid glands become autonomous, and a condition of tertiary hyperparathyroidism can develop, with PTH levels often greater than 2 to 3 times normal.

Diagnostic Approach

The diagnosis of primary hyperparathyroidism is usually straightforward and only requires the demonstration of

elevated PTH levels in the setting of hypercalcemia. The calcium level should be confirmed because venipuncture alone can falsely elevate the serum level. A PTH determination should be performed using the two-site immunoassay. Radiologic studies are not necessary to confirm the diagnosis, but they may be important when considering surgical management. PTH can be in the normal range in some individuals, which is inappropriate for an elevated calcium level. Less commonly, the calcium level remains normal, while the PTH level is elevated. A search for a secondary cause should be considered in these cases, particularly ruling out vitamin D deficiency by measuring 25-hydroxyvitamin D levels. In primary hyperparathyroidism alone, 25-hydroxyvitamin D levels tend to be at the lower end of the normal range, with 1,25-dihydroxyvitamin D levels being normal or even elevated (PTH drives the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D).

Although phosphorus is released from bone, there is an increase in urinary phosphorus excretion induced by hyperparathyroidism. Serum phosphorus is, therefore, usually low or at the lower end of normal range. Typically, total urinary calcium excretion is at the upper end of normal, with up to 40% of patients being hypercalciuric (>300 mg/day). Other bone turnover markers (e.g., alkaline phosphatase, urinary *N*-telopeptides, deoxypyridinoline) tend to be elevated, but usually do not aid in the diagnosis or management of primary hyperparathyroidism.

Management and Therapy

Optimum Treatment

Primary hyperparathyroidism can be cured by surgical removal of the parathyroid glands and generally represents the preferred therapy for symptomatic patients. Current accepted surgical indications in symptomatic patients include nephrolithiasis or nephrocalcinosis, osteitis fibrosa cystica, classic neuromuscular disease, or an acute episode of severe hypercalcemia. An experienced surgeon performing a bilateral neck exploration can achieve cure rates of more than 90% (defined as a reduction in serum calcium and PTH levels), with a less than 1% operative mortality rate. Surgical morbidity is low (<5%) but can include bleeding, recurrent laryngeal nerve damage, and rarely, hypoparathyroidism. Many symptoms or signs may improve after parathyroidectomy. There is a significant reduction in recurrent nephrolithiasis after surgery, although no significant improvement in renal insufficiency occurs. Bone mineral density (BMD) also improves consistently by 6% in the first year and up to 10% to 12% after 10 years. Interestingly, BMD gains are usually greatest in cancellous bone and less so in cortical bone. There are conflicting data regarding reduction in fracture risk, with some retrospective studies suggesting a decreased risk and others showing

no change. Classic symptoms of osteitis fibrosa cystica and neuromuscular disease are rare today and can be reversed by surgery. In contrast, cardiac manifestations do not necessarily reverse after surgery, causing some to question their causal association. Specifically, hypertension does not usually improve after parathyroidectomy. Left ventricular hypertrophy may or may not regress after surgery, and cardiac calcifications usually remain unchanged. Neuropsychiatric symptoms also do not improve consistently. The role of surgery in asymptomatic individuals is less clear and continues to be debated. The National Institutes of Health convened a consensus conference in 2002 on the management of asymptomatic primary hyperparathyroidism. The updated recommendations for surgical intervention include the following: total serum calcium levels >1 mg/dL above normal reference ranges, urinary calcium excretion >400 mg/day, reduced creatinine clearance by 30% without other causes, age less than 50 years, and decreased BMD at any site less than 2.5 standard deviations below peak bone density (T score <-2.5).

These recommendations are largely based on expert opinion because few randomized controlled trials exist. One important longitudinal observational study of mild primary hyperparathyroidism enrolled 61 subjects who underwent parathyroidectomy; 60 subjects who did not were followed for 10 years. Surgical management resulted in normalization of biochemical parameters (calcium, PTH, and urinary calcium excretion) that persisted at 10-year follow-up study. There were no recurrences of nephrolithiasis. Subjects had sustained improvements in BMD at the femoral neck and spine throughout the study period (14% and 12% increases over 10 years, respectively). The untreated group also did well overall, with remarkable stability in their disease parameters over 10 years. There was little progression of hypercalcemia or worsening of biochemical profiles. BMD at the spine, hip, and distal radius was unchanged, which was unexpected given that the average age of subjects was 58 years and that more than half of the subjects were postmenopausal women. Subgroup analysis suggested that perimenopausal women did continue to lose bone mass at rates similar to those of normocalcemic healthy women. Additionally, 27% had the development of one or more new indications for parathyroidectomy (calcium >12 mg/dL, increased urinary calcium excretion or distal radius Z score <-2.0). Taken together, these data demonstrate that surgery results in lasting improvements in biochemical parameters and BMD changes, whereas untreated groups overall did not have significant progression. Both sides of the debate have used these data to support their positions. In general, it is thought that additional factors favoring surgical management should include recent fracture in the absence of major trauma; moderate to severe vitamin D deficiency (<15 ng/mL); and perimenopausal women.

The traditional initial surgical approach is bilateral neck dissection. This approach is favored by many experienced

surgeons. Because most individuals have a solitary adenoma, surgical techniques for localized exploration (often termed “minimally invasive”) have been developed. These are dependent on adequate preoperative or intraoperative localization of the adenoma. Preoperative localization studies include ultrasound, nuclear imaging with technetium-sestamibi scans, computed tomography, magnetic resonance imaging, and selective venous catheterization for PTH measurements. Intraoperative techniques for localization include rapid PTH assays as well as use of sestamibi gamma probes, which allow less extensive and shorter operations. The impact of this approach on surgical cure rates is not proved. Local preferences are important because individual surgeons and institutions have variable expertise in these techniques. For persistent or recurrent disease, there is little debate that bilateral neck dissection is necessary. In this setting, preoperative localization increases the cure rate from about 60% to more than 90%.

Medical therapy should be considered for symptomatic patients awaiting surgery and in those for whom surgery is not an option. Outpatients with mild to moderate hypercalcemia should consume 1 to 1.5 L of fluid per day. Although moderate calcium dietary intake should be maintained, medications such as thiazides, which exacerbate hypercalcemia, should be discontinued. Oral bisphosphonates can be used to decrease bone turnover and improve BMD, but they do not necessarily alter calcium or PTH levels, as reported in a 2-year randomized controlled trial of alendronate. Intermittent intravenous bisphosphonates are another alternative but are rarely used in outpatients except those with severe hypercalcemia awaiting or unable to have surgery (e.g., pamidronate, 30 to 60 mg intravenously every 3 months). Estrogen and progestin therapy has been given to reduce bone resorption, particularly in perimenopausal women, without adversely affecting PTH levels. A calcium-sensing receptor mimetic, cinacalcet, has been studied in mild primary hyperparathyroidism and is effective in lowering calcium at 1 year with a reduction in PTH but no improvement in BMD. Cinacalcet works by mimicking the effect of calcium on the calcium-sensing receptor, which results in lower PTH secretion. However, its use is limited by cost and lack of long-term data. All patients should be encouraged to exercise to maintain bone mass. Calcium levels should be assessed every 4 to 6 months and PTH and creatinine measured at least yearly.

Avoiding Treatment Errors

Furosemide use for outpatient mild hypercalcemia (20 to 40 mg orally once daily) is often not very effective; if used, it is important that adequate hydration be maintained. Patients with primary hyperparathyroidism often have coexistent vitamin D deficiency. Replacement of vitamin

D may be necessary, particularly in patients in whom medical rather than surgical therapy will be pursued. Generally, vitamin D, 400 to 800 IU per day, is safe and does not result in significant hypercalcemia. However, more aggressive vitamin D repletion regimens (e.g., 50,000 IU ergocalciferol once a week for 8 weeks) may result in hypercalcemia.

Future Directions

Surgical approaches will continue to be refined, and data will be forthcoming comparing various techniques. Ongoing clinical studies should provide a better understanding of fracture risks and the surgical indications in patients with cardiac and neuropsychiatric manifestations. Future studies should also clarify the role of calcimimetic agents and bisphosphonates in the management of primary hyperparathyroidism.

Disorders of the Adrenal Cortex

Introduction

Adrenocorticotropic hormone (ACTH) is the chief determinant of the secretion of cortisol and androgenic steroids by the adrenal cortex. ACTH secretion is controlled by corticotropin-releasing hormone (CRH) from the hypothalamus (Fig. 44-1). At any given moment, ACTH secretion represents a balance between the stimulatory effects of the central nervous system, mediated by CRH, and negative feedback control exerted by circulating glucocorticoids. The secretion of both CRH and ACTH is subject to a diurnal rhythm, reaching a peak at about the time of awakening in the morning, and a nadir in the evening before sleep. Stressful stimuli such as trauma, infection, hemorrhage, or hypoglycemia normally activate CRH and ACTH secretion, causing cortisol levels to rise.

Aldosterone secretion is governed by the renin-angiotensin system (see Fig. 44-1). The chief determinant of aldosterone secretion is angiotensin II, which is generated under the influence of renin. Reduced systemic blood pressure and reduced renal perfusion are responsible for causing the release of renin. In humans, the synthesis of aldosterone is confined to the outer glomerulosa layer of the adrenal cortex; cortisol and androgens are produced by the fasciculata and reticularis layers.

The steroid products of both the adrenal glands and the gonads are derived from a series of biosynthetic steps beginning with cholesterol (Fig. 44-2). The glucocorticoid, cortisol, and the mineralocorticoid, aldosterone, are the most active and important hormones produced by the adrenal cortex. The enzymes involved in steroidogenesis are members of a family of cytochrome P450 oxidases. Each individual enzyme is capable of handling more than one substrate. As a result, a few distinct enzymes are capable of catalyzing transformations leading to more than a dozen steroid products. In the testes, an additional enzyme is present that converts the weak adrenal androgen androstenedione into testosterone. In the ovaries, an aromatase enzyme converts testosterone to estradiol. These terminal steps in the gonads do not occur to an appreciable extent in normal adrenal glands.

ADRENAL INSUFFICIENCY

Adrenal insufficiency arises whenever the quantity of circulating cortisol is insufficient to meet the needs of the body. Under basal conditions, cortisol is needed to maintain normal vascular tone, normal hepatic gluconeogenesis, and normal glycogen stores (hence the name glucocorticoid). Higher concentrations are needed during stress. Lack of adequate cortisol can lead to hypotension, shock, and hypoglycemia. Patients with cortisol deficiency may have variable deficiencies of aldosterone and adrenal androgens as well. Mineralocorticoid deficiency leads to

renal wasting of sodium, retention of potassium, and a reduced intravascular volume. Adrenal androgen deficiency leads to a significant reduction of the overall androgen supply in women and can result in a loss of body hair and libido. In men who maintain normal testosterone production from the gonads, loss of adrenal androgens does not lead to an overall androgen deficiency.

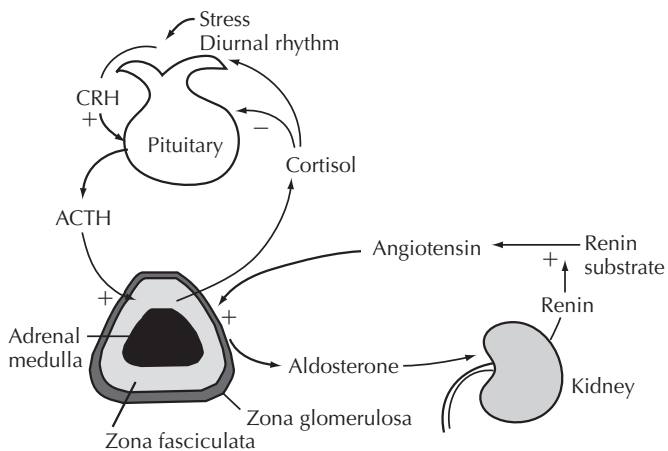

Etiology and Pathogenesis

Any disease process causing direct injury to the adrenal cortex can cause primary adrenal insufficiency. Diseases

affecting the hypothalamus or pituitary cause secondary adrenal insufficiency by reducing the secretion of ACTH (Box 44-1).

Primary adrenal insufficiency (Addison's disease) is most commonly the result of chronic autoimmune destruction of the adrenal cortex. Lymphocytic infiltration is the usual histologic feature. The adrenal glands are small, and cortical cells are largely absent, although the medulla is preserved. Antibodies to adrenal cortical antigens, including the enzyme 21-hydroxylase, are present early in the disease process. Patients with autoimmune adrenal disease are more likely to have polyglandular autoimmune syndromes causing deficiency of other endocrine glands, including the thyroid, parathyroids, gonads, and pancreatic β cells.

Figure 44-1 Control of the Secretion of Cortisol and Aldosterone.

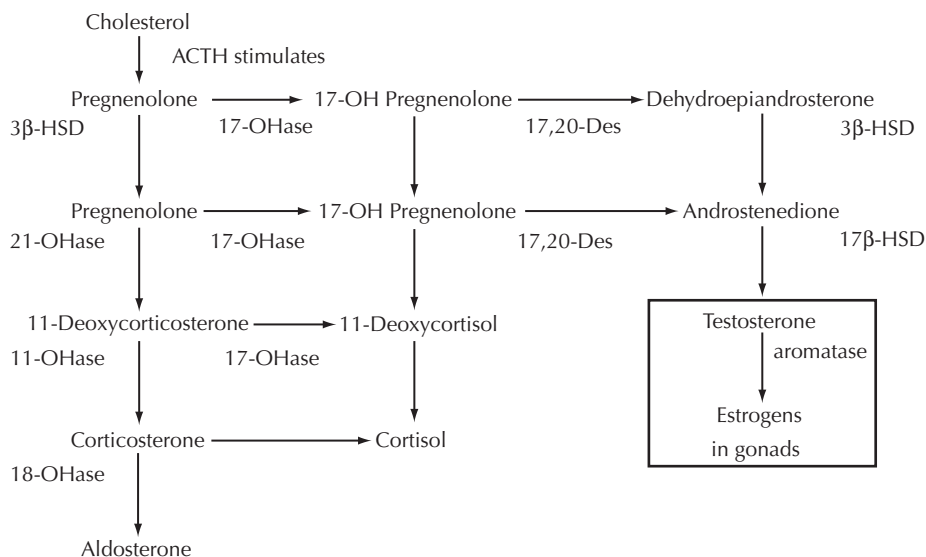

Several other mechanisms can cause primary adrenal insufficiency. Bilateral adrenal hemorrhage occurs in critically ill patients who are taking anticoagulants or who have coagulopathies. The primary antiphospholipid antibody syndrome (lupus anticoagulant) is a common cause of adrenal hemorrhage. The importance of tuberculosis as a cause of adrenal insufficiency has waned in the United States, but not in other parts of the world where it is common. Up to 5% of patients with terminal AIDS may have evidence of adrenal insufficiency, usually due to superinfection with agents such as cytomegalovirus.

The congenital adrenal hyperplasia syndromes are due to inherited defects in specific enzymes involved in the biosynthetic pathway for cortisol production (see Fig. 44-2). The mode of inheritance is usually autosomal recessive. The most common inherited deficiency is of 21-hydroxylase, followed by 11-hydroxylase. These disorders may cause a deficiency of cortisol, aldosterone, or both, and present in infants and children with acute adrenal insufficiency. There is a characteristic overproduction of steroid precursors before the defective enzyme step. In 21-hydroxylase deficiency, these precursors give rise to excessive production of adrenal androgens.

Clinical Presentation

Acute adrenal insufficiency or adrenal crisis should be suspected in patients with unexplained volume depletion and shock, often accompanied by hyperkalemia, acidosis, or hypoglycemia. Chronic insufficiency usually develops more insidiously with symptoms such as weakness, weight loss, anorexia, and postural hypotension. Increased skin pigmentation develops in patients with primary, but not

Figure 44-2 Synthetic Pathways for the Adrenal Steroids.

Box 44-1 Causes of Adrenal Insufficiency**Primary Insufficiency**

Autoimmune destruction
 Infectious diseases (tuberculosis, histoplasmosis, HIV)
 Iatrogenic destruction (bilateral adrenalectomy)
 Infiltrative diseases (metastatic tumors, amyloidosis, hemochromatosis)
 Acute bilateral adrenal hemorrhage
 Adrenal leukodystrophy
 Congenital adrenal hyperplasias

Secondary Insufficiency

Pituitary or hypothalamic tumors
 Iatrogenic ablation (hypophysectomy, radiation therapy)
 Pituitary infarction (postpartum necrosis or apoplexy)
 Infection (tuberculosis, syphilis)
 Sarcoidosis and granulomatous diseases
 Idiopathic hypopituitarism
 Withdrawal of high dose glucocorticoid therapy

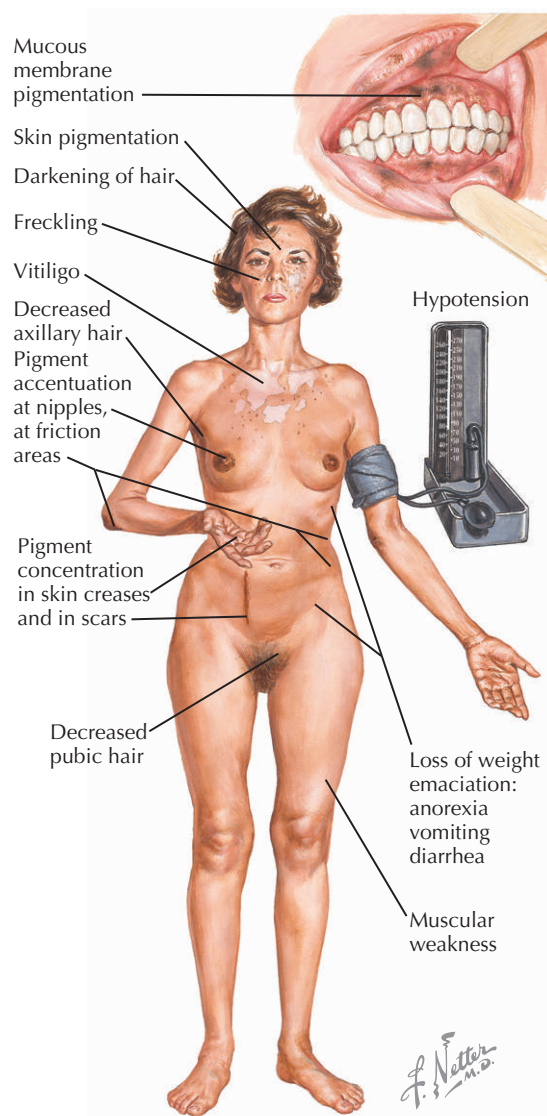

secondary, chronic insufficiency due to the melanocyte-stimulating activity of chronically high levels of ACTH and related peptides (Fig. 44-3).

Differential Diagnosis

Volume depletion and vascular collapse can occur with a large number of other conditions causing hypotension, including hemorrhage and sepsis. There are fewer conditions that mimic chronic adrenal insufficiency. Among these are chronic starvation (anorexia nervosa); chronic gastrointestinal disease (inflammation or malignancy); other diseases causing hyperpigmentation (drugs and heavy metals); or fatigue and lassitude (chronic fatigue syndrome). A high level of clinical suspicion is the key to correct diagnosis of both acute and chronic adrenal insufficiency.

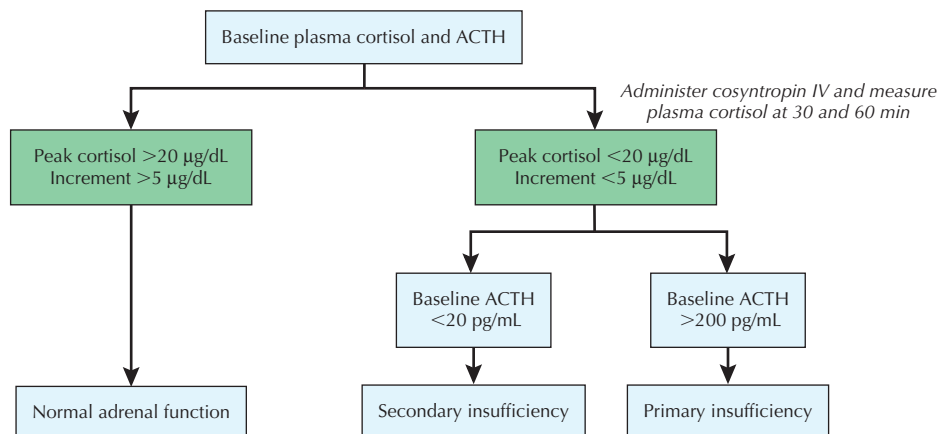

Diagnostic Approach

Confirmation of a suspected clinical diagnosis consists of demonstrating inappropriately low cortisol secretion, determining whether the low cortisol level is due to a deficiency of ACTH, and seeking a treatable cause. Baseline measurements of plasma cortisol and ACTH are best obtained in the early morning when levels of both are normally high. A very low morning cortisol level of less than 3 µg/dL strongly suggests adrenal insufficiency, whereas a level of less than 10 µg/dL should arouse suspicion. Administration of synthetic ACTH (cosyntropin) helps in defining adrenal insufficiency in borderline situations and in distinguishing primary from secondary adrenal insufficiency. Normal subjects show a peak cortisol response to greater than 20 µg/dL after cosyntropin, whereas patients with both primary and secondary adrenal insufficiency do not. Primary and secondary insufficiency may then be distinguished by the baseline levels of ACTH, which are high in primary insufficiency only (Fig. 44-4).

Figure 44-3 Chronic Primary Adrenal Cortical Insufficiency (Addison's Disease).

In addition, patients with primary insufficiency fail to respond to repeated administration of cosyntropin, whereas patients with secondary insufficiency show an increasing response to repeated testing. In the early stages of primary insufficiency, some patients show evidence of aldosterone deficiency before developing cortisol deficiency. These individuals have low serum levels of aldosterone and high levels of plasma renin activity even before abnormalities in cortisol secretion can be demonstrated.

Patients suspected of having adrenal insufficiency due to congenital adrenal hyperplasia may be diagnosed with the aid of cortisol and ACTH measurements, but further measurement of specific steroid intermediates is essential to identify the specific enzyme defect. For example, in patients with the common form of 21-hydroxylase deficiency, plasma levels of 17-hydroxyprogesterone are markedly elevated (see Fig. 44-2).

Figure 44-4 Outline of Tests for the Differential Diagnosis of Adrenal Insufficiency.

Management and Therapy

Treatment of primary adrenal insufficiency consists of replacement of both glucocorticoids and mineralocorticoids. A combination of hydrocortisone or prednisone, to meet the glucocorticoid requirement, and fludrocortisone, to meet the mineralocorticoid requirement, is usually required. Patients with secondary insufficiency may not require a mineralocorticoid because aldosterone production remains responsive to control by renin and angiotensin. In monitoring therapy, persistent signs and symptoms of adrenal insufficiency should be sought. Periodic laboratory measurement of serum electrolytes, cortisol, and ACTH may also be helpful. Measurement of plasma renin activity is useful in assessing the adequacy of mineralocorticoid replacement.

Avoiding Treatment Errors

During periods of acute illness or stress, the requirement for glucocorticoids typically increases by 2- to 10-fold. To avoid the risk for acute adrenal insufficiency, the dose of glucocorticoid must be increased temporarily until the acute stress is resolved. Patients should carry identification so that unfamiliar caregivers will recognize their need for steroid replacement in case of emergencies. Chronic overtreatment with glucocorticoids can cause insidious side effects, including excessive weight gain, hypertension, glucose intolerance, and osteoporosis. Patients receiving excess glucocorticoid replacement exhibit suppressed early-morning concentrations of serum ACTH.

Optimum Treatment

Patients receiving appropriate replacement therapy for adrenal insufficiency will be well educated about dealing with symptoms of glucocorticoid and mineralocorticoid deficiency during both basal and stress conditions. They will also understand how to avoid the long-term complica-

tions of excessive therapy. Optimum therapy for congenital adrenal hyperplasia includes not only providing for basal glucocorticoid and mineralocorticoid requirements but also suppressing the production of excessive steroid byproducts. To suppress excessive androgen production in 21-hydroxylase deficiency, it may be necessary to give high doses of glucocorticoids initially to suppress ACTH and reduce the degree of adrenal hyperplasia. Once control is achieved, the glucocorticoid dose can be reduced for physiologic maintenance.

ADRENOCORTICAL HYPERFUNCTION: CUSHING'S SYNDROME

Chronic glucocorticoid excess leads to a constellation of findings known as Cushing's syndrome. Chronic mineralocorticoid excess leads to a different set of findings, primarily hypertension and hypokalemia.

Etiology and Pathogenesis

Cushing's syndrome is classified as being either ACTH dependent or ACTH independent (Box 44-2).

About 70% of reported cases are due to excess ACTH secretion by a pituitary adenoma (also known as *Cushing's disease*). These adenomas contain basophilic granules and tend to be smaller than adenomas secreting growth hormone or prolactin.

Larger tumors may appear chromophobic on histologic study. ACTH-secreting pituitary tumors usually continue to exhibit feedback suppression by glucocorticoids but require higher than normal levels.

Certain malignant tumors of nonpituitary origin (small cell lung carcinomas, carcinoid tumors, pancreatic islet cell tumors, medullary carcinoma of the thyroid, and pheochromocytomas) have the capacity to secrete ACTH. Ectopic ACTH production accounts for about 10% of all cases of Cushing's syndrome. Typically, these tumors do not exhibit suppression of their production of ACTH,

Box 44-2 Causes of Cushing's Syndrome**ACTH Dependent**

ACTH-secreting pituitary tumor (Cushing's disease)

 CRH-secreting tumor

ACTH Independent

Cortisol-secreting adrenal tumor; adenoma or carcinoma
 Nodular adrenal hyperplasia
 Food dependent (GIP-mediated)
 Exogenous glucocorticoids (iatrogenic or factitious)

ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; GIP, gastric inhibitory peptide.

even at very high glucocorticoid levels. Rarely, a tumor produces ectopic CRH, causing increased ACTH secretion by the normal pituitary gland.

Among the ACTH-independent causes, administration of high doses of exogenous glucocorticoids is by far the most common. Excess production of cortisol by an adrenal tumor is the most common endogenous cause, accounting for about 15% of all spontaneous cases. Food-induced Cushing's syndrome is mediated by gastric inhibitory peptide, which is normally released upon eating and stimulates the adrenal cortex in a few individuals.

Clinical Presentation

Obesity is the most common complaint, occurring in 90% of cases. The distribution of excess fat is typically central, with thin arms and legs (Fig. 44-5). Other features due to chronic glucocorticoid excess include weakening of the connective tissues in the skin (striae, easy bruising), osteoporosis, glucose intolerance, psychiatric disturbances, and increased susceptibility to infections. The manifestations of mineralocorticoid excess include hypertension, edema, hypokalemia, and metabolic alkalosis. Androgen excess in females causes hirsutism, acne, and amenorrhea.

Differential Diagnosis

Most patients with obesity, hypertension, and diabetes mellitus do not have Cushing's syndrome but have exogenous obesity, which is far more common. Most women with obesity, hirsutism, and amenorrhea have the polycystic ovary syndrome, not hypercortisolism. Some patients may have increased secretion of cortisol secondary to another disorder. Examples include patients with primary depression or alcoholism.

Diagnostic Approach

The first step is to demonstrate the presence of inappropriately high cortisol secretion; the second step is to determine the cause of hypercortisolism (Fig. 44-6). The initial

step is collection of a 24-hour urine sample for measurement of free cortisol. If this value is normal, the patient is unlikely to have Cushing's syndrome. If the initial cortisol value is elevated, the patient is given a low dose of dexamethasone (2 mg/day for 2 days), and the urine collection is repeated during the second day. If urinary free cortisol is suppressed by more than 50%, the patient is unlikely to have Cushing's syndrome. If low-dose dexamethasone does not suppress the urinary free cortisol by 50%, the suppression test should be repeated with a higher dose of dexamethasone (8 mg/day for 2 days). Patients with an ACTH-producing pituitary tumor usually suppress at the higher dose, whereas patients with adrenal tumors or the ectopic ACTH syndrome do not suppress. The latter two diagnoses may then be distinguished by the baseline ACTH level. In the ectopic ACTH syndrome, ACTH is elevated. In Cushing's syndrome due to functioning adrenal tumors, the ACTH is suppressed.

Magnetic resonance imaging allows visualization of a pituitary tumor in about 80% of cases. If baseline ACTH levels are suppressed, suggesting an adrenal tumor, it is possible to visualize the tumor in 90% of cases with a computed tomography scan of the abdomen.

Management and Therapy

ACTH-secreting pituitary tumors are treated initially by resection, usually through a trans-sphenoidal surgical approach. The cure rate ranges from 60% to 85%. If surgery fails in removing the entire tumor, external pituitary radiation, combined with drug therapy to inhibit cortisol synthesis, induces remissions in most patients. Ketoconazole is the inhibitory drug used most frequently.

Cortisol-secreting adrenal tumors are primarily treated by surgical resection. The cure rate for adenomas is high, but it is much lower for carcinomas because metastases are commonly present at surgery. Second-line therapy for an inoperable tumor involves the use of blockers of cortisol synthesis. Tumors producing ectopic ACTH are almost always malignant. If they are not surgically resectable, they may be controlled with radiation therapy or chemotherapy.

Avoiding Treatment Errors

An accurate diagnosis of the cause of Cushing's syndrome is essential for appropriate therapy. Failure to diagnose an ACTH-secreting pituitary tumor may occur when the tumor is too small to be identified by imaging techniques. Likewise, small nonpituitary tumors producing ACTH ectopically, such as carcinoid tumors of the lung, may be overlooked. In cases in which a tumor is not obvious, direct catheterization of the petrosal sinuses draining the pituitary bed may reveal an ACTH gradient, confirming a pituitary source.

Figure 44-5 Cushing's Syndrome (Clinical Findings).

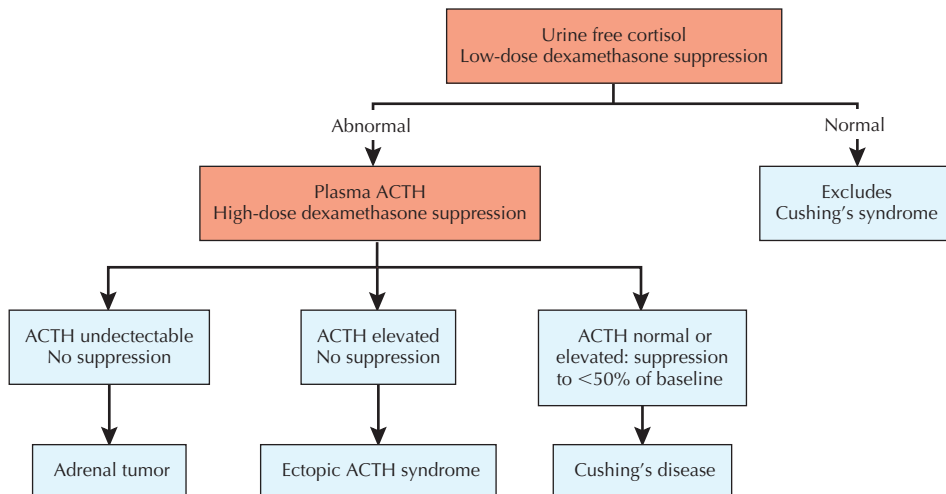

Figure 44-6 Outline of Tests for the Differential Diagnosis of Cushing's Syndrome.

Small adrenal cortical tumors are frequently discovered incidentally on computed tomography studies of the abdomen done to investigate an unrelated disease. Although most of these tumors are nonfunctioning, as many as 5% to 10% can produce cortisol and potentially cause Cushing's syndrome. Thus, careful investigation of cortisol secretion is indicated in all patients presenting with adrenal "incidentalomas."

Future Directions

Refinements in the management of adrenal insufficiency are constantly being proposed and tested. The replacement of adrenal androgens, as well as glucocorticoids and mineralocorticoids, may be important in women with adrenal insufficiency. Management of the hyperandrogenism in congenital adrenal hyperplasia continues to be a challenge because the higher doses of glucocorticoids required for full suppression often induce Cushing's syndrome. Drugs capable of blocking androgen receptors may be useful adjuncts in this case. Virilization of the external genitalia in female infants may be reduced by treatment of the mother with dexamethasone during the first trimester of pregnancy.

The accurate diagnosis of ACTH-dependent Cushing syndrome remains difficult in cases in which a pituitary tumor cannot be depicted by current radiologic methods. Improved imaging techniques and petrosal sinus catheterization should identify the correct source of ACTH in all but a few cases.

This retrospective review of 75 AIDS patients with clinical or biochemical manifestations of adrenal insufficiency compares the results of basal and ACTH-stimulated cortisol levels.

8. Yu L, Brewer KW, Gates S, et al: DRB104 and DQ alleles: Expression of 21-hydroxylase autoantibodies and risk of progression to Addison's disease. *J Clin Endocrinol Metab* 84(1):328-335, 1999.

An immunogenetic study in 957 patients with type 1 diabetes showed a strong association between the DQ8/DQ2 genotype, the presence of 21-hydroxylase autoantibodies, and the development of Addison's disease.

9. Zelissen PM, Crougns RJ, van Rijk PP, Raymakers JA: Effect of glucocorticoid replacement therapy on bone density in patients with Addison disease. *Ann Intern Med* 120(3):207-210, 1994.

In this report on 91 patients with Addison's disease treated with glucocorticoids for a mean of 10.6 years, low bone mineral density was found in 10 of 31 men and 4 of 60 women. In men with low bone mineral density, the mean glucocorticoid dose was significantly higher than in men with normal bone density. There was no correlation between low bone density and glucocorticoid dose in women.

Pituitary Diseases

Introduction

The anterior lobe of the pituitary gland produces six polypeptide hormones that regulate the function of other endocrine glands, such as the thyroid and the adrenal glands. The posterior lobe produces hormones that are involved in regulation of salt and water balance. Because of its strategic location, tumors that occur within the sella turcica, the cavernous sinuses, or the hypothalamus can lead to disruption of pituitary hormonal function. From a functional perspective, diseases of the pituitary are grouped into those that destroy or impair hormone function and those that result in increased hormone secretion.

Etiology and Pathogenesis

Normal Pituitary Anatomy and Physiology

The pituitary gland is encased within the sphenoid bone at the base of the brain and is connected directly to the hypothalamus. The hypothalamus contains specific neurons that, following electrochemical stimulation, release peptides termed *releasing factors*. The releasing factors that have been identified include growth hormone–releasing hormone (GHRH); gonadotropin-releasing hormone, which stimulates both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) secretion; thyrotropin-releasing hormone; and corticotropin-releasing factor. Prolactin secretion is negatively regulated by dopamine that is released from hypothalamic neurons. Following direct stimulation, hypothalamic neurons release these polypeptides into the hypophyseal portal vessels where they are transported to the anterior pituitary cells. Each releasing factor stimulates the synthesis and release of the appropriate trophic hormone by a specific pituitary cell type into the general circulation.

Each pituitary hormone acts at specific sites to produce its target effects. Growth hormone (GH) acts upon connective tissue cells to stimulate the synthesis of insulin-like growth factor (IGF)-I. IGF-I in turn stimulates trophic actions related to growth, including protein synthesis, inhibition of protein breakdown, and growth of connective tissue cell types such as bone, muscle, and cartilage. GH is necessary for normal statural growth and for maintenance of normal muscle and bone mass in adults. GH has

several important metabolic functions, including stimulation of lipolysis resulting in release of free fatty acids that are used as an energy source; thus, it regulates normal glucose homeostasis and fat stores. GH also stimulates amino acid flux in muscle and contributes to the normal balance between bone formation and absorption. Prolactin acts primarily on the breast to stimulate milk production in the postpartum period. It antagonizes the effects of estrogen, and supraphysiologic concentrations impair normal fertility and estrogen action. Thyroid-stimulating hormone (TSH) acts directly upon the thyroid gland to increase the synthesis and secretion of both T_3 and T_4 . Adrenocorticotrophic hormone (ACTH) has a similar effect on the adrenal gland, stimulating the conversion of cholesterol to various adrenal steroids, the most important of which is cortisol. LH and FSH act in concert to stimulate gonadal function in males and females. FSH in males is primarily a stimulator of spermatogenesis and Sertoli cell function, and LH functions primarily to stimulate testosterone biosynthesis by the Leydig cells. In females, FSH stimulates follicle maturation, whereas LH is primarily responsible for stimulation of corpus luteal function.

Negative Feedback Regulation

All hormones produced by target cell types are secreted into the general circulation. They provide feedback on the normal pituitary gland and suppress trophic hormone secretion. For example, IGF-I feeds back directly on the somatotropes to inhibit GH release; T_4 inhibits TSH production; cortisol inhibits ACTH secretion; and

testosterone in men and estrogen in women inhibit LH and FSH release.

Regulation of posterior pituitary hormone secretion is quite different. The hypothalamus maintains direct neural connections to the posterior pituitary gland through axonal processes. Following their synthesis in the hypothalamic neurons, these small peptides are transported down axonal processes and stored in secretory granules within the posterior pituitary gland. Neural inputs regulate the release of vasopressin, which acts directly on the kidney to control free water clearance. Similarly, under the appropriate stimulus, the brain releases oxytocin, which stimulates uterine contractions. Suckling results in loss of dopaminergic inhibition of prolactin secretion due to a direct reduction in dopamine levels. Lesions that sever the stalk while causing a major loss of stimulation of anterior pituitary hormone synthesis may not cause a complete ablation of posterior pituitary hormone synthesis because these hormones may be released by the severed neurons directly after hypothalamic stimulation. This type of lesion will increase prolactin secretion due to loss of dopamine inhibition.

A number of disease processes—tumors, other destructive lesions, vascular insults—interrupt the delicate balance of the hypothalamic-pituitary axis. A discussion of a selected group of disorders follows.

Clinical Presentation, Differential Diagnosis, Diagnostic Approach, Management, and Therapy

Diseases of the Anterior Pituitary Gland

Most cases of anterior pituitary gland dysfunction are caused by tumors (Fig. 45-1). Usually benign, these tumors disrupt normal pituitary gland function because of their anatomic location. Functionally, tumors are grouped into mass lesions that result in destruction of pituitary hormone secretion and those that result in adenomatous expansion of the specific cell type that produces a single hormone resulting in a hormonal overproduction syndrome.

Mass lesions that can result in pituitary cell destruction and hypofunction include cysts, such as Rathke cleft cyst, arachnoid, and dermoid; and tumors, such as craniopharyngioma, chordoma, glioma, sarcoma, hamartoma, dysgerminoma, metastases, and hormone-secreting or nonfunctional pituitary adenomas. Miscellaneous causes, such as aneurysms, hypophysitis, sarcoidosis, histiocytosis X, Sheehan's syndrome, and traumatic brain injury, can destroy pituitary function.

Usually, tumors destroy multiple cell types. Mass lesions that result in pituitary dysfunction can be divided into three groups: those that arise within the sella turcica; those within the parasellar areas; and those within the hypothalamus. Hypothalamic tumors can cause anterior pituitary dysfunction by destroying hypothalamic-releasing factor production and usually not through expansion within the

sella turcica. Chromophobe adenomas arise within the sella turcica, often secreting only the α subunit of LH or FSH; therefore, they are hormonally silent. These tumors grow slowly and may destroy the entire anterior pituitary gland by pressure necrosis. Extensive proliferation can lead to invasion into the cavernous sinus, or if they extend superiorly, tumors will exert pressure on the optic chiasm, leading to bitemporal hemianopsia.

Other lesions that arise within the pituitary gland include cystic lesions that develop from partial infarction of preexisting pituitary tumors, and granulomatous diseases such as histiocytosis X or sarcoidosis. Hamartomas also occur within the region of the sella turcica, resulting in hypopituitarism. Sheehan's syndrome, a postpartum pituitary infarction due to massive blood loss at delivery that results in panhypopituitarism, is one of the most common circulatory diseases involving the pituitary gland. Carotid artery aneurysms can destroy the pituitary gland. Parasellar and hypothalamic lesions that may produce hormonal dysfunction include meningiomas and craniopharyngiomas. These tumors, which often arise in the hypothalamus, result in disruption of hypothalamic hormone production. Dysgerminomas of the third ventricle can result in hypothalamic dysfunction.

Iatrogenic Causes of Hypopituitarism

Surgery for intrasellar or parasellar lesions can inadvertently result in destruction of the normal pituitary gland by damage to the hypothalamic neurons, stalk section, or direct damage to the anterior pituitary gland. Radiation treatment for pituitary tumors often results in destruction of the normal pituitary gland. Radiation for diseases such as gliomas, central nervous system leukemia or lymphoma, or head and neck tumors can produce sufficient scatter radiation to destroy anterior pituitary gland function.

Consequences of Loss of Hormonal Function

Large mass lesions of the pituitary gland or hypothalamic region can result in complete anterior pituitary hormone destruction (see Fig. 45-1). Generally, the first hormone to be lost is GH, followed by LH and FSH, followed by ACTH and TSH, and lastly, by prolactin. Loss of normal GH secretion in children can result in significant growth failure and hypoglycemia as well as increased body fat and loss of normal muscle mass. In adults, GH deficiency is more likely to lead to changes in body composition with loss of muscle and bone mass. Hypoglycemia in adults is rare. Loss of gonadotrophin secretion in women results in anovulation first followed by amenorrhea and loss of secondary sexual characteristics. In men, loss of gonadotrophin secretion is associated with erectile dysfunction, decreased testicular size, and loss of male secondary sexual characteristics. Loss of TSH secretion results in secondary hypothyroidism. The symptoms—dry skin, constipation, cold intolerance, weight gain, and loss of energy with increased fatigability—are similar to those of primary

Figure 45-1 Pituitary Anterior Lobe Deficiency in the Adult.

hypothyroidism. Loss of ACTH secretion leads to secondary hypoadrenalism with weight loss, loss of appetite, early satiety, nausea, extreme weakness and lassitude, and inability to mount a normal stress response with resulting circulatory collapse if the deficiency is severe. Unlike primary adrenal insufficiency, mineralocorticoid secretion remains nearly normal; therefore, severe disturbances of sodium and water balance are less common, although hyponatremia results from the loss of direct effect of cortisol on free water clearance.

The loss of prolactin secretion due to diseases such as Sheehan's syndrome results in failure of postpartum lactation. Symptoms of antidiuretic hormone (ADH) deficiency include polyuria, polydipsia, postural hypotension, and hyperosmolarity. Patients with large tumors can present

with symptoms due to the mass lesion, including visual field loss, diplopia, and headaches. The physical signs depend on which hormonal deficits have occurred. Patients with panhypopituitarism often present with dry thin skin, increased truncal fat, decreased muscle mass, loss of pubic and axillary hair, and deep tendon reflexes showing delayed relaxation phase. Ancillary laboratory abnormalities that may occur include anemia, hyponatremia (low cortisol), hypernatremia, hyperosmolarity (ADH deficiency), and hypoglycemia (low GH). Usually the diagnosis of panhypopituitarism or of partial loss of pituitary hormone secretion is confirmed by stimulation tests (Table 45-1). When a hormonal deficit has been confirmed, magnetic resonance imaging of the sella turcica and parasellar region can determine whether a mass lesion is present. Treatment

Table 45-1 Diagnostic Tests Used to Confirm Pituitary Hormone Deficiencies

Hormone	Screening Test	Stimulation Test	Peak Response
GH	IGF-I decreased in 57% of cases	Insulin tolerance test, <i>or</i> Arginine infusion plus GHRH	<3 ng/mL <9 ng/ml
FSH/LH*	Testosterone plus LH (men) Estrogen plus FSH and LH (women)	GnRH	<10 IU/mL
TSH*	Free T ₄ and TSH	TRH	<5 μU/μL
ACTH	Urine cortisol	ACTH stimulation test	Serum cortisol <18 μg/dL
ADH	Polyuria >3 L/24 hr with serum osmolality >295 mOsm Urine osmolality <300 mOsm	Water deprivation test	Correction of osmolality to <298 mOsm after ADH administration

*Usually these deficiencies are confirmed with screening tests, and stimulation testing is usually not required.

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; FSH, follicle-stimulating hormone; GH, growth hormone; GnRH, gonadotropin-releasing hormone; GHRH, growth hormone-releasing hormone; IGF, insulin-like growth factor; LH, luteinizing hormone; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone.

usually includes removal of the tumor and institution of hormone replacement therapy. Thyroid hormone and cortisol are replaced orally, and gonadal steroids are replaced either orally (estrogen and progesterone), transdermally, or by injection. GH can be replaced only by injection. ADH is replaced orally or intranasally.

Avoiding Treatment Errors

Hormone replacement in hypopituitarism is challenging because of the inability to use laboratory testing to directly monitor therapy in all cases. For example, ADH replacement is monitored indirectly by measuring urine and serum sodium osmolality. Thyroid replacement is easily accomplished using direct measurement of free T₄. Cortisol replacement is usually monitored using clinical signs (e.g., appetite and weight) as well as electrolyte balance. Cortisol metabolism is decreased with hypothyroidism and GH deficiency; therefore, patients with hypopituitarism often require lower doses than patients with primary adrenal insufficiency.

Pituitary Dysfunction Due to Hypersecretion of Specific Hormones

Adenoma formation with subsequent expansion of somatotropes, thyrotropes, gonadotropes, or lactotropes results in hypersecretion of each of these hormones (Figs. 45-2, 45-3, and 45-4). The most common disorder is prolactin hypersecretion, which accounts for more than half of pituitary adenomas, followed by GH and ACTH hypersecretion. TSH and gonadotropin hypersecretion are rare. The etiology of these tumors in most cases is unknown; however, they represent clonal expansion of a small group of cells. Mutations of oncogenes, such as *PTTG* (pituitary tumor-transforming gene), that are cell growth activators, or mutations of tumor suppressor genes, such as G-protein subunit- α and *menin*, can result in the formation of pituitary tumors that overproduce hormones. To date, no spe-

cific mutation has been determined in most patients who present with these symptoms. *Menin* gene mutations result in multiple endocrine neoplasia type 1 syndrome, which is accompanied not only by pituitary mass lesions but also by tumors of the parathyroid gland and pancreas.

Hyperprolactinemia

Overproduction of prolactin leads to different syndromes in men and women. Specifically, modest overproduction of prolactin by very small tumors (<1.0 cm) in women results first in anovulation and then leads to amenorrhea due to direct antagonism of gonadotrophin action in the ovary and attenuation of estrogen action in target tissues such as the endometrium. Severe hyperprolactinemia results in major attenuation of estrogen action, with breast and vaginal atrophy, hot flashes, and development of osteoporosis. Spontaneous lactation occurs in women who are producing sufficient estrogen to stimulate milk production. These patients often present with galactorrhea and amenorrhea. Laboratory diagnosis of hyperprolactinemia is confirmed by serum prolactin measurement greater than 25 ng/mL. Treatment depends on whether a microadenoma or a macroadenoma is present. Almost all prolactin-secreting tumors respond to dopaminergic agonists. Usually, dopaminergic agonist treatment is instituted first, then the decision whether to do surgery or utilize radiation therapy is made, depending on tumor responsiveness. If prolactin values are less than 150 ng/mL, other etiologies, such as medications (e.g., phenothiazines) or hypothyroidism, should be excluded. Prolactin values greater than 150 ng/mL are almost always a result of pituitary tumors. Hypothalamic tumors that result in compression of the pituitary stalk (e.g., craniopharyngiomas) may also cause an increase in prolactin.

Acromegaly

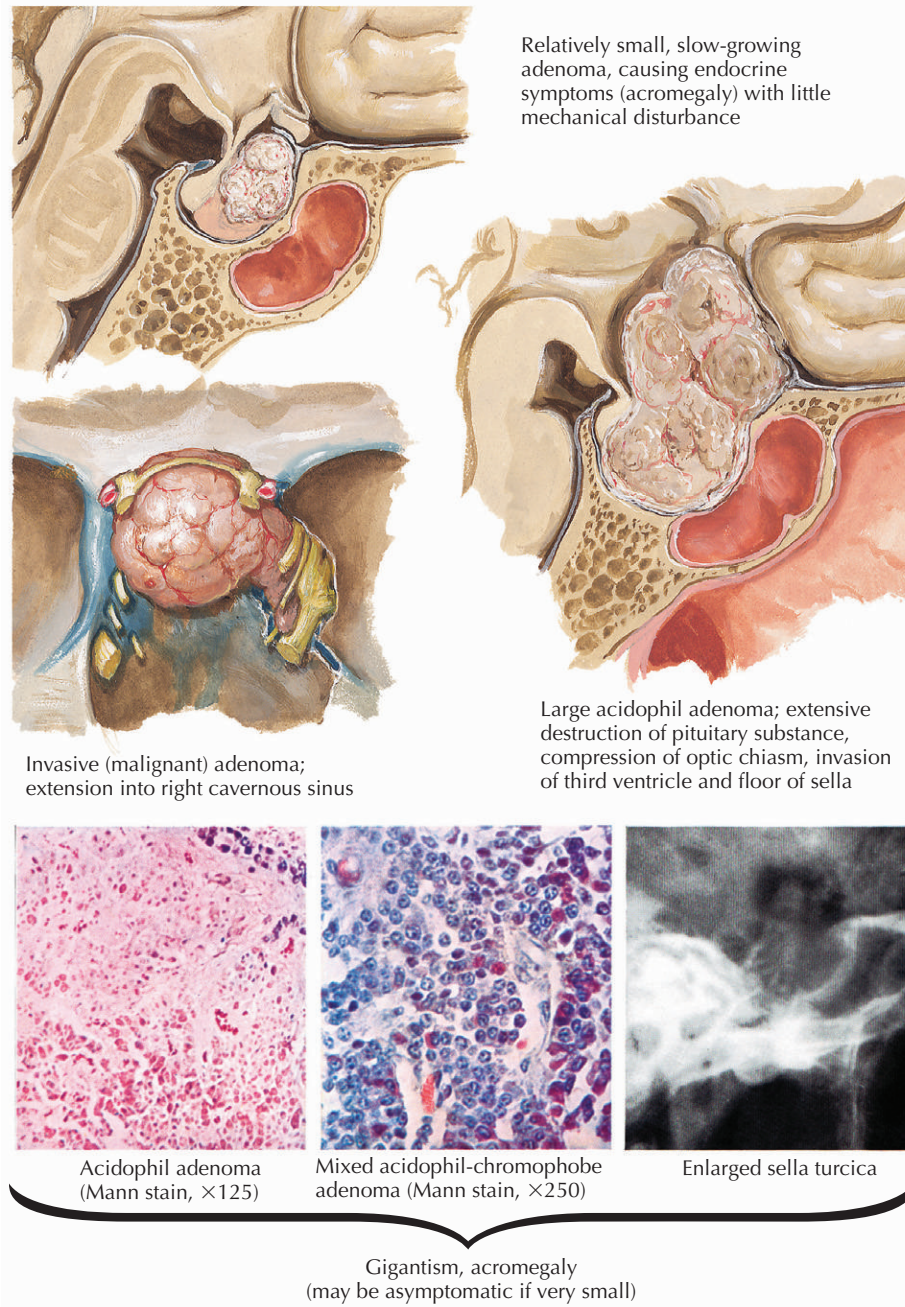

Overproduction of GH leads to gigantism in children and acromegaly in adults (see Figs. 45-2 and 45-3). The physi-

Figure 45-2 Acromegaly.

cal features in adults are distinctive and occur because the long bones have undergone epiphyseal fusion but there is overgrowth of the hands and feet, supraorbital ridge, and mandible. Enlargement of soft tissues, including the tongue and skin, and visceromegaly are usually present. Symptoms include sweating, weakness, easy fatigability, and arthralgias. Laboratory abnormalities include fasting hyperglycemia, hyperinsulinemia, and hyperphosphatemia. Treatment includes surgery to remove the primary GH-producing

lesion and, sometimes, follow-up radiation therapy. Medical therapy with dopaminergic antagonists, long-acting forms of somatostatin, and GH receptor antagonists is an effective means for reducing the growth-promoting effects of GH. Left untreated, this disease is associated with increased mortality and morbidity, primarily from cardiovascular disease. Because of the increase in mortality, the treatment goals should be normalization of serum IGF-I. The diagnosis of acromegaly is established either

Figure 45-3 Acidophil Adenoma.

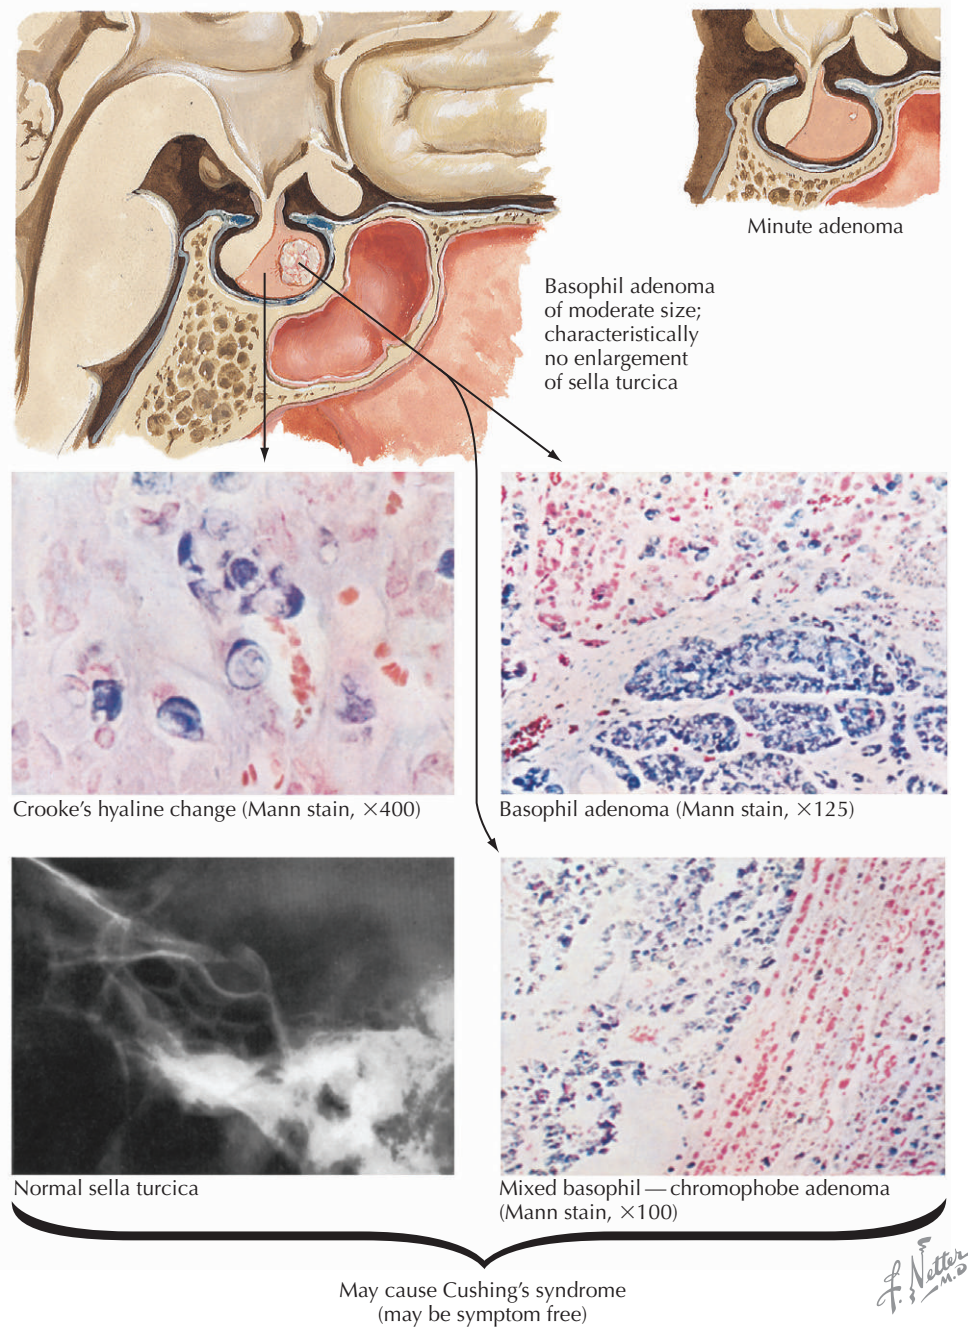

by obtaining an IGF-I value or by determining that GH cannot be suppressed to less than 0.5 ng/mL after ingestion of 75 g of glucose.

Cushing's Disease

Overproduction of ACTH by the pituitary results in excessive secretion and the development of Cushing's syndrome. This entity presents with a distinct phenotypic appearance, including fat redistribution over the posterior cervical area (buffalo hump), supraclavicular fat pads, and truncal obesity

(see Chapter 44, Fig. 44-5). Connective tissue breakdown leads to the distinct appearance of striae over the abdomen, and easy bruisability results from capillary fragility. Other symptoms are hypertension secondary to increased sodium and water retention; hirsutism and amenorrhea (70% of females); weight gain (20 to 30 lb is common); proximal muscle weakness and poor wound healing; and, in most patients, a distinctive facial flush. Laboratory evaluation often reveals hypokalemia, decreased serum urea nitrogen, and decreased bone mineral density. The diagnosis is based

Figure 45-4 Basophil Adenoma.

on an elevated total urinary cortisol excretion over a 24-hour period ($>120 \mu\text{g}/\text{day}$). If this test result is positive, one must distinguish between pituitary tumors and other causes of Cushing's syndrome. This is done by administering dexamethasone, 2.0 mg every 6 hours for 48 hours. Urinary cortisol is suppressed by 50% or greater in patients with ACTH-producing pituitary tumors. Adequate treatment of Cushing's disease requires removal of the ACTH-producing tumor. If a surgical cure is not achieved, radiation treatment and consideration of adrenalectomy are necessary to alleviate the hormonal overproduction. If

left untreated, Cushing's syndrome has a 50% 5-year mortality. Therefore, eliminating the hormonal abnormality is imperative.

Future Directions

Major advances have been made in the past decade in the quality of pituitary imaging and trans-sphenoidal surgery. Progress in these areas is likely to accelerate. Specifically, surgery is now performed endoscopically and in many cases has been extremely successful with much less in-

hospital and postoperative morbidity. Improvement in radiation therapy that utilizes techniques that localize radiation to the pituitary mass and limit damage to surrounding structures will continue. Molecular genetics is likely to continue to improve our ability to predict the development of pituitary tumors. Hormonal assays with improved sensitivity and specificity will allow more reliable and rapid diagnostic testing. Whether these tests will be sufficiently precise to obviate stimulation or suppression testing remains uncertain at this time.

Hirsutism

Introduction

Hirsutism, which affects about 10% of adult women, is characterized by the presence of terminal hairs that occur in androgen-dependent areas of a woman's body. The prevalence varies according to ethnicity and societal norms. Although most cases are benign, the condition can be extremely distressing to affected patients. The physician must distinguish benign from serious causes and counsel the patient with regard to the efficacy and availability of treatment options.

Etiology and Pathogenesis

Hirsutism results from increased production of androgens by the ovary, adrenal glands, or both, or from increased sensitivity of hair follicles to normal circulating levels of androgens (Fig. 46-1). The latter is frequently caused by increased 5 α -reductase activity, which converts testosterone to dihydrotestosterone, a more potent metabolite. Hyperandrogenism, resulting from any of these factors, prolongs the anagen (growth) phase of androgen-sensitive hairs, resulting in their conversion from fine, light, vellus hairs to coarse, dark, terminal hairs.

In women, testosterone is derived mainly from the ovary. About 25% of the total pool is secreted directly by the ovary, and the remainder is produced by peripheral conversion from ovarian and adrenally derived precursors. Androstenedione, a less potent androgen, is produced in equal quantities by both the adrenal gland and ovary. Dehydroepiandrosterone sulfate (DHEAS), also a weak androgen, is secreted almost exclusively by the adrenal gland. Increased testosterone levels indicate ovarian hyperandrogenism; increased DHEAS levels imply adrenal hyperandrogenism. If neither is elevated, and other causes are excluded, increased peripheral conversion is generally assumed.

Circulating androgen levels also affect the concentration of sex hormone-binding globulin (SHBG). SHBG binds testosterone in the circulation. In general, about 80% of testosterone is bound to SHBG, 19% is bound to albumin, and 1% circulates free. Hyperandrogenism and obesity can reduce SHBG concentrations, resulting in a

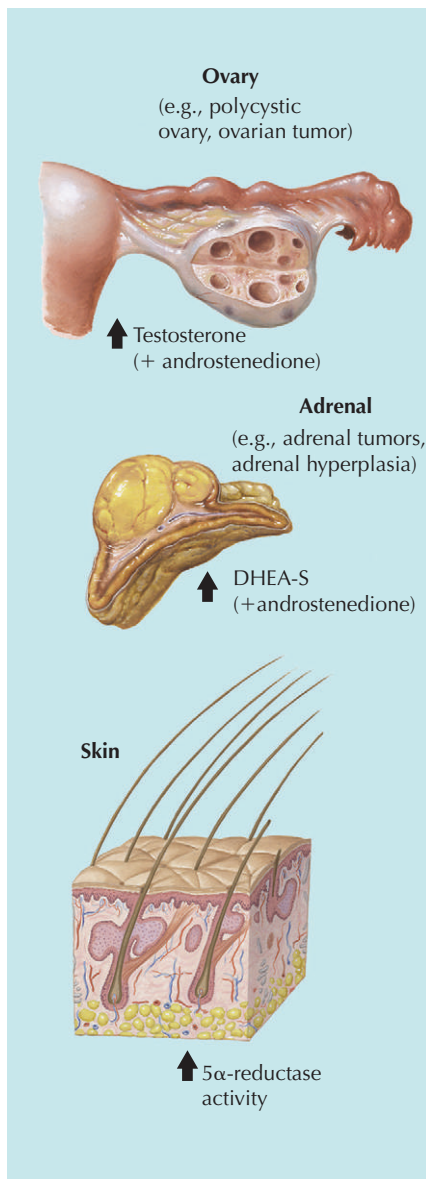

greater percentage of the total testosterone as the free, unbound, active hormone.

Clinical Presentation

The universal feature is an abnormal quantity and quality of sexual hair in the midline body areas. Most commonly, the face, chest, areola, linea alba, buttock, sacrum, inner thigh, and external genitalia are affected (Fig. 46-2). The severity of hirsutism can be quantified based on the Ferriman and Gallwey system, which evaluates nine body areas for absent to severe hirsutism with scores of 0 to 4. A score greater than 7 (of a possible 36) is considered abnormal. Other androgen-dependent symptoms that occur frequently include acne, menstrual irregularity, temporal recession, and frontal alopecia.

Classically, hirsutism is distinguished from virilization, which encompasses more advanced masculinizing features, including increased muscle mass, loss of female body contour, flattening of breasts, deepening of the voice from laryngeal hypertrophy, and clitoral enlargement (greater than 1 cm if measured transversely at base of shaft). This extreme manifestation of hyperandrogenism rarely occurs unless androgen levels are very elevated (>2 to 3 times the upper limit of normal), and if present, suggests ovarian or adrenal neoplasm, or possibly anabolic steroid use.

Hirsutism should also be distinguished from hypertrichosis, which is a diffuse increase in fine, vellus hairs in nonandrogen-dependent areas (often prominent on the cheeks, arms) and can result from glucocorticoid excess,

Figure 46-1 Sources of Hyperandrogenism in Women.**Figure 46-2 Clinical Manifestations of Hyperandrogenism.**

medications (phenytoin, penicillamine, cyclosporine, minoxidil, diazoxide), and systemic disorders (anorexia nervosa, hypothyroidism, porphyrias, dermatomyositis); it can also be familial.

Differential Diagnosis

Most cases of hirsutism in adult women are due to polycystic ovary syndrome (PCOS; about 80%) or idiopathic hirsutism (IH; 15% to 20%). These conditions generally begin in the perimenarcheal or late teen years and progress in a gradual fashion. In contrast, neoplasms of the ovary or adrenal gland present abruptly, progress rapidly, and are

more frequently associated with virilization. More specific characteristics of these disorders, as well as less common etiologies of hirsutism, are presented next.

Common Causes

Polycystic Ovary Syndrome

The criteria for the diagnosis of PCOS were redefined in 2003 to include two of the following three features: (1) *hyperandrogenism*, which may be based on clinical findings such as hirsutism or other androgen-dependent features, or biochemical evidence of increased androgen levels; (2) *oligomenorrhea* (≤ 8 menses/year); or (3) *polycystic ovaries*

visualized on ultrasound. The diagnosis also requires exclusion of other potentially causative conditions.

Insulin resistance affects ovarian androgen production by dysregulating an ovarian P450 cytochrome-oxidase 17 α -dependent pathway involving the conversion of progesterone to androstenedione. Insulin-mediated abnormalities of pituitary luteinizing hormone (LH) secretion may also contribute. Although commonly associated with obesity, cases of PCOS in thin women who are also insulin resistant have been well documented.

In this condition, testosterone is most often mild to moderately elevated, and there may be associated mild elevations in prolactin and DHEAS through mechanisms that are incompletely defined.

Idiopathic Hirsutism

A uniform definition of IH is evolving; a recent review suggests the inclusion of (1) *hirsutism*, (2) *normal androgen levels*, and (3) *regular menses* with normal ovulatory function. Normal ovulatory function can be confirmed by basal body temperature measurement or midluteal phase progesterone measurement. If there is evidence of anovulation despite regular menses, the patient is considered to have PCOS. Pathogenesis of IH involves increased 5 α -reductase activity as well as a possible alteration in androgen receptor function, resulting in increased sensitivity of the hair follicle to normal androgen levels.

Rare Causes

Adrenal Hyperplasia

Classic congenital adrenal hyperplasia (21-hydroxylase deficiency) is an autosomal recessive condition diagnosed in infancy because it causes ambiguous genitalia in female infants. A partial form of this condition, nonclassic (late-onset) congenital adrenal hyperplasia (NCAH), may present as a slowly progressive form of hirsutism in adulthood. The pathogenesis involves an enzymatic deficiency in adrenal steroidogenesis, resulting in accumulation of androgen precursors. Clinical features and laboratory findings may be similar to those of PCOS, but can be distinguished by evaluating 17-hydroxyprogesterone levels, which are mild to moderately (>200 ng/dL) elevated at baseline in NCAH and rise to more than 1500 ng/dL after ACTH stimulation. The prevalence of NCAH is less than 3%, although it is known to be particularly common in Ashkenazi Jewish women (prevalence, 1 : 27).

Cushing's Syndrome

Cushing's syndrome presents with hypercortisolemia caused by a cortisol-secreting pituitary adenoma (Cushing's disease), an adrenal adenoma, or an ectopic adrenocorticotrophic hormone. It is a rare cause of hirsutism unless induced iatrogenically by glucocorticoid administration. Often, other clinical features predominate (facial plethora,

telangiectasias, suboccipital fat pad, violaceous abdominal striae, obesity, hypertrichosis) in this condition.

Ovarian Tumor

Epithelial tumors, which are generally malignant, can cause hyperandrogenism by stimulating adjacent stroma. Androgen-secreting functional ovarian tumors include Sertoli-Leydig (arrhenoblastoma), lipoid cell, and hilus cell tumors. Characteristic features are more severe, and progressive hirsutism and testosterone levels are higher than 150 to 200 ng/dL. Together, these tumors represent less than 1% of causes of hirsutism.

Adrenal Tumor

Adrenal adenomas and carcinomas usually secrete DHEAS, although they can also co-secrete testosterone, cortisol, or both. They are also unusual, with a prevalence of less than 1% of the cases of hirsutism, and are associated with more severe degrees of hirsutism and hormonal elevations (particularly DHEAS) than the more common benign etiologies.

Hyperprolactinemia

Hyperprolactinemia presents with galactorrhea, amenorrhea, and sometimes hirsutism. Prolactin may stimulate adrenal androgen secretion, although most cases of hyperprolactinemia do not have significant hirsutism associated clinically.

Drugs

Danazol, anabolic steroids, glucocorticoids, and certain progestins (norgestrel and levonorgestrel) present in certain oral contraceptive pills can cause hirsutism.

Diagnostic Approach

The evaluation should focus on the age of onset, pattern of progression, severity (evidence of virilization), menstrual history, and ethnicity. Women of Mediterranean, Middle Eastern, Ashkenazi Jewish, and Indian subcontinent origins are more prone to idiopathic hirsutism. The family history of hirsutism is also important. A medication history should be obtained, as well as a history about the extent of mechanical methods (frequency of shaving, tweezing, depilation, or electrolysis) used by the patient to control the condition.

Recommended laboratory tests for all patients are testosterone and DHEAS. Prolactin and thyroid-stimulating hormone should be added if hirsutism is associated with amenorrhea or oligomenorrhea. More extensive laboratory evaluation is seldom indicated because the findings rarely influence treatment. However, additional tests can include 17-hydroxyprogesterone to diagnose NCAH, 3 α -androstenediol glucuronide (a metabolite of testosterone used as a marker of 5 α -reductase activity), and measurements of free testosterone or SHBG concentrations.

Cortisol (by 24-hour urine collection or overnight 1-mg dexamethasone suppression test) should be assessed if there are clinical features of Cushing's syndrome but otherwise does not need to be part of the routine evaluation for hirsutism.

Management and Therapy

If the laboratory evaluation suggests an ovarian tumor (testosterone levels >150 to 200 ng/dL) or an adrenal gland tumor (DHEAS >700 µg/dL or 2.5 times the upper limit of normal), abdominal and pelvic imaging with ultrasound, computed tomography, or magnetic resonance imaging is indicated, with surgical referral if a mass is detected.

In most other cases, medical therapy is directed at the underlying causative factors. Most agents require 3 to 6 months to achieve a noticeable effect on hirsutism, and patients should be counseled accordingly. Treatment of Cushing's syndrome, a rare cause of hirsutism, is discussed in Chapters 44 and 45.

Suppressing Androgen Production

Combination oral contraceptives decrease ovarian androgen production, and the estrogen component (30 to 35 µg is sufficient) increases the production of SHBG. Agents containing the least androgenic progestins (norgestimate, desogestrel, ethynodiol, drospirenone) are generally recommended, although clinical trial data supporting their superiority over other oral contraceptives in the treatment of hirsutism are lacking. Drospirenone may be particularly useful in light of its structural and antiandrogenic similarities to spironolactone.

Glucocorticoids are indicated for the treatment of NCAH. Dexamethasone, 0.125 to 0.25 mg given at bedtime, suppresses adrenal androgen secretion effectively.

Androgen Receptor Blockers

Spironolactone blocks androgen action peripherally at the level of the hair follicle. The overall response is favorable, with 60% to 70% of patients showing improvement at 6 months. Doses of 50 to 200 mg/daily have been used. The effect is generally dose related, with more than half of patients requiring the maximal dose to benefit. Side effects include a transient initial diuresis and occasional gastrointestinal symptoms. Hyperkalemia occurs but is rare in healthy patients. Spironolactone should be used only in conjunction with adequate contraception because of its potential feminizing effect on a male fetus.

Flutamide at doses of 125 to 250 mg twice daily is similar in efficacy to spironolactone. The potential side effect of liver toxicity and high cost limit its feasibility for routine treatment.

Finasteride, a 5 α -reductase inhibitor (at a dose of 5 mg daily), is similar in efficacy to spironolactone and flutamide. It is also costly, and because of its ability to induce

ambiguous genitalia in a male fetus, appropriate contraceptive measures are mandatory.

Cyproterone acetate, a progestin with antiandrogenic activity, is used extensively in Europe for the treatment of hirsutism. In several studies in which cyproterone acetate was compared to other drug treatments for hirsutism, no difference in clinical outcome was noted, despite differences produced in hormonal parameters. This drug is not approved for use in the United States because of concerns about it causing cancer in laboratory animals at high doses.

Improving Insulin Sensitivity

Modest weight loss, with resultant improvement in insulin sensitivity, improves the clinical and biochemical features of PCOS. *Pharmacologic insulin sensitizers (metformin and thiazolidinediones)* also improve manifestations of PCOS, although their effects on the hirsutism tend to be milder than those achieved with antiandrogens. Metformin is considered first-line therapy for PCOS, at doses of 500 mg 3 times daily to 1000 mg 2 times a day. Dose titration by 500 mg at weekly intervals to limit gastrointestinal side effects is recommended. Thiazolidinediones (rosiglitazone, pioglitazone) also improve the features of PCOS with results similar to those achieved with metformin. Unlike metformin, however, which is weight neutral and available in a generic formulation, thiazolidinediones are expensive and often associated with modest weight gain, which limits their desirability and feasibility as a long-term treatment option.

Topical and Mechanical Treatments

Eflornithine hydrochloride cream 13.9% became available in 2001 for the treatment of facial hirsutism. Its mechanism of action is to inhibit keratin protein synthesis in the hair follicle, which slows the rate of hair growth. It may reduce the frequency of mechanical treatments, although it will not enhance the conversion of terminal to vellus hair, as will some of the androgen suppression treatments. It is applied twice daily, and effects occur within 4 to 8 weeks; 30% to 60% of patients achieve some degree of clinical improvement. Minor skin irritation, generally infrequent, is the most common side effect.

Electrolysis removes hair permanently by deploying an electrical current through a fine needle to destroy the dermal papilla at the base of the hair. The procedure can be costly and time consuming because only a small number of follicles can be treated in a single session.

Laser treatment has been used recently. Treatment results are roughly equivalent with various types of laser (ruby, alexandrite, diode, which deliver light at a single wavelength) or intense pulsed light (IPL) treatments. Results tend to be best in light-skinned women with dark hair because the contrast improves efficacy. The procedure is generally well tolerated, although it can be very costly

because several treatments are usually necessary to achieve complete and permanent hair removal.

Optimum Treatment

A combination of pharmacologic agents and cosmetic measures are usually required to achieve a satisfactory result.

For PCOS associated with obesity, a brief trial of weight loss achieved through diet and exercise is the initial preferred treatment. If unsuccessful, metformin should be added, with the addition of oral contraceptives, spironolactone, or eflornithine hydrochloride cream as needed. Assessment of glucose and lipid levels should be done in PCOS, given its strong association with these metabolic disturbances.

For IH, if very mild, a trial of eflornithine hydrochloride cream is reasonable, although most cases require a contraceptive for adequate hormonal suppression, and many require the addition of spironolactone for optimal hormonal control.

For both conditions, after a period of hormonal treatment, mechanical measures may then be suggested, and these are often more effective after hormonal therapy has been used to reduce androgen levels or decrease androgen action.

Avoiding Treatment Errors

Patients should be adequately counseled so that their expectations are appropriate. Response to hormonal treatment often requires 6 months, and it is reasonable to wait that long to assess the need for additional agents. Moreover, many women with this condition feel frustrated that the condition is hopeless, having seen minimal effects from mechanical treatments previously tried. The value of controlling the underlying hormonal abnormalities to enhance the effectiveness and permanence of mechanical measures should be appropriately stressed.

Future Directions

Multiple agents are available that exert their effects on hirsutism by different mechanisms. Additional data are needed regarding the most successful and cost-effective treatment combinations. Initial hormonal treatment followed by ever-improving mechanical treatments will likely remain the mainstay of treatment for the near future.

Trials evaluating newer treatment modalities including somatostatin analogues for PCOS are underway. Recognition and treatment of hirsutism diminishes the psychological burden for patients and, for those with PCOS, the potential long-term sequelae of chronic anovulation.

Hypogonadism in the Male

Introduction

Hypogonadism in a male refers to a deficiency of either testosterone production or sperm production, or both. Disorders causing hypogonadism may result from direct damage to the testes (primary hypogonadism) or to the hypothalamus or pituitary (secondary hypogonadism).

The adult male testis consists of two main components: seminiferous tubules, which make up more than 80% of the total testicular mass and contain Sertoli cells and germ cells or sperm; and Leydig or interstitial cells. Sertoli cells, in response to stimulation by pituitary follicle-stimulating hormone (FSH), secrete an androgen-binding protein that increases the concentration of testosterone in the tubular lumen (Fig. 47-1). They also provide an environment necessary for germ cell differentiation into mature sperm. Leydig cells produce testosterone and related steroids in response to stimulation by pituitary luteinizing hormone (LH). Testosterone acts locally on seminiferous tubules to promote sperm formation.

In the adult male, more than 95% of available testosterone is secreted by Leydig cells. In peripheral tissues, a portion of the secreted testosterone is converted into dihydrotestosterone, which is responsible for the androgenic effects of testosterone in some target tissues. Testosterone can also be converted into the potent estrogen, estradiol, in tissues possessing an aromatase enzyme. Adipose tissue and the central nervous system are capable of converting androgens into estrogens by this mechanism.

Most of the activities of the testes, including sperm formation and secretion of testosterone, are controlled by the pituitary gonadotropins, LH and FSH. These hormones are in turn controlled by a peptide hormone produced by the hypothalamus, called gonadotropin-releasing hormone (GnRH). The hormonal control of testicular function is shown in Figure 47-1. GnRH binds to gonadotropin-producing cells in the pituitary and stimulates the secretion of both LH and FSH. Receptors for LH are located on Leydig cells, whereas receptors for FSH are located on Sertoli cells. The testosterone produced by Leydig cells exerts a negative feedback on both the pituitary and the hypothalamus to reduce the release of GnRH, LH, and FSH. Stimulation of Sertoli cells, which have FSH receptors, results in the production of an androgen-binding protein. Under the influence of FSH, the Sertoli cell also secretes proteins called inhibins. These proteins are capable of selectively inhibiting the secretion of FSH by the pituitary. Thus, any process leading to damage of seminiferous tubules will result in a rise of serum FSH, whereas damage to the Leydig cells will result in a rise of both FSH and LH.

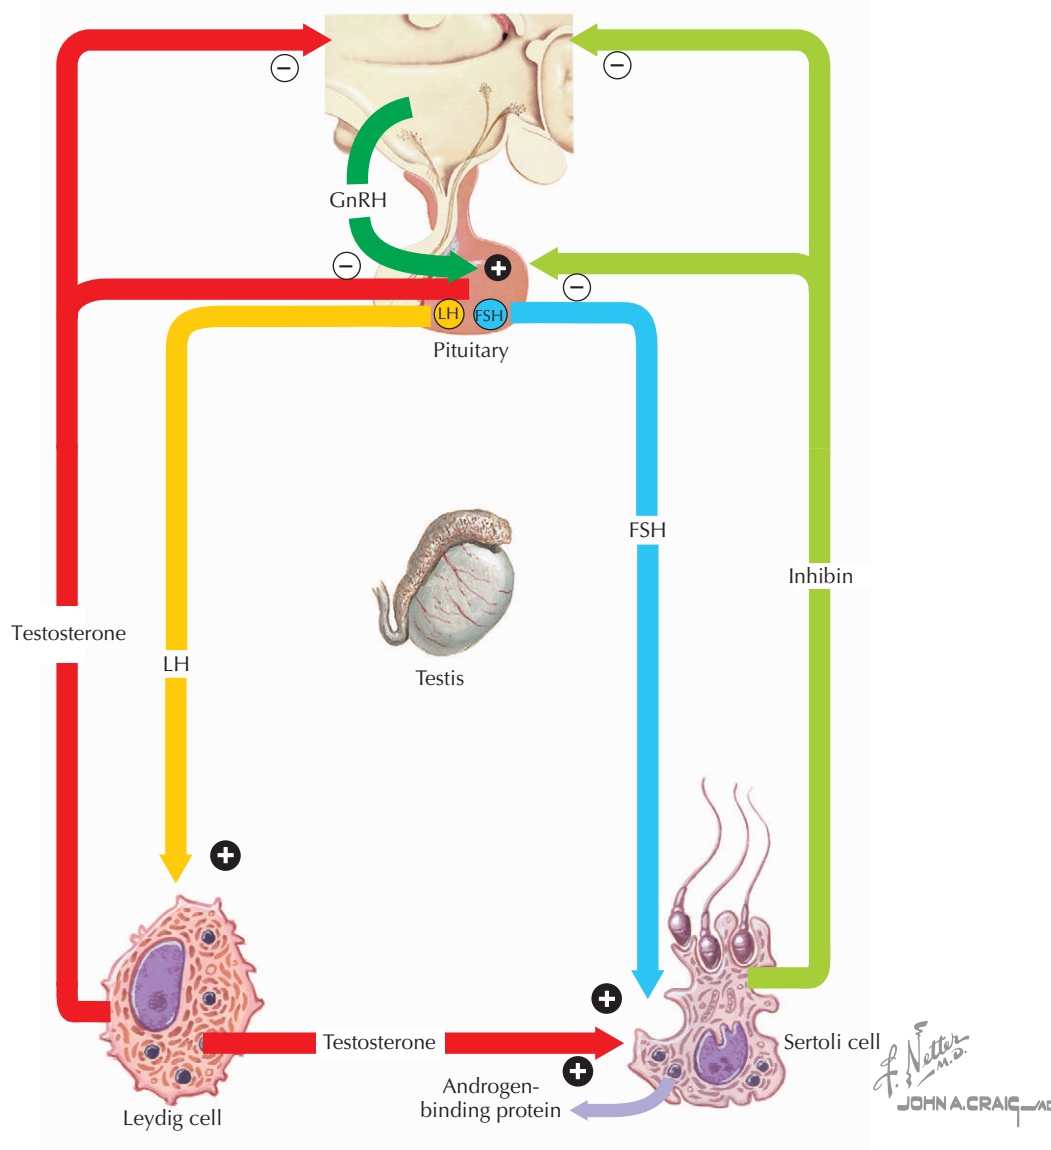

Etiology and Pathogenesis

Primary Hypogonadism

Patients have reduced testosterone secretion, reduced sperm production, and increased serum gonadotropins. The disease processes causing primary hypogonadism may damage the seminiferous tubules and Leydig cells to varying degrees, but tend to cause greater damage

to sperm production than to testosterone secretion (Box 47-1).

Klinefelter's syndrome, the most common congenital cause of primary hypogonadism in males, is due to the presence of an extra X chromosome. The most common genotype, 47, XXY, is due to nondisjunction of the maternal oocyte, yielding an egg with two X chromosomes. Other chromosomal patterns having extra X chromosome

Figure 47-1 Hypogonadism.

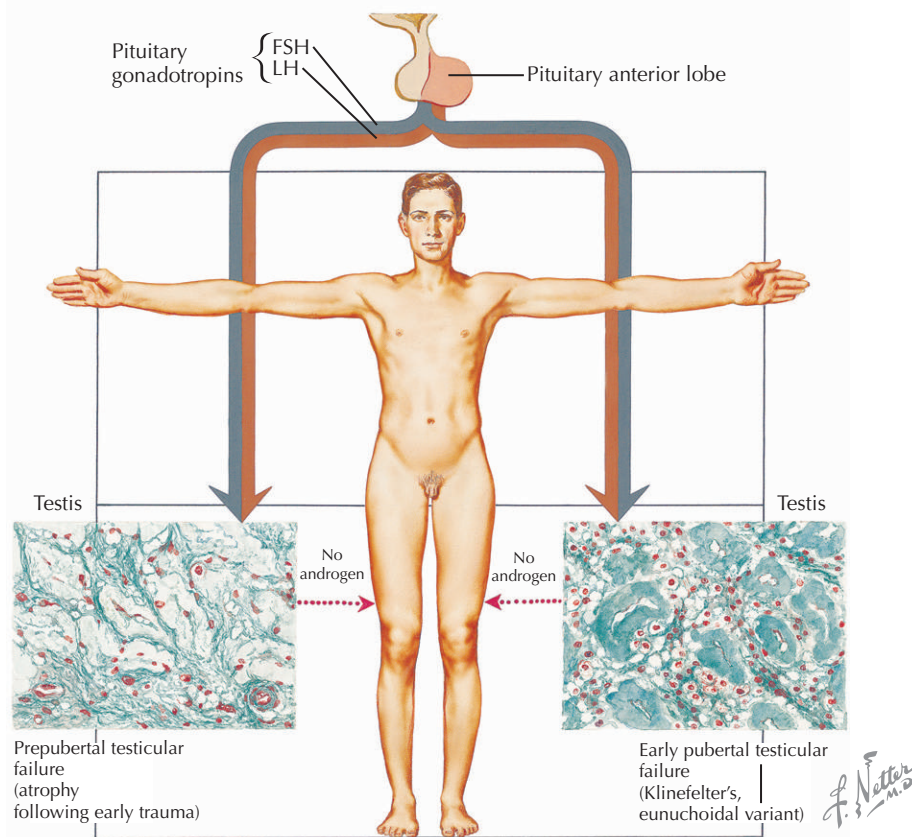

material may include 48, XXXY; 49, XXXXY; or mosaics such as 46, XY/47, XXY. Klinefelter's syndrome occurs in 1 out of every 1000 live births. Likelihood increases with increasing maternal age. The chromosomal germ cell defect causes severe damage to the seminiferous tubules and variable damage to the Leydig cells. Individuals usually appear normal at birth and may experience normal pubertal development. As adult males, they have small, firm testes, azoospermia, gynecomastia, and usually low testosterone levels. Body proportions are affected, as shown in Figure 47-2. Other abnormalities not directly related to testosterone deficiency occur more frequently, including chronic bronchitis, germ cell tumors, varicose veins, and diabetes mellitus.

Cryptorchidism refers to testes that have not descended from the abdominal cavity into the scrotum by 1 year of age. One or both testes may be involved. About 5% of

males have undescended testes at birth, but in 90%, descent occurs during the first year. The testis may fail to descend because of prenatal androgen deficiency, often due to defective testicular development in utero. In unilateral cryptorchidism, the descended testicle often exhibits abnormalities, including a low sperm count. The undescended testicle may be damaged further because of exposure to higher temperatures inside the abdomen.

Myotonic dystrophy, an autosomal dominant disorder leading to muscle atrophy, is accompanied by hypogonadism that usually develops after puberty. Congenital deficiencies in specific enzymes essential for androgen biosynthesis are rare autosomal recessive disorders that lead to testosterone deficiency during the first trimester of pregnancy, and hence to incomplete virilization of the male infant.

Acquired diseases affecting the testes typically cause greater damage to the seminiferous tubules than to Leydig

cells. The infection most commonly associated with testicular damage is mumps orchitis. Radiation and certain chemotherapeutic drugs used in the treatment of cancer can cause seminiferous tubule damage proportionate to the exposure. Alkylating agents such as cyclophosphamide and

chlorambucil commonly cause oligospermia and elevations in serum FSH. Cisplatin or carboplatin can also decrease the sperm count, but at least partial recovery is usually seen. Many chronic systemic illnesses can cause hypogonadism, both by direct testicular injury and by causing reduced gonadotropin secretion. Cirrhosis, chronic renal failure, and AIDS are all associated with reduced testosterone secretion and variable levels of LH and FSH.

Spermatic Duct Obstruction or Dysplasia

Defects of the epididymis or vas deferens can cause absence of sperm in the semen (azoospermia), whereas spermatogenesis and testosterone secretion by the testes may be normal. Disorders of sperm transport may be either congenital or acquired. Most males with cystic fibrosis have congenital absence of the vas deferens. Acquired obstruction may result from infection (gonorrhea, chlamydia, tuberculosis) or surgical ligation (vasectomy).

Varicoceles are dilations of the venous plexus in the scrotum that exist in 10% to 15% of normal men. Because varicoceles exist in an even higher proportion of infertile men, they have long been proposed as a cause of infertility, perhaps by increasing temperatures within the scrotum. Whether fertility can be improved by ligation of varicoceles remains controversial.

Secondary Hypogonadism

Patients have reduced sperm production, reduced testosterone secretion, and low or normal serum gonadotropins. Sexual differentiation is normal because Leydig cell function during the first trimester, when differentiation occurs, is stimulated by chorionic gonadotropin from the placenta. In contrast, penile growth during the third trimester is dependent on testosterone stimulated by LH from the fetal pituitary (Box 47-2).

Most cases of congenital hypogonadotropic hypogonadism are due to a lack of GnRH, as evidenced by a normal response of serum LH after repetitive administration of synthetic GnRH. In some cases, there are other associated abnormalities, as in the Prader-Willi syndrome, in which hypogonadism is associated with mental retardation and obesity. Kallmann's syndrome is caused by a deletion in a gene on the short arm of the X chromosome that codes for an adhesion molecule, *KALIG-1*. Lack of this molecule leads to a failure of GnRH-secreting neurons to migrate during embryogenesis from the olfactory placode to the olfactory bulb and arcuate nucleus of the hypothalamus. The consequences are anosmia and hypogonadotropic hypogonadism. Most cases of Kallmann's syndrome are sporadic, but familial inheritance also occurs. Inheritance is usually X linked.

Any acquired disease affecting the hypothalamic-pituitary axis can cause hypogonadotropic hypogonadism. Mass lesions in the pituitary or hypothalamus are more likely to diminish the secretion of gonadotropins than of adrenocorticotrophic hormone or thyroid-stimulating hormone. Thus, affected men may have hypogonadism without evidence of adrenal or thyroid deficiency. As a

rule, most masses are large enough to cause dysfunction by compressing and damaging surrounding structures in the hypothalamus or pituitary. Prolactin-secreting pituitary adenomas may be an exception. High concentrations of prolactin produced by these tumors can act to inhibit production of GnRH in the hypothalamus. If prolactin concentrations are lowered by appropriate drugs such as bromocriptine, gonadotropin secretion may resume even though the tumor remains.

Meningitis is a rare cause of hypogonadism in the United States, but tuberculous meningitis is seen in countries where tuberculosis is common. Inflammatory diseases such as sarcoidosis and Langerhans cell histiocytosis (eosinophilic granuloma) impair GnRH secretion by damaging the hypothalamus, whereas hemochromatosis damages the pituitary by iron deposition.

Hypogonadism due to pituitary apoplexy occurs with sudden hemorrhage into the pituitary, usually from a pre-existing pituitary tumor. Trauma to the base of the skull, as in a basilar skull fracture, can damage the pituitary stalk and impair the movement of GnRH from the hypothalamus to the pituitary. Both apoplexy and basilar skull fracture are usually associated with a deficiency of other pituitary hormones in addition to gonadotropins. Other conditions causing impaired secretion of gonadotropins include severe malnutrition and chronic administration of opioid analgesics.

Clinical Presentation

The clinical manifestations of impaired spermatogenesis are infertility and decreased testicular size. In a normal adult male, both testes should be 4.0 to 7.0 cm in length. The clinical manifestations of testosterone deficiency depend on age at the onset of the deficiency. During embryonic life, testosterone acts to promote differentiation of the external genitalia along male lines. A lack of testosterone in a male infant during early uterine life will result in differentiation along female lines. If the deficiency is complete, the external genitalia may consist of a clitoris and labia, with the vagina ending in a blind pouch. Partial deficiencies lead to incomplete virilization, ranging from posterior labial fusion when the deficiency is more severe to hypospadias when it is mild. Insufficient testosterone late in pregnancy will not prevent normal differentiation of the external genitalia but will result in a very small penis (micropenis).

Lack of testosterone before puberty will result in failure of pubertal development. In the absence of testosterone, the epiphyses of the long bones may fail to close at the usual time, so that linear growth may be prolonged, leading to a eunuchoid body habitus (Fig. 47-3). The lower body segment (floor to pubis) is characteristically more than 2 cm greater than the upper body segment, and arm span is more than 2 cm greater than total height. Testosterone deficiency occurring during adult life results in a loss of

Figure 47-3 Testicular Failure: Seminiferous Tubular Dysgenesis (Klinefelter's Syndrome).

libido and overall energy, as well as decreased muscle mass and diminished growth of body hair. Longer-term effects also include a loss of bone mass and development of osteoporosis. Erectile dysfunction, a common problem among adult men, is accompanied by testosterone deficiency in only 5% to 30% of cases. However, testosterone should be measured in men with this complaint because replacement therapy can be helpful when severe deficiency is present.

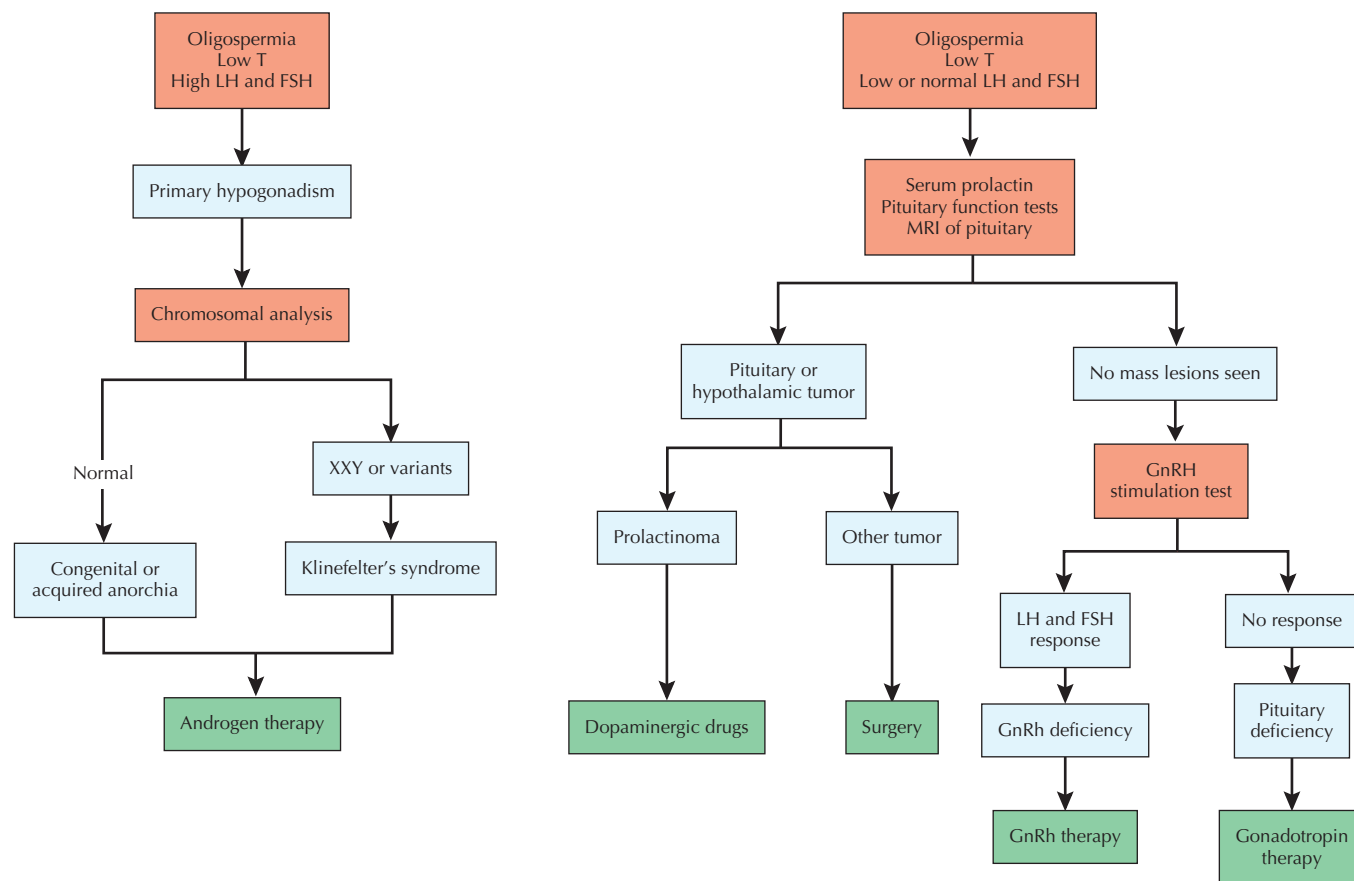

Differential Diagnosis

Depending on the results of the patient's history and physical examination, measurement of serum testosterone is the most useful test for confirming the presence of hypogonadism in adult males. Semen analysis is indicated when there is a clinical concern regarding fertility. Low testosterone measurements can be difficult to interpret in the teenage boy who is not undergoing pubertal changes at an expected rate, and the differential diagnosis includes constitutionally delayed puberty as well as pathologic causes of secondary hypogonadism. A history of constitutional short stature or delayed dental maturation or a family history of delayed puberty makes a diagnosis of delayed

puberty more likely. A borderline low serum testosterone is also difficult to interpret in the elderly male, in whom the differential diagnosis includes the normal decline in testosterone secretion due to aging. The underlying cause of hypogonadism is often suggested by history and physical examination. For example, a patient with secondary hypogonadism from a large pituitary or hypothalamic mass often has neurologic abnormalities such as visual field defects and evidence of a deficiency of other pituitary hormones. Men with primary hypogonadism are more likely to have breast enlargement (gynecomastia) due to the effects of elevated LH in stimulating testicular aromatase activity.

Diagnostic Approach

Once a low testosterone level is demonstrated, other tests are helpful in arriving at a specific etiologic diagnosis. A simplified scheme for differential diagnosis is shown in Figure 47-4. Semen analysis involves the measurement of the number of sperm in an ejaculated specimen, as well as their motility. Normal men produce more than 20 million sperm per milliliter of ejaculate, or 40 million per total ejaculate, and more than 60% are motile. Serum total

Figure 47-4 Approach to the Differential Diagnosis of Primary and Secondary Hypogonadism.

testosterone measurement, which includes free plus protein-bound hormone, is usually the best test for evaluating testosterone secretion. Exceptions occur in obese men, in whom the concentration of sex hormone-binding globulin is frequently low, and in elderly men, in whom it may be high. In such individuals, measurement of the free (unbound) or bioavailable fraction of serum testosterone is a more accurate means of assessment. LH and FSH should also be measured to interpret the significance of a low or borderline testosterone level: elevated gonadotropins confirm the diagnosis of primary hypogonadism even when testosterone is in the low-normal range. Normal gonadotropins in the presence of a low testosterone level indicate secondary hypogonadism.

Management and Therapy

Testosterone replacement is indicated in most adult men with low serum testosterone levels, except in those in whom the underlying cause may be reversible. The preferred testosterone preparations are either testosterone esters for intramuscular injection or special formulations for transdermal administration. Buccal tablets are also available. In the United States, testosterone enanthate and

testosterone cypionate are the most frequently used intramuscular forms. Doses of 200 mg every 2 weeks or 300 mg every 3 weeks will maintain serum levels within the normal range throughout most of the dosing interval. Longer dosing cycles result in subnormal serum levels toward the end of the interval. Transdermal formulations are available through skin patches that deliver 5 mg of testosterone every 24 hours and maintain serum testosterone within the normal range. The patch must be changed daily. Testosterone is also available in a hydroalcoholic gel applied in doses of 50 to 100 mg, enough to maintain normal serum levels for 24 hours. Adverse effects can include an increase in acne and aggressive behavior in adolescent boys, and exacerbation of benign prostatic hyperplasia and possibly prostate cancer in older men. Testosterone therapy can also induce erythrocytosis and exacerbate sleep apnea.

Optimum Treatment

Before initiating therapy, a prostate exam should be done, as well as measurements of serum prostate-specific antigen and hematocrit. In older men, bone mineral density should be measured. Serum testosterone should be remeasured after therapy is initiated to ensure that the dose and route

of administration are effective in restoring normal serum levels. Within weeks or months, normalization of serum testosterone should lead to improved libido in hypogonadal men and pubertal development in prepubertal boys. Over time, energy, bone mass, and muscle strength should all improve. If no improvement in hypogonadal symptoms is seen after a suitable interval, consider other causes for the symptoms. Monitoring in adults includes repeating the baseline measurements above and inquiring about symptoms of sleep apnea.

Gonadotropin replacement is generally limited to cases of secondary hypogonadism in which fertility is the objective because it is more complex and expensive than testosterone replacement. Some patients are stimulated to produce sufficient sperm for fertilization by injections of human chorionic gonadotropin (hCG), which replicates the effects of LH. Others require combination therapy with hCG and human menopausal gonadotropin, which contains both FSH and LH activity. Monitor effects by repeated semen analysis and measurement of the serum testosterone.

Avoiding Treatment Errors

In younger men, there is no evidence that achieving testosterone levels above the normal range is beneficial. Overtreatment should be avoided in all patients because of the increased risk for side effects. In elderly men with typical age-related declines in serum total and free testosterone, the benefits of testosterone supplements are still unclear, and the risks of untoward effects are higher. Therefore, replacement therapy is not recommended unless there are clear indications of an underlying pituitary or testicular disease.

Future Directions

Improved recognition of the adverse effects of drugs and environmental toxins on testicular function should reduce the incidence of male hypogonadism worldwide. For example, exposure to the nematocide dibromodichloropropane is known to decrease spermatogenesis in farm workers using it in the fields. It is severely restricted in the United States, but it is still exported to and used in other countries. In men undergoing cancer chemotherapy with alkylating agents and other toxic drugs, concurrent suppression of gonadotropins with testosterone or inhibitory analogs of GnRH may protect gonadal function. Further understanding of the benefits and risks of testosterone replacement in aging men will require more data from randomized clinical trials.

Rapid progress in assisted reproductive technology may enable more men with severe oligospermia or low sperm motility to be fertile. Intracytoplasmic sperm injection (ICSI) involves the direct injection of a single spermatozoon into the cytoplasm of an oocyte, previously collected from follicles produced under controlled ovarian stimulation. When there are no sperm in the ejaculate but there are germ cells in the testes, this technique can be performed using spermatozoa isolated from testicular biopsy specimens. ICSI has been successful in some men with Klinefelter's syndrome.

The authors describe a meta-analysis of clinical trials on the skeletal effects of testosterone supplementation. Intramuscular testosterone increased lumbar bone density in hypogonadal men, but insufficient information is available to determine whether fracture risk is decreased.

Osteoporosis

Introduction

Osteoporosis is the most common bone disease and a major risk factor for fractures. In the United States, there are more than 1.5 million osteoporotic fractures each year, with an annual cost of \$15 billion in health care and disability expenses. The average 50-year-old white woman in the United States has a 50% chance of suffering at least one osteoporotic fracture during her remaining lifetime. Because of the aging of our population and the increased occurrence of osteoporosis in elderly people, the incidence of osteoporotic fractures could double over the next 30 years without better methods for prevention and treatment.

Osteoporosis is defined as a low overall bone mass together with a disruption of normal bone architecture, leading to diminished strength and greater risk for fractures after minimal trauma. Histologically, there is an equivalent decrease in both bone mineral (composed of calcium and phosphorus) and bone matrix (composed of collagen and other bone proteins). The normal three-dimensional structure of trabecular bone is altered (Fig. 48-1). In osteoporotic bone, there are fewer connecting bony spicules or “struts,” and they are thinner than normal. Thus, both the radiologic density and mechanical strength of osteoporotic bone are diminished. The World Health Organization defines osteoporosis in terms of bone density measurements. Osteoporosis is present when the measured bone density is more than 2.5 standard deviations below the mean for a normal young individual of the same sex and race. This amounts to a loss of 25% to 30% from normal peak bone mass. Osteopenia refers to a lesser degree of bone loss, in which the measured density is between 1.0 and 2.5 standard deviations below normal peak bone mass, amounting to a loss of 10% to 25%.

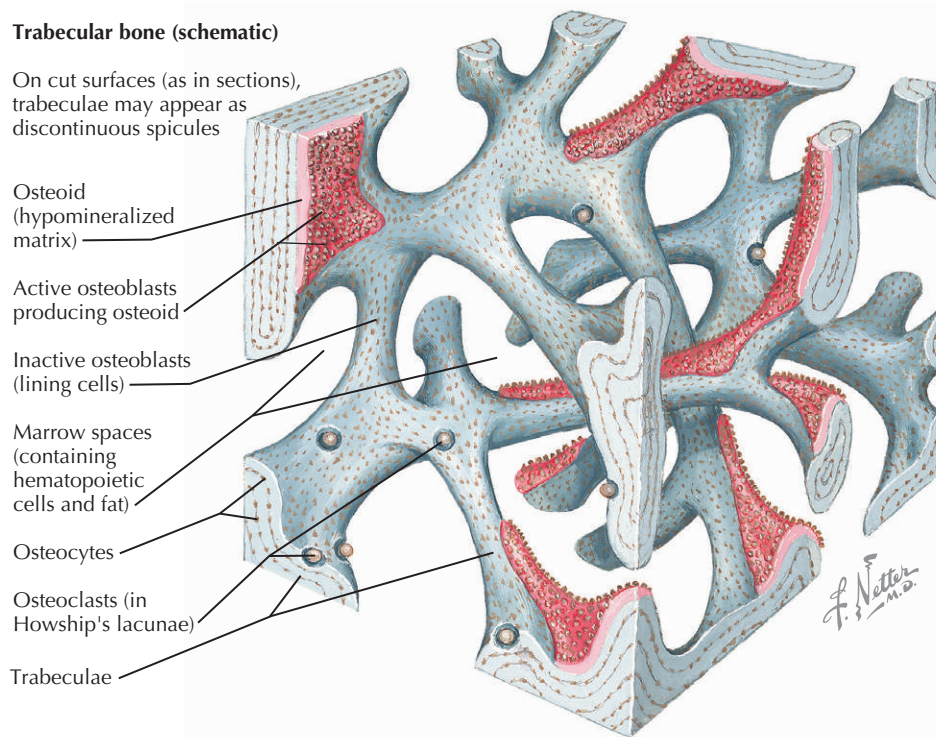

Bone is a dynamic tissue in which new mineral is constantly being laid down, while previously mineralized sections are being resorbed. This remodeling process is illustrated in Figure 48-2. The cells governing the process are osteoblasts and osteoclasts. Osteoblasts are bone-forming cells derived from connective tissue stem cells that also give rise to fibroblasts. Mature osteoblasts synthesize collagen and other bone matrix proteins such as osteocalcin. They produce the enzyme, alkaline phosphatase, which is believed to play a role in the mineralization process. Osteoclasts are the most important cells involved in bone resorption. They are derived from stem cells in the bone marrow resembling macrophages. Mature osteoclasts are large, multinucleated cells located adjacent to mineralized bone surfaces. These cells contain lysosomes capable of releasing enzymes that can degrade bone matrix proteins.

Etiology and Pathogenesis

A variety of inherited and acquired factors can predispose to low bone mass. Inherited or congenital risk factors include gender (female > male), race (white > African American), body build (thin with small frame), and family history. Acquired risk factors include increasing age, a diet low in calcium and vitamin D, early menopause, a sedentary lifestyle, and cigarette smoking. Osteoporosis results when there is too much bone resorption, too little bone formation, or a combination of both. Estrogen deficiency associ-

ated with menopause in normal women is the most common cause of increased bone resorption. Accelerated bone loss continues for about 10 years after menopause, and then the rate of decline decreases to near that of normal aging. Estrogen replacement in the postmenopausal period reduces the rate of resorption and stabilizes bone mass. Men with hypogonadism have accelerated bone loss similar to that of postmenopausal women. Hyperparathyroidism and hyperthyroidism can also cause increased bone resorption.

Age-related bone loss affects both men and women and may be due in part to decreased dietary calcium

Figure 48-1 Structure of Trabecular Bone.

absorption. In very elderly individuals, the rate of bone formation is often low. Exposure to certain drugs, such as glucocorticoids, and immobilization or lack of mechanical stress on bone itself can cause impaired bone formation.

Heredity undoubtedly plays a major role in determining both the peak bone mass of young adults and the rate of bone loss in older individuals. Multiple genes are likely to influence bone mass and strength. Ongoing research suggests that natural variations (polymorphisms) in a number of genes, including genes for the vitamin D receptor, the estrogen receptor, and type 1 collagen matrix protein, appear to affect bone mass. However, the genes of greatest importance in determining fracture risk are still to be determined.

Clinical Presentation

As bone is lost, there are no symptoms until fractures occur, typically with minimal trauma. Compression fractures of the vertebra are most common, followed by fractures of the proximal femur and the distal radius (Colles's fracture). As a result of vertebral compression with anterior wedging, patients lose height and develop a kyphosis deformity of the spine (Fig. 48-3). Patients who have experienced vertebral compression fractures often have chronic back pain. Proximal femur (hip) fractures are the most disabling, often leading to immobilization and a loss of independent living in elderly men and women. Because the entire skeleton is fragile, fractures are more likely to occur

Figure 48-2 Bone Remodeling.

at other sites as well, including the pelvis, ribs, and long bones.

Differential Diagnosis

Other metabolic bone diseases that can cause structural weakness of bone include osteomalacia and osteitis fibrosa. Osteomalacia occurs when bone mineral fails to be deposited in normally formed bone matrix. Rickets in children is the equivalent of osteomalacia in adults. Osteitis fibrosa is due to high circulating levels of parathyroid hormone (PTH), causing abnormally increased bone resorption.

A number of specific diseases can cause secondary bone loss and should be considered in the differential diagnosis of any patient presenting with low bone mass (Box 48-1).

It is important to identify these conditions because appropriate treatment of the primary problem can often lead to improvement in bone mass as well.

Diagnostic Approach

Plain x-rays of bone can show several types of abnormalities that suggest osteoporosis or another metabolic bone disease. The most common finding is nonspecific osteopenia, or reduced radiographic density. With more advanced disease, deformities or fractures may occur. In early disease, standard x-rays may appear normal. At least 30% of total bone mass must be lost before abnormalities in density are detectable by plain radiographs (Fig. 48-4).

Figure 48-3 Clinical Manifestations of Osteoporosis.

Quantitative measurement of bone density is the primary means of diagnosing osteoporosis, using World Health Organization standards. The most widely used method for measuring bone mass is dual energy x-ray absorptiometry (DEXA), which uses x-ray beams of two different energy levels. Tissues of differing densities (bone and soft tissue) conduct the beams differently, allowing specific densities to be calculated. Quantitative bone density measurement is used to document the presence of osteopenia or osteoporosis and to predict the risk for fracture. A decline of 1 standard deviation below young normal bone density implies a doubling of fracture risk. The risk doubles again for each standard deviation decline.

Routine laboratory evaluation is limited and used to rule out causes of secondary osteoporosis. Serum creatinine, calcium, phosphorus, alkaline phosphatase, and thyroid-

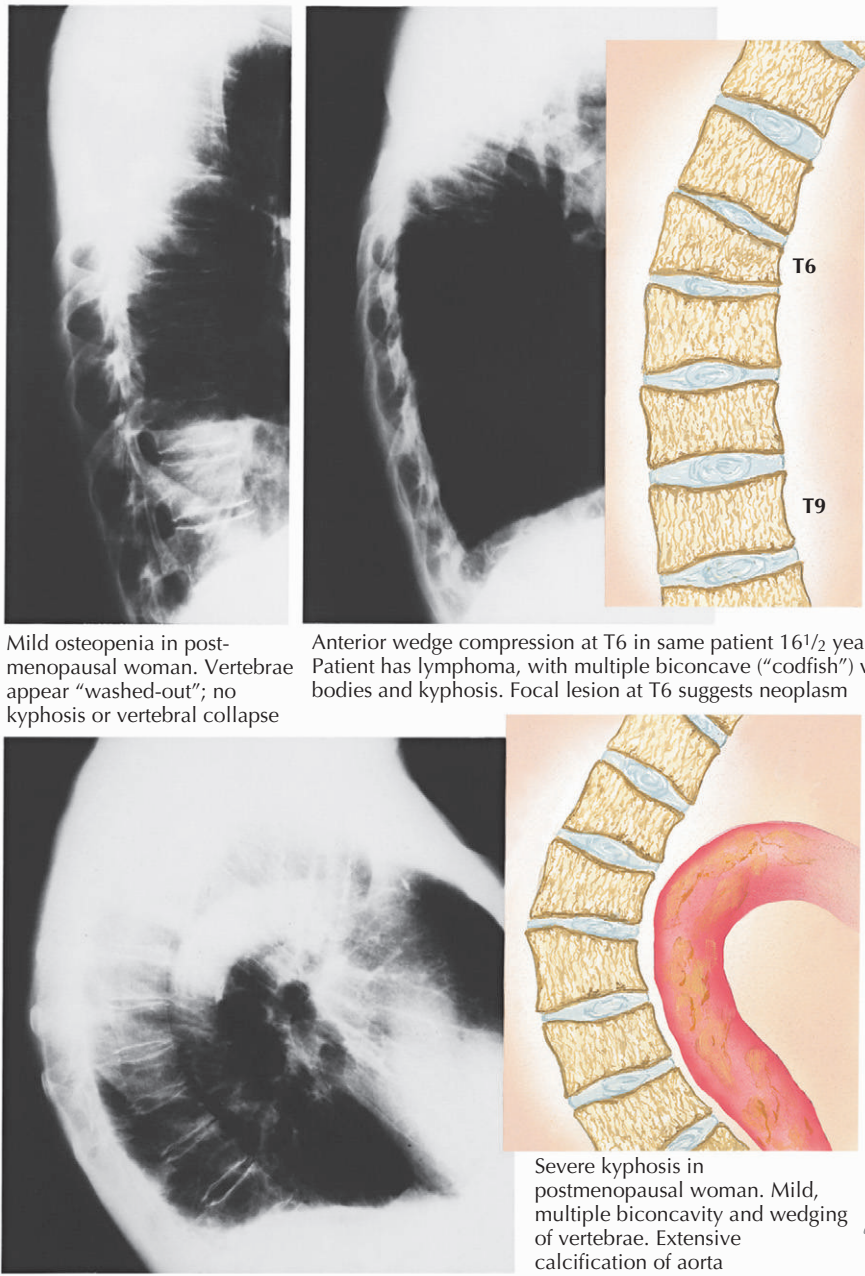

stimulating hormone, as well as complete blood count, should be obtained in most patients. Patients with elevated serum calcium should have a measurement of serum PTH. Those at clinical risk for vitamin D deficiency, especially homebound or institutionalized individuals, should have a measurement of 25-hydroxyvitamin D.

Management and Therapy

Prevention

Osteoporosis is better prevented than cured. The health habits of individuals in early and middle life play a role in their risk for osteoporosis in later life. Adequate dietary intake of calcium and vitamin D, active physical exercise, and avoidance of excessive alcohol, tobacco, and drugs

Figure 48-4 Radiographic Findings in Axial Osteoporosis.

Mild osteopenia in postmenopausal woman. Vertebrae appear “washed-out”; no kyphosis or vertebral collapse

Anterior wedge compression at T6 in same patient 16½ years later. Patient has lymphoma, with multiple biconcave (“codfish”) vertebral bodies and kyphosis. Focal lesion at T6 suggests neoplasm

Severe kyphosis in postmenopausal woman. Mild, multiple biconcavity and wedging of vertebrae. Extensive calcification of aorta

known to cause osteopenia are all useful measures for the prevention of osteoporosis (Table 48-1).

The recommended daily allowance of vitamin D for most healthy individuals is 400 IU, but for the elderly, 800 IU is preferred.

Drug Therapy

The objectives of therapy include prevention of further bone loss, promotion of bone formation, prevention of fractures, reduction or elimination of pain, and restoration

of physical function. A growing number of therapeutic agents have been shown to improve bone density and to reduce the incidence of certain fractures in randomized clinical trials. Estrogens, selective estrogen receptor modulators (SERMs), calcitonin, and bisphosphonates are considered to be *antiresorptive agents*, acting primarily to reduce rates of bone resorption by reducing osteoclast activity. PTH analogues, in contrast, are *anabolic agents*, stimulating bone formation through a primary action on osteoblasts.

Ideally the decision to treat with an antiosteoporosis drug should be based on an accurate prediction of the

absolute fracture risk in the individual patient. There is currently no generally accepted formula for estimating the probability of future fractures. However, the most powerful predictor is a history of prior fragility fractures. Other key factors known to have independent power to predict fractures include advancing age and low bone mineral density, as measured by DEXA. Thus, antiosteoporosis drug therapy should be strongly considered for both adult women and men with recent fragility fractures, regardless

of age. In patients without a history of fractures, drug therapy is usually justified in women and men older than 60 years with bone density measurements more than 2.5 standard deviations below young controls. In younger individuals with low bone density but no history of fractures, drug therapy may be deferred in favor of preventive strategies, with monitoring of bone density every 2 to 3 years.

Estrogen replacement in postmenopausal women prevents the excessive bone loss due to estrogen deficiency. Estrogens should be given together with a progestin in women who have an intact uterus to avoid the increased risk for endometrial cancer. The Women's Health Initiative clinical trial of estrogen replacement in postmenopausal women demonstrated a significant reduction in the risk for hip fracture. Clinical trials have shown that estradiol administered transdermally is also beneficial in postmenopausal osteoporosis. Prolonged administration of estrogens may increase the risk for breast cancer and venous blood clots in susceptible individuals, and estrogens are therefore not the treatment of choice for osteoporosis in many women.

SERMs are synthetic analogues of estrogen that have some of the biologic effects of natural estrogen but lack other effects. Drugs in this class include tamoxifen, a drug used to treat breast cancer, and raloxifene, a drug approved for the treatment of osteoporosis. Raloxifene acts as an estrogen agonist with respect to bone and lipoprotein metabolism. It increases bone density and lowers serum cholesterol when given to postmenopausal women. Clinical trials have demonstrated that raloxifene reduces the risk for vertebral fractures but not hip fractures in postmenopausal women with osteoporosis. Raloxifene does not stimulate the endometrium, and like tamoxifen, it acts as an estrogen antagonist in breast tissue. Thus, raloxifene is a good choice as an antiosteoporosis drug in women at high risk for breast cancer.

Bisphosphonates are a family of compounds that resemble pyrophosphate and are incorporated into the mineral structure of bone. There they inhibit bone resorption and promote increased bone mass. Clinical trials of several bisphosphonates, including etidronate, alendronate, risedronate, and ibandronate, indicate that bone density is increased in postmenopausal women after 2 or more years of treatment. Further trials with orally administered alendronate and risedronate provide strong evidence that these drugs can reduce fracture risk by 40% to 60% at both the spine and the hip, whereas ibandronate reduces fracture risk at the spine. These drugs are effective in men as well as women. Alendronate, risedronate, and ibandronate are currently approved in the United States for treatment of osteoporosis, but other drugs of this class are likely to be approved in the near future.

calcitonin in patients with osteoporosis causes a reduction in bone resorption and a modest increase in bone density. Clinical trials have found that intranasal calcitonin therapy reduces the occurrence of vertebral fractures in postmenopausal women. Large doses of calcitonin may have an analgesic effect through an independent action on the central nervous system.

PTH agonists, including recombinant human PTH 1-34 (teriparatide) and human PTH 1-84, constitute a class of antiosteoporosis drugs whose primary effect is to promote new bone formation. In one clinical trial, teriparatide, given as a daily subcutaneous dose in postmenopausal women, promoted increased bone density and reduced both vertebral and nonvertebral fractures. Teriparatide is also effective in increasing bone mineral density in osteoporotic men. Teriparatide has been approved in the United States for the treatment of osteoporosis. Other drugs of this class are likely to be introduced in the near future.

Optimum Treatment

Osteoporosis is a chronic disease requiring long-term therapy to prevent major complications and morbidity. Effective management requires education of the patient about the risks and benefits of therapy as well as development of an overall therapeutic plan that is acceptable and sustainable. Allied health professionals, including nutritionists and physical therapists, are often helpful in implementing optimal diet and exercise programs. Regular follow-up and monitoring of bone density as well as potential side effects are essential.

Avoiding Treatment Errors

Failure to implement effective strategies for the prevention or treatment of osteoporosis is common. Patients at high risk for developing osteoporosis due to the presence of other diseases or ongoing therapy with agents such as glucocorticoids should be monitored with measurements of bone density and started on antiosteoporosis therapy whenever their bone density is found to be low. Unfortunately, many elderly patients presenting with fragility fractures still receive neither bone density testing nor antiosteoporosis therapy, even though effective treatment is now widely available.

Future Directions

Improved public knowledge about dietary and lifestyle issues affecting risk may offer the greatest promise for avoiding a growing epidemic of osteoporotic fractures. More widely available and affordable screening procedures for low bone density should allow earlier recognition of high-risk individuals. Development of better algorithms

for predicting absolute fracture risk should also enable physicians to select those patients most likely to benefit from long-term therapy with antiosteoporosis drugs. New therapeutic strategies involving both drugs that promote active bone formation and drugs that prevent bone resorption are being studied. The sequential use of bone-forming drugs, such as PTH, followed by antiresorptive drugs, such as bisphosphonates, may provide greater long-term efficacy than the use of either drug alone. Finally, randomized clinical trials allowing head-to-head comparisons of a growing number of antiosteoporosis drugs should eventually lead to improved treatment guidelines and more informed drug selection.

EVIDENCE

1. Black DM, Cummings SR, Karpf DB, et al: Randomised trial of effect of alendronate on risk of fracture in women with existing vertebral fractures. *Fracture Intervention Trial Research Group. Lancet* 348(9041):1535-1541, 1996.

In this randomized clinical trial of oral alendronate in 2027 postmenopausal women with low bone mineral density and previous vertebral fractures, results showed reduction in fracture risk for both vertebral and nonvertebral fractures, including hip fracture in the treated group.

2. Chapuy MC, Arlot ME, Duboeuf F, et al: Vitamin D3 and calcium to prevent hip fractures in elderly women. *N Engl J Med* 327(23):1637-1642, 1992.

In a randomized clinical trial in 3270 elderly women with average age of 84 years, supplementation with 1.2 g of calcium and 800 IU of

vitamin D₃ reduced the risk for both vertebral and nonvertebral fractures in the treated group.

3. Chesnut CH 3rd, Silverman S, Andriano K, et al: A randomized trial of nasal spray salmon calcitonin in postmenopausal women with established osteoporosis: The Prevent Recurrence of Osteoporotic Fractures Study. PROOF Study Group. *Am J Med* 109(4):267-276, 2000.

In a randomized clinical trial of intranasal salmon calcitonin in 1255 postmenopausal women with established osteoporosis using doses of 100, 200, and 400 IU daily, women receiving 200 IU had fewer new vertebral fractures than the control group.

4. Chesnut CH 3rd, Skag A, Christiansen C, et al: Effects of oral ibandronate administered daily or intermittently on fracture risk in postmenopausal osteoporosis. *J Bone Miner Res* 19(8):1241-1249, 2004.

Results of a randomized clinical trial of ibandronate in 2946 osteoporotic women with previous vertebral fractures showed a reduction in risk for new vertebral fractures compared with placebo. Nonvertebral fractures were not significantly reduced except in a higher risk subgroup with bone density T scores of less than 3.0.

5. Cummings SR, Black DM, Thompson DE, et al: Effect of alendronate on risk of fracture in women with low bone density but without vertebral fractures: Results from the Fracture Intervention Trial. *JAMA* 280(24):2077-2082, 1998.

In a randomized clinical trial with oral alendronate in 4432 women with low bone density but no previous vertebral fractures, more than 4 years of alendronate reduced fracture risk significantly in a subgroup of women with osteoporosis of the femoral neck (T score ≤ -2.5), but there was no significant reduction in women having higher bone density.

6. Ettinger B, Black DM, Mitlak BH, et al: Reduction of vertebral fracture risk in postmenopausal women with osteoporosis treated with raloxifene: Results from a 3-year randomized clinical trial. Multiple Outcomes of Raloxifene Evaluation (MORE) Investigators. *JAMA* 282(7):637-645, 1999.

In a randomized clinical trial of raloxifene in 7705 postmenopausal women who had osteoporosis according to World Health Organization Standards, treatment with raloxifene, 60 mg per day, significantly reduced the risk for vertebral but not nonvertebral fractures.

7. Harris ST, Watts NB, Genant HK, et al: Effects of risendronate treatment on vertebral and nonvertebral fractures in women with postmenopausal osteoporosis: A randomized controlled trial.

Vertebral Efficacy with Risedronate Therapy (VERT) Study Group. *JAMA* 282(14):1344-1352, 1999.

The authors report on a 3-year clinical trial with risedronate in 2458 postmenopausal women who had at least one vertebral fracture treated with oral risedronate or placebo. The treated group had a significant reduction in both vertebral and nonvertebral fractures.

8. Liberman UA, Weiss SR, Broll J, et al: Effect of oral alendronate on bone mineral density and the incidence of fractures in postmenopausal osteoporosis. The Alendronate Phase III Osteoporosis Treatment Study Group. *N Engl J Med* 333(22):1437-1443, 1995.

This report on the original trial with alendronate in 994 postmenopausal women with osteoporosis showed that reduction in the risk for new vertebral fractures as well as improvements in bone mineral density of the spine and hip.

9. McClung MR, Geusens P, Miller PD, et al: Effect of risedronate on the risk of hip fracture in elderly women. Hip Intervention Program Study Group. *N Engl J Med* 344(5):333-340, 2001.

This clinical trial of oral risedronate in 3886 women at least 80 years old showed reduction in hip fracture risk in a subset who had osteoporosis of the femoral neck (T score ≤ 3). There was no significant reduction of hip fracture with therapy in a subset who had higher bone mineral density.

10. Neer RM, Arnaud CD, Zanchetta JR, et al: Effect of parathyroid hormone (1-34) on fractures and bone mineral density in postmenopausal osteoporosis. *N Engl J Med* 344(19):1434-1441, 2001.

This report of a clinical trial with subcutaneous PTH (1-34) in 1637 postmenopausal women with prior vertebral fractures showed reduction in the risk for both vertebral and nonvertebral fractures in the treated group. The 20-μg dose reduced fractures as much as a 40-μg dose but had fewer side effects.

11. Rossouw JE, Anderson GL, Prentice RL, et al: Risks and benefits of estrogen plus progestin in healthy postmenopausal women: Principal results from the Women's Health Initiative randomized controlled trial. *JAMA* 288(3):321-333, 2002.

This article summarizes the overall results of an important clinical trial of estrogen replacement in 16,608 postmenopausal women with an intact uterus. Treatment with 0.6 mg conjugated estrogens plus 2.5 mg medroxyprogesterone daily for 5.2 years significantly reduced hip fractures but not the occurrence of cardiovascular events or all-cause mortality.

Paget's Disease of Bone

Introduction

Paget's disease of bone, also known as *osteitis deformans*, is a disorder of accelerated bone turnover. It is characterized by abnormal osteoclast activity that results in increased bone breakdown. Because bone formation and resorption are coupled, there is a concomitant increase in bone formation. However, the new bone that is laid down is abnormal in its organization. Bone biopsy specimens demonstrate loss of the usual lamellar structure that is important for bone strength. As a result, the bone is weakened, with an abnormal bone remodeling surface.

The incidence and prevalence of Paget's disease are difficult to estimate because the disease is largely asymptomatic. Autopsy and radiologic series have found the prevalence to be 3% to 3.7% of patients older than 55 years. Overall, it appears to be a disease of individuals of Anglo-Saxon descent and is much less common in Asian individuals. Nearly all those affected present at a later age, usually older than 40 years. Some series report a male predominance, whereas others suggest that males are equally as affected as females.

Etiology and Pathogenesis

The exact etiology is unknown. Microscopically, osteoclasts are structurally abnormal, of increased size, and found in increased number. They have multinucleated structures with inclusion bodies similar to nucleocapsids found in paramyxoviruses such as measles, respiratory syncytial virus, and canine distemper virus. It has been postulated, but not definitively proved, that Paget's disease results from a viral infection. The involved osteoclasts appear to have an increased sensitivity to substances that alter osteoclast activity, such as 1,25-dihydroxyvitamin D (calcitriol) and RANK-ligand, an important signaling protein secreted by osteoblasts to control osteoclast activity (Fig. 49-1).

Paget's disease may also have a genetic predisposition. It has been reported that 15% to 40% of patients have an affected first-degree relative. Heterozygous mutations of at least two genes have been documented in Paget's disease. A susceptibility gene on the long arm of chromosome 18 has recently been identified in at least one study. This was discovered after an abnormality at a different location on the same chromosome was identified in familial expansile osteolysis, a rare disorder in which osteoclasts also have paramyxovirus-like inclusions. Possibly, viral infection ini-

tiates abnormal osteoclast activity and the onset of Paget's disease in individuals with a genetic susceptibility.

Clinical Presentation

Most individuals with Paget's disease of bone are asymptomatic. Often, it is incidentally diagnosed after serum alkaline phosphatase levels are obtained or plain radiographs are performed for unrelated reasons. It predominantly affects the calvarium and axial skeleton, most often involving vertebral bodies, pelvis, and long bones. It can occur in a monostotic form, with a single site affected. However, most patients have polyostotic disease with multiple sites involved (Fig. 49-2). Only 5% of individuals present with bone pain, often described as a dull or persistent ache exacerbated by activity. However, pain is not a good indicator of extent of disease. In one study, only 30% of 863 sites of disease caused symptoms in 170 patients. Bone pain may result from irritation of the periosteum, increased vascularity in affected bone, or mechanical stress with microfractures. There may be warmth at the site of involvement with Paget's disease. Pain in or near a joint may reflect underlying osteoarthritic changes such as osteophyte formation due to the presence of Paget's disease

Figure 49-1 Pathophysiology and Treatment of Paget's Disease of Bone.

Electron-microscopic view of multinucleated osteoclast with nuclear inclusions that may be viruses (arrows). N, nuclei; C, cytoplasm

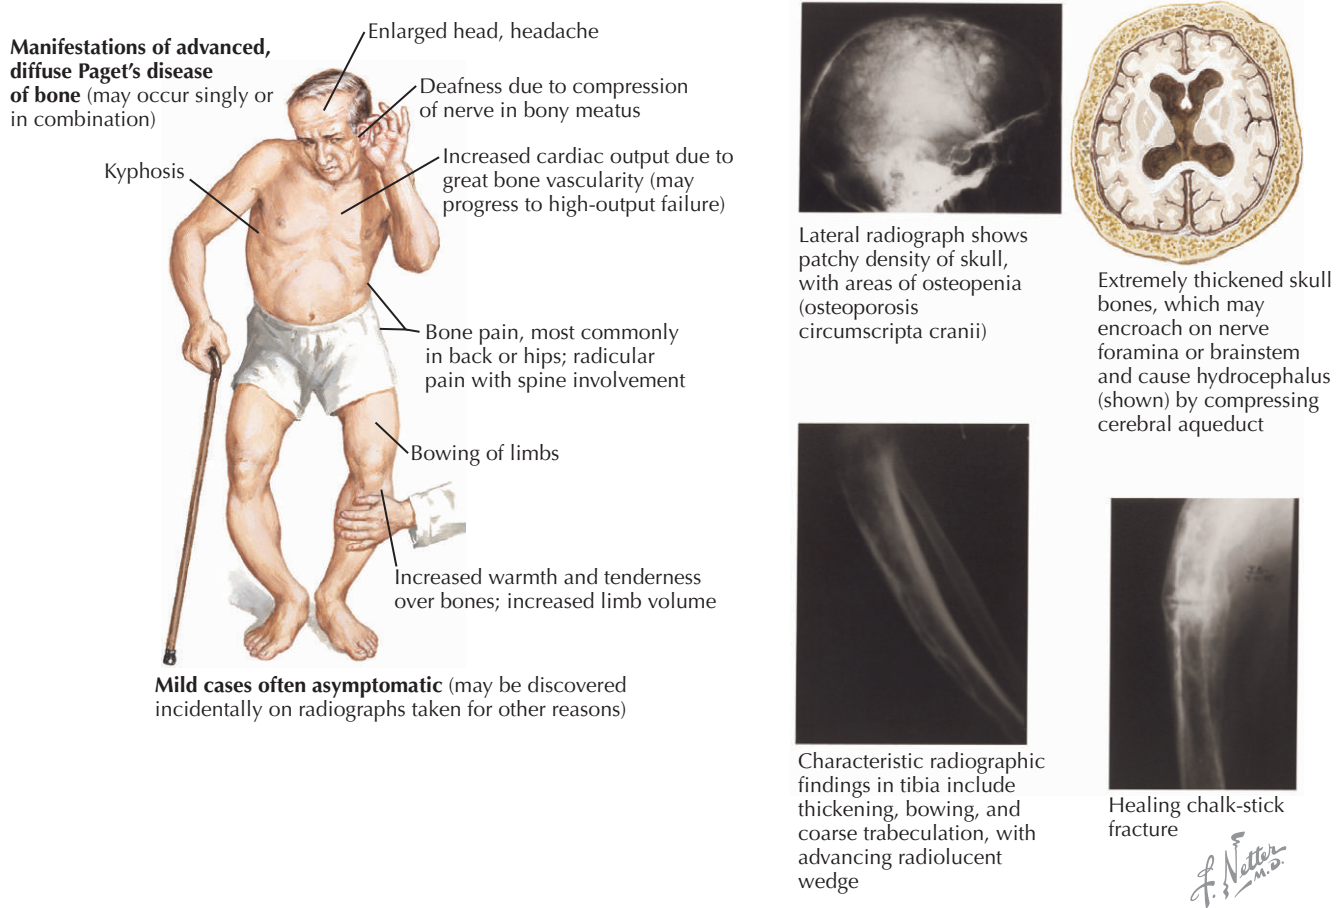

F. Netter M.D.

in the adjoining long bone, which may deteriorate cartilage and alter the joint surface. Significant joint deformities can occur with bowing of the lower extremities as well as abnormal facial structures such as frontal bossing. Fractures are a common complication in weight-bearing bones as a result of disorganized bone structure. Neurologic compromise is a concerning complication. Involvement of the vertebral column can result in spinal cord or peripheral nerve root compression. Cranial nerves, particularly ocular and auditory nerves, can be affected as a result of skull deformities. Hearing loss has been reported in up to 37% of individuals and may also be due to acquired bony abnor-

malities in the cochlea. Rarely, hydrocephalus results from deformities at the skull base. With active, widespread disease, high-output congestive heart failure may be caused by increased vascularity of the bone remodeling surface. A rare but dreaded complication is the development of osteosarcoma, which is estimated to occur in less than 1% of patients with long-standing disease.

Differential Diagnosis

Other conditions that can present with bone pain, lytic lesions, and elevated alkaline phosphatase levels include

Figure 49-2 Paget's Disease of Bone.

malignancies, primary or metastatic disease, and infiltrative diseases such as infections and sarcoidosis. With widespread involvement, it can be difficult to distinguish Paget's disease from an underlying malignancy. Usually, the underlying malignancy is more obvious on clinical examination, and the bone metastases are a later complication. Paget's disease is much more likely if previous radiographs demonstrate relative stability of the lesions over time. A distinguishing radiologic feature of Paget's disease is the increase in the diameter of the affected bones, which remains unchanged in infiltrating or metastatic diseases. An isolated pagetic focus in a vertebral body may resemble vertebral hemangiomas or compression fractures. Unfortunately, bone scans do not distinguish among these conditions. Biochemical findings, such as anemia, hypoalbuminemia, or hypercalcemia, may suggest other underlying disorders. Paget's disease may cause hypercalcemia but only with prolonged immobilization or recent fracture. Although characteristic radiographic features exist, the diagnosis of Paget's disease is not always clear, and a search for an underlying malignancy or other disorder may need

to be pursued, including obtaining a bone biopsy specimen in some instances.

Diagnostic Approach

A diagnosis of Paget's disease is often made based on characteristic findings on plain radiographs. Early in the disease, lytic lesions predominate, reflecting increased areas of osteoclast resorption. They are characterized by flame or V-shaped resorption fronts on long bones, or isolated lytic lesions in the skull (also known as *osteoporosis circumscripta*). As the disease progresses, cortical thickening and sclerotic areas result from excessive bone formation from increased osteoblast activity. Bone scans demonstrate increased activity at the involved sites. The extent of the disease varies among individuals. Radiologic identification of sites of involvement is important to document the extent of the disease and to identify asymptomatic lesions located in fracture-prone sites that may require treatment. Although the disease may progress with advancing resorption fronts

in a particular bone, there is usually not extensive spread to new bones after the initial diagnosis is made.

On laboratory examination, a significantly elevated alkaline phosphatase level occurs in about 95% of individuals. Baseline values are often greater than 3 times the upper limit of normal. However, monostotic or isolated Paget's disease may have a normal alkaline phosphatase level. The sensitivity of bone-specific alkaline phosphatase is slightly better than that of total alkaline phosphatase. The level of alkaline phosphatase usually correlates with disease activity if followed over time in a single individual. Serum levels of calcium, phosphate, parathyroid hormone, and vitamin D metabolites are usually normal. Hypercalcemia only occurs when the rates of bone formation decrease while the rate of bone resorption remains high, such as during prolonged immobilization or recent fracture. Bone turnover markers or collagen breakdown products, such as urinary *N*-telopeptides and deoxypyridinoline, are consistently elevated in active, extensive Paget's disease. However, these markers are not specific and have wide intrinsic variability, making their use difficult in treatment of patients. Other markers of osteoblast function, such as osteocalcin, are not helpful in the diagnosis or management of Paget's disease.

Management and Therapy

Optimum Treatment

Treatment of Paget's disease has significantly improved since the availability of potent oral bisphosphonates. Multiple studies have demonstrated an improvement in symptoms, notably bone pain, and a reduction in alkaline phosphatase and other bone turnover markers. Bisphosphonates have been shown to restore normal bone structure on bone biopsy specimens. However, there are no prospective long-term data that demonstrate prevention of future complications after treatment is initiated, and therefore treatment recommendations are often guided by clinical experience or expert consensus panels due to the paucity of randomized long-term clinical trials. Mild disease with isolated involvement in a location unlikely to cause complications, such as the scapula or pelvis, may not need to be treated. Short-term treatment with bisphosphonates or calcitonin may be indicated before orthopedic procedures to prevent excessive blood loss resulting from the hypervascularity of bone. The most common indications for therapy are bone pain, involvement of fracture-prone sites (weight-bearing bones, vertebral bodies), periarticular bone lesions, extensive skull involvement, prior orthopedic procedures, and prolonged immobilization.

Bisphosphonates are pyrophosphate analogs that decrease bone resorption rates by decreasing osteoclast activity and that make the hydroxyapatite structure of the bone matrix less susceptible to resorption. Several preparations are available and are generally given in 3- to 6-month cycles every 1 to 2 years or 1 to 2 months before elective

surgery. Etidronate, the initial drug available, is less potent than newer agents and has been associated with osteomalacia when used at higher doses. Tiludronate, alendronate, and risedronate, potent oral bisphosphonates, are also approved by the U.S. Food and Drug Administration (FDA) for the treatment of Paget's disease (400 mg orally once daily, 40 mg orally once daily, and 30 mg orally once daily, respectively). One randomized controlled clinical trial of 89 patients comparing alendronate (40 mg once daily) and etidronate (400 mg once daily) for 6 months demonstrated a normalization of alkaline phosphatase in 63% of patients taking alendronate compared with only 17% taking etidronate. There were significant decreases in urinary bone turnover markers as well as improvements in pain and functional scores on alendronate. A follow-up extension study showed that 52% still had normal alkaline phosphatase levels 25 to 30 months after treatment ended. Radiographic evidence of improvement has varied, with some studies demonstrating regression of bone resorption fronts, but others not showing a significant change. Similar improvements in bone turnover markers are seen with either risedronate or alendronate. Pamidronate is highly effective but must be given in intravenous (IV) form. Dosing has varied from 60 mg given as a single infusion for mild disease to 20 to 60 mg given IV every 3 to 6 months. A randomized controlled study reported that zoledronate (5 mg IV) given as a single infusion reduced bone turnover for the 2-year duration of the trial, which appeared to be more sustained than an oral regimen of risedronate (30 mg once daily for 60 days).

Calcitonin is approved by the FDA in both salmon and human subcutaneous forms for the treatment of Paget's disease. However, bisphosphonates have superior efficacy in inducing and maintaining a remission, which has relegated calcitonin to second-line therapy if bisphosphonates are not tolerated. Calcitonin has a role in perioperative management because it is fast acting and effective for decreasing blood loss during surgery. Other treatment options have included gallium and plicamycin, although they are rarely used today. Often, analgesics and joint replacement surgery need to be considered to treat the associated osteoarthritic changes.

The general goal of treatment is to normalize alkaline phosphatase levels and decrease pain. Serum levels are often measured every 4 to 6 months. An additional treatment course should be considered when the alkaline phosphatase level has increased more than 25% of that achieved after the initial treatment. Bone turnover markers, such as urinary *N*-telopeptides, may respond earlier than alkaline phosphatase to bisphosphonate therapy. A single 3- to 6-month course of a bisphosphonate can induce a remission for 1 to 2 years or longer. Plain radiographs show changes over time, but they do not always correlate with alkaline phosphatase levels or symptomatic improvement. Bone scans are more reliable for following changes, although radiation exposure and expense limit their use. Although

uncontrolled studies suggest there are decreased fracture rates, there is no solid proof that treating individuals will prevent future complications.

Avoiding Treatment Errors

It is important to distinguish radiologic changes associated with Paget's disease from lytic lesions associated with malignant or infiltrating conditions, as discussed under "Differential Diagnosis." An experienced radiologist is instrumental in this regard.

Future Directions

Patients can become less responsive to a single bisphosphonate after successive treatment courses. At least one study suggests, however, that these patients may retain responsiveness when changed to a different bisphosphonate. Combination therapy may prove to be a more effective strategy in the future. Newer, more potent bisphosphonates continue to be developed and may prove even more efficacious for the treatment of Paget's disease of bone. The PRISM (Paget's Disease: A Randomised Trial of Intensive vs. Symptomatic Management) trial is an ongoing United Kingdom multicenter trial comparing treatment strategies for Paget's disease and their impact on clinically relevant outcomes; these forthcoming data may alter management strategies.

Gastroesophageal Reflux Disease

Introduction

Gastroesophageal reflux disease (GERD) is one of the most common disorders encountered in medical practice. Almost half of Americans suffer heartburn symptoms at least once a month, and greater than 10% experience heartburn weekly. Once considered a nuisance problem, GERD is now associated with several serious conditions, including esophageal strictures, asthma, and esophageal adenocarcinoma. The toll of reflux on quality of life can be substantial. Patients with GERD sometimes rate their quality of life as worse than those with severe chronic diseases such as angina and mild heart failure. For these reasons, clinicians should be aggressive in the management of this disease.

Etiology and Pathogenesis

The pathophysiology of GERD is complex and multifactorial. The body has developed an elegant system of defense mechanisms that allows it to keep gastric acid with a pH of 1 to 2 in proximity to sensitive esophageal tissues. Even minor perturbations of this defense may result in acid injury from reflux.

To a minor degree, reflux occurs in most individuals. However, small amounts of acid refluxate are usually neutralized by salivary secretions and propelled back into the stomach by peristalsis. In GERD, several deficiencies in this defense system are often present. Patients with severe GERD, on average, have decreased lower esophageal sphincter (LES) pressure compared with normal subjects, although there is much overlap between normal subjects and those with reflux. Perhaps more importantly, these subjects have an increased number of transient LES relaxations. Although these short periods of sphincter relaxation occur in normal individuals as well, those with reflux appear to have them more commonly and also have a higher incidence of reflux during the relaxations. Hiatal hernia, or displacement of the stomach through the hiatus so that part of the stomach is in the chest, occurs commonly in those with GERD, impairing the efficiency of the LES. Some patients demonstrate impaired peristalsis, decreasing their ability to propel the refluxate back into

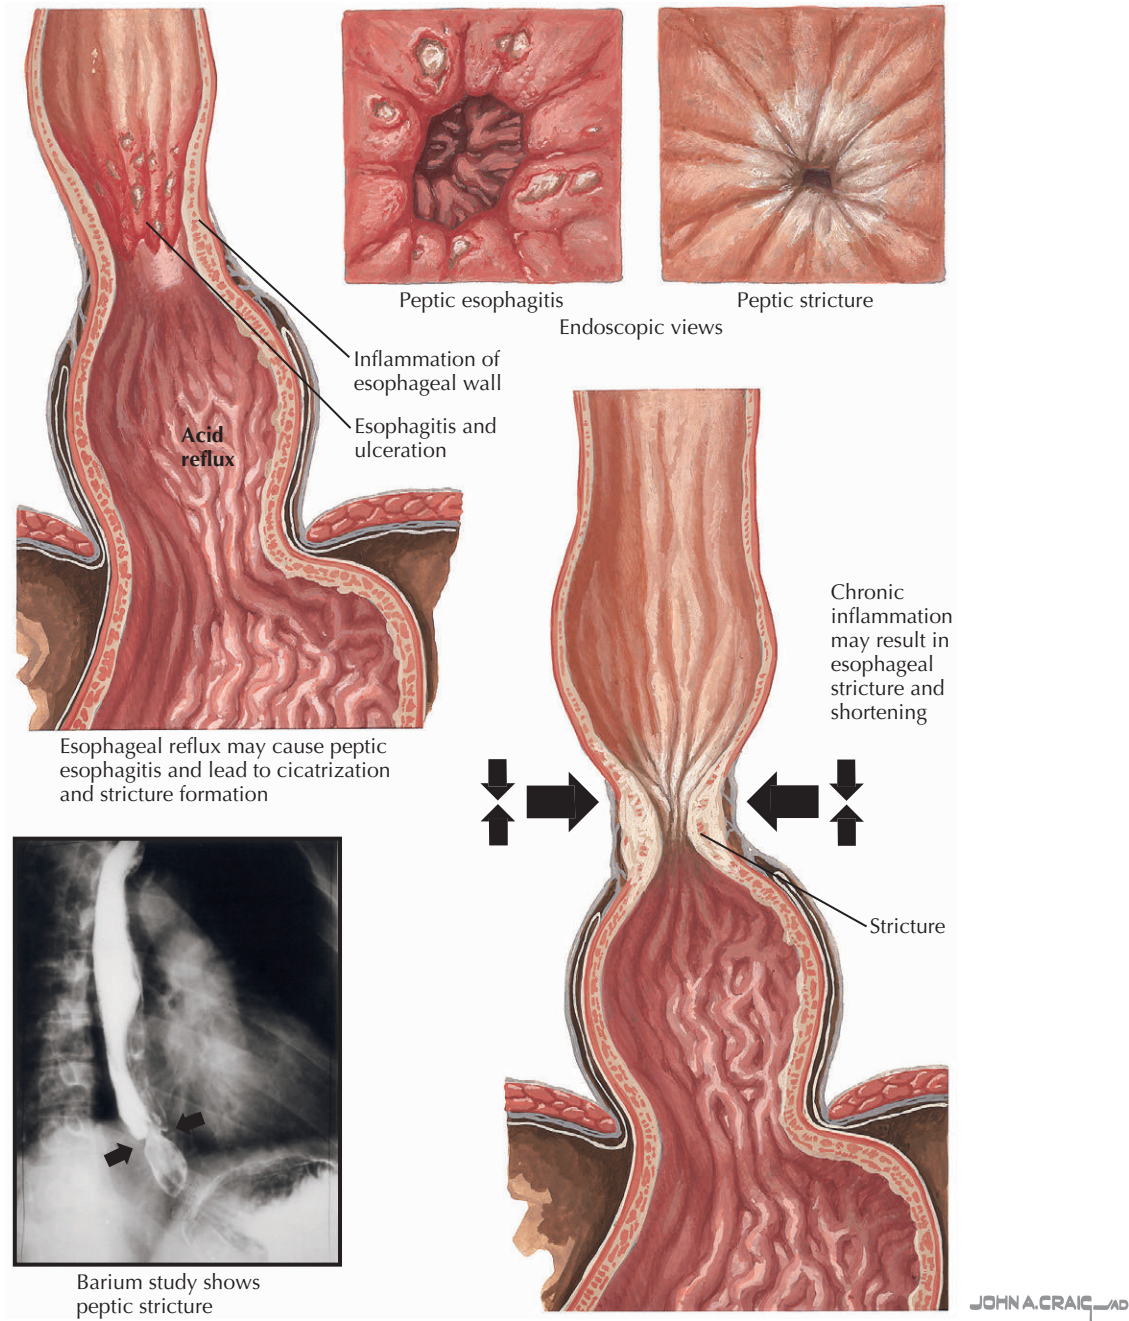

the stomach. Other mechanisms, such as differences in the potency and composition of the refluxate, are postulated but are less well understood.

Some manifestations of GERD, including esophagitis, esophageal peptic strictures, and Barrett's esophagus, occur only in those with the most severe disease (Fig. 50-1). Esophagitis is the breakdown of mucosal tissue, so that erosions, exudates, and ulcers replace the normal squamous epithelium. Esophageal peptic stricture, or narrowing of the esophagus secondary to chronic acid exposure, sometimes requires endoscopic dilation and, rarely, surgery. Barrett's esophagus is a metaplastic change of the lining of the esophagus so that it switches from its normal squamous epithelium to a columnar epithelium with goblet cells. It appears that chronic acid exposure is a necessary prerequisite in the pathogenesis. However, because many subjects with severe GERD never develop Barrett's esophagus, other poorly understood host factors must also play a role.

Clinical Presentation

Heartburn, or substernal chest burning, is the most common clinical presentation of GERD (Fig. 50-2). This sensation is often worse when recumbent or after a large meal. Regurgitation of food, water brash (a filling of the

Figure 50-1 Complications of Peptic Reflux (Esophagitis and Stricture).

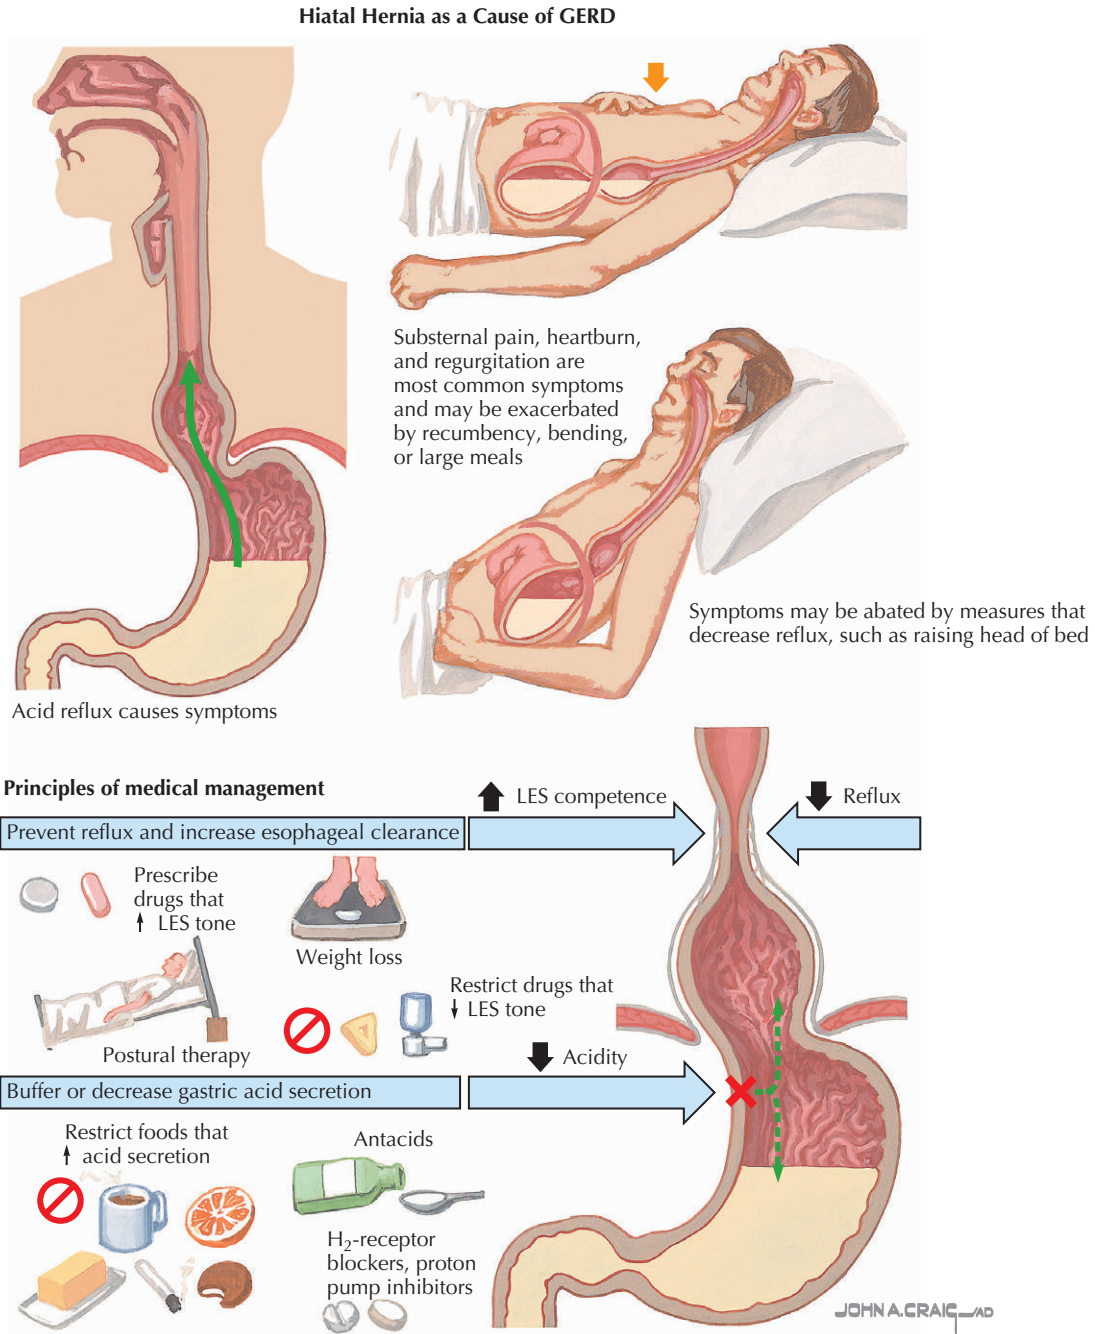

mouth with saliva), dysphagia (difficulty swallowing), odynophagia (pain with swallowing), and chest pain are also common.

Recently, there has been an increased appreciation for the extraesophageal manifestations of reflux. GERD may cause a variety of pulmonary and ear, nose, and throat conditions, including asthma, bronchitis, chronic cough, halitosis, hoarseness, pulmonary fibrosis, aspiration pneumonia, and erosion of the dental enamel.

Differential Diagnosis

The presentation of GERD can be similar to many other conditions. Patients with heart disease may describe their chest pain as “burning.” Among those complaining of chest pain, it is essential to rule out cardiac disease, especially in high-risk subgroups. Dysphagia is associated with esophageal cancer and esophageal strictures. The extraesophageal symptoms of GERD may be especially

Figure 50-2 Symptoms and Medical Management of GERD.

hard to recognize. GERD-induced asthma is a commonly missed diagnosis and should be considered in patients who do not respond as expected to therapies directed at asthma.

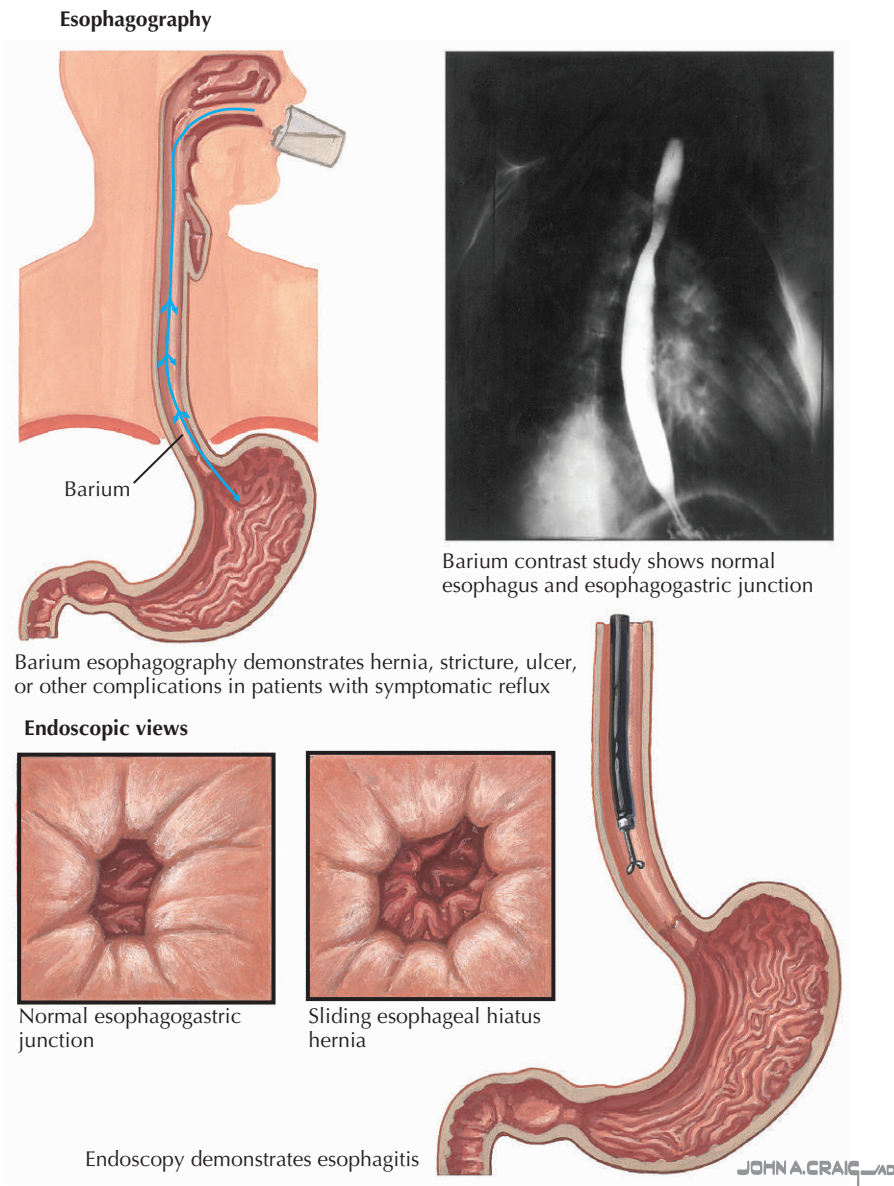

Diagnostic Approach

Most individuals with classic reflux symptoms do not require further diagnostic workup beyond a good history and physical examination (see Fig. 50-2). In these patients, an empiric trial of antacid therapy may be used as both a

diagnostic and therapeutic measure. Appropriate response to therapy confirms the diagnosis and obviates further workup.

Invasive workup in reflux disease is generally reserved for three categories of patients: those with alarm symptoms (dysphagia, weight loss, bleeding, and anemia); those with uncommon or unclear presentations, in whom the diagnosis is uncertain; and those who do not demonstrate the expected clinical response to therapy.

Several tests are available to evaluate symptoms (Fig. 50-3). Upper endoscopy is a sensitive test for assessing

Figure 50-3 Diagnostic Techniques.

mucosal damage and detecting strictures and cancers. Normal results of upper endoscopy do not rule out GERD because many patients have nonerosive reflux disease. The 24-hour pH probe is a small tube placed through the nares into the esophagus. It continually monitors and electronically records esophageal acid, allowing the clinician to note the extent of reflux, how high up the esophagus the reflux travels, and the relation of reflux episodes to other symptoms such as coughing or wheezing. Esophageal manometry assesses the contractions of the esophagus and the function of the LES. Because many patients have normal esophageal motility, it is not sensitive for reflux. Barium radiographs are excellent for identifying the presence and

extent of esophageal strictures or cancer but are not sensitive or specific for the presence of reflux. Other tests, such as the Bernstein acid perfusion test, scintigraphy, and esophageal impedance studies, either lack specificity or are not commonly available.

Some authorities advocate a once-in-a-lifetime upper endoscopy for those with chronic reflux symptoms, both to screen for adenocarcinoma and to identify those with Barrett's esophagus who might then be enrolled in endoscopic surveillance programs to identify any resultant cancer at an early and potentially curable stage. Neither the efficacy nor cost effectiveness of such a screening endoscopy has been substantiated.

Management and Therapy

Optimum Treatment

The goal of management is complete relief of symptoms and prevention of complications. Given the armamentarium of medical and surgical therapies available, this goal is achievable in most patients. Optimum treatment depends on the severity of the disease and the patient's response to therapy. Generally, therapy commences with conservative measures, is escalated through pharmacologic therapy if necessary, and proceeds to surgical therapy in a small number of severely afflicted patients.

Conservative Therapy

Some GERD patients may respond to simple dietary and lifestyle modifications (see Fig. 50-2). Elevating the head of the bed, preferably on blocks, is a simple measure that is especially effective in those with nighttime symptoms. Weight loss reduces intra-abdominal pressure and may reduce symptoms. Avoidance of late-night meals gives the stomach adequate time to empty before recumbency. Smoking decreases LES pressure, and smoking cessation may improve symptoms. Caffeine, fatty foods, and alcohol may all decrease LES pressure, and limited intake of these items is recommended.

Pharmacologic Therapy

For those with very occasional GERD symptoms precipitated by dietary indiscretion, self-medication with either antacids or over-the-counter H₂-receptor antagonists appears to be safe and is widely practiced. Patients with severe or frequent symptoms require more intensive therapy. Both H₂-receptor antagonists, such as cimetidine, ranitidine, famotidine, and nizatidine, and proton pump inhibitors, such as omeprazole, pantoprazole, rabeprazole, lansoprazole, and esomeprazole, may provide symptomatic relief. The proton pump inhibitors are more effective at decreasing acid production than the H₂-receptor antagonists, but are more expensive. Some authorities have advocated a step-up approach to therapy with these agents; the clinician starts by treating with an H₂-receptor antagonist and steps up therapy to a proton pump inhibitor only in patients unresponsive to the H₂-receptor antagonist. Others advocate a step-down approach, so that therapy is initiated with a proton pump inhibitor to achieve symptom control, and then the patient is stepped down to the lowest level of acid inhibition that still provides good symptom control. No matter which strategy is adopted, it is important to assess symptom response shortly after the initiation of therapy and to adjust the medication regimen appropriately.

It is rare that patients do not achieve good symptom control with standard doses of proton pump inhibitors. In these situations, the dose of the proton pump inhibitor

may be increased to twice a day. If the patient continues to be unresponsive, the clinician should question the diagnosis and consider further workup. If twice-a-day proton pump inhibitors do not control GERD, the addition of a nighttime H₂-receptor antagonist to the two doses of proton pump inhibitor or a third dose of proton pump inhibitor may help. Use of a promotility agent in addition to the anti-acid regimen is reasonable. Unfortunately, few agents are available. Use of metoclopramide is limited. Cisapride is also effective, but safety concerns have curtailed its use and availability. Other promotility agents may soon be available. Sucralfate, a mucosal coating agent, may be used either alone or in combination with acid inhibition, but its frequent dosing interval and efficacy make it a less commonly used drug in reflux.

Surgical Therapy

A surgical antireflux procedure for control of symptoms warrants consideration in patients who require chronic pharmacologic therapy, especially high-dose proton pump inhibition. Laparoscopic Nissen fundoplication is the most common antireflux surgical procedure performed in the United States. The recovery time is short, and the procedure is generally well tolerated. Studies indicate that most patients obtain symptom relief and are not taking antireflux medications at 2 years. Long-term outcomes are less clear; data suggest that operator experience and appropriate patient selection are key to improving outcomes.

Multiple endoscopic antireflux devices have been developed to attempt to change the anatomy of the hiatus without a surgical intervention. These include devices that form a plication at the gastroesophageal junction and that apply energy to the submucosal tissue to cause thickening of the area of the LES. The long-term utility of these devices remains unclear.

Avoiding Treatment Errors

Duration of therapy is a commonly overlooked issue in reflux disease. GERD is a chronic condition often requiring chronic therapy. In the subgroup of patients with erosive esophagitis, most of those healed with medication have recurrence of their esophagitis if taken off therapy. In these patients, symptom control after initial treatment may be maintained with less intensive therapy. For instance, a patient initially requiring proton pump inhibitors to heal erosive esophagitis may remain symptom- and disease-free on H₂-receptor antagonists. However, healing of erosive esophagitis does not always ensure complete symptom relief, and patients may still require aggressive acid suppression to maintain symptom control.

Future Directions

Several avenues hold promise for improving care of patients with reflux. Several new promotility agents are

under development and are likely to be useful in GERD. Endoscopic alterations of the anatomy offer the chance to improve symptoms without subjecting the patient to surgery. Better treatments for the complications of reflux, such as strictures and Barrett's esophagus, may decrease the number of subjects who suffer the most severe manifestations of this disease. Finally, objective analysis of our practices in caring for the reflux patient should allow us to recognize the most cost-effective approaches to therapy.

This systematic review reports that the therapeutic gain of proton pump inhibitors for heartburn resolution is lower in nonerosive reflux disease than in erosive disease.

2. DeVault KR, Castell DO: Updated guidelines for the diagnosis and treatment of gastroesophageal reflux disease. *Am J Gastroenterol* 100(1):190-200, 2005.

This excellent guideline critically reviews the level of evidence for various strategies for diagnosis and management of GERD.

3. Fass R, Fennerty MB, Ofman JJ, et al: The clinical and economic value of a short course of omeprazole in patients with noncardiac chest pain. *Gastroenterology* 115(1):42-49, 1998.

The empiric "omeprazole test" for noncardiac chest pain is shown to be an accurate noninvasive method for diagnosing GERD in these patients.

4. Spechler SJ, Lee E, Ahnen D, et al: Long-term outcome of medical and surgical therapies for gastroesophageal reflux disease: Follow-up of a randomized controlled trial. *JAMA* 285(18):2331-2338, 2001.

This investigation reveals that 62% of patients who underwent open fundoplication for treatment of GERD in a randomized controlled trial had resumed taking antireflux medications after a mean of 9 years.

Peptic Ulcer Disease

Introduction

Peptic ulcers are gastrointestinal mucosal defects that extend through the muscularis mucosa that can be symptomatic or asymptomatic. Peptic ulcer disease (PUD) is associated with significant morbidity and expenditures related to work loss, hospitalizations, and outpatient care (excluding medications) of more than \$5 billion per year in the United States. Major advances have been made in the past two decades with the etiologic linkage of *Helicobacter pylori* to PUD and the development of more effective medical therapies. However, despite advances in diagnosis and therapy, the prevalence of PUD remains unaltered, and the cumulative mortality rate in complicated ulcer disease remains significant.

The estimated worldwide lifetime incidence of PUD is 5% to 10%. These estimates double in those harboring *H. pylori* infection. The incidence of PUD increases with age for two major reasons in developed nations. First, the incidence of *H. pylori* infection is decreasing in people younger than 40 years, primarily as a result of improved socioeconomic conditions. Despite this, about 75% of duodenal ulcers and 75% of gastric ulcers not caused by nonsteroidal anti-inflammatory drugs (NSAIDs) are a result of *H. pylori*. The second leading cause of peptic ulcers, the use of NSAIDs, increases with age. NSAID use is an independent predictor of experiencing a gastrointestinal complication such as peptic ulcer disease.

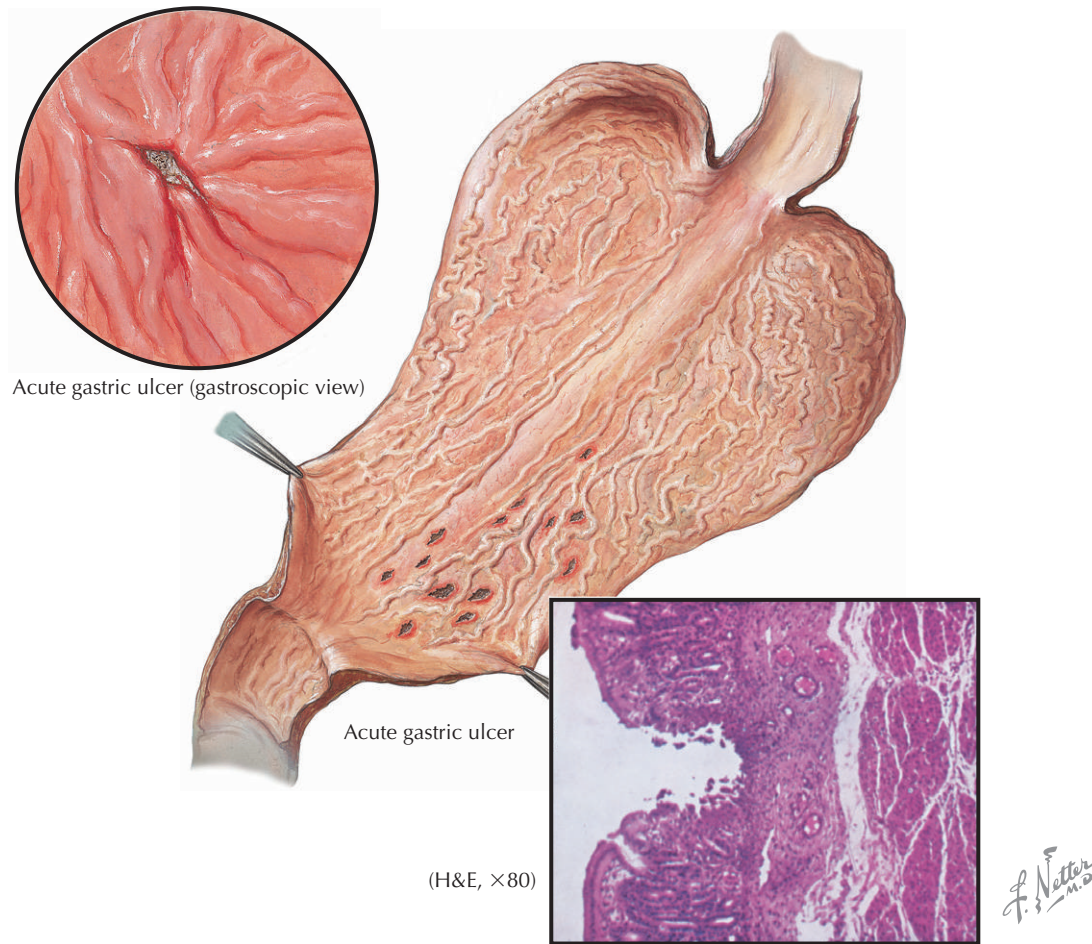

Etiology and Pathogenesis

Although *H. pylori* infection and NSAID use account for most cases of PUD, there are important, less common causes, including hypersecretory states, stress ulcers, neoplasia, and idiopathic ulcers. Cigarette smoking can increase the risk for relapse and delay healing. Corticosteroid use is a risk factor for PUD, but only when used in combination with NSAIDs.

More than half of the world's population is infected with *H. pylori*, most with a mild infection and without clinical manifestations. *H. pylori* infection can result in either or both peptic ulcers and gastric cancer. The interaction between host factors (e.g., genetic), *H. pylori* virulence factors (particularly cytotoxin-associated gene A), and other environmental factors (e.g., diet) drives a subset of patients either to an antral predominant gastritis, the ulcer pathway, or a corpus predominant gastritis, the gastric cancer pathway. In antral gastritis, there is an inhibition of somatostatin and increased gastrin production. These two hormonal alterations cause parietal cells to increase secretion of acid in the gastric body. The increased acid secretion creates an increased duodenal acid load and may contribute

to gastric metaplasia in the duodenal bulb, with possible *H. pylori* colonization. This explains, in part, the paradoxical observation that *H. pylori* causes duodenal ulceration but is generally not resident in normal duodenal epithelium.

NSAID use is the second most important etiologic factor in PUD in this country. With the aging of the American population and the ready availability of these agents over the counter, NSAID-induced gastrointestinal toxicity has risen in incidence during the past 3 decades. The U.S. Food and Drug Administration approximates the risk for a clinically significant gastrointestinal event, including perforations, ulcerations, or bleeding, to be 1% to 4% per year for the nonselective class of NSAIDs. The mechanisms by which NSAIDs cause ulceration involve both direct topical injury and systemic effects mediated by endogenous prostaglandins. NSAID use induces changes in the local mucosal blood flow of the stomach and duodenum. These changes impede repair of damaged mucosa. Also, traditional NSAIDs inhibit both the cyclooxygenase (COX-1 and COX-2) isoenzymes. Although inhibition of the COX-2 isoenzyme leads to the anti-inflammatory effects that provide the NSAIDs beneficial effects, inhibition of the COX-1 isoenzyme causes an impaired response

Figure 51-1 Peptic Ulcer Disease: Acute Gastric Ulcers.

to mucosal damage. Because the COX-1 isoenzyme is involved in multiple housekeeping functions, such as hemostasis and protection of the gastric mucosa, inhibition of this enzyme is thought to be responsible for most of the mucosal toxicity of NSAIDs. Nearly 100% of people ingesting NSAIDs have endoscopic evidence of erosions. However, symptoms of clinically important ulcers develop in only a minority of these individuals (Fig. 51-1).

Clinical Presentation

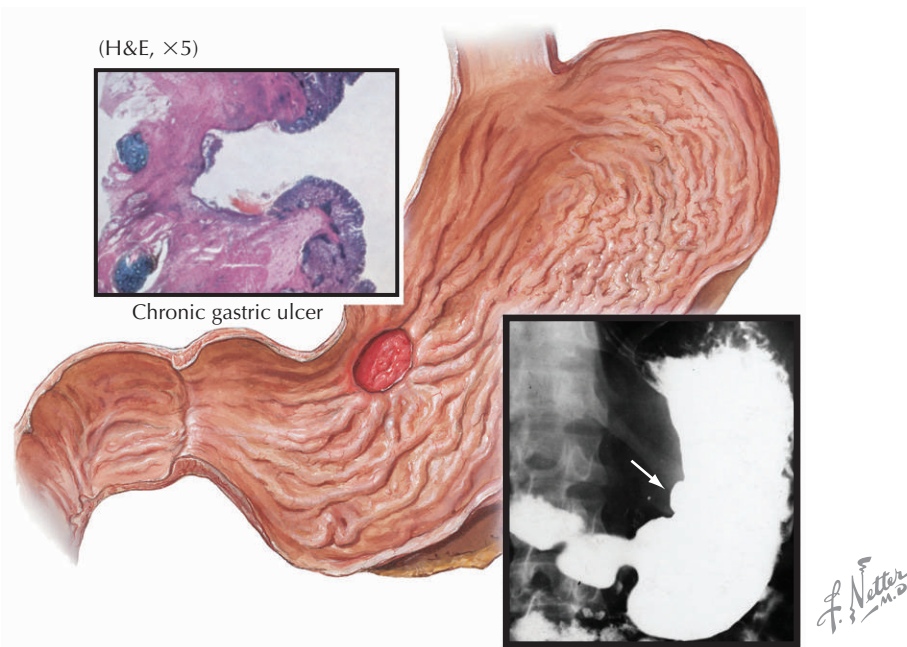

The most common presenting complaint in patients with PUD is dyspepsia. Classic teaching suggests that duodenal ulcers characteristically present with symptoms of burning hunger-type pain that occurs 2 to 3 hours after eating or awakening a patient from sleep and is relieved with antacids. These symptoms lack sensitivity and specificity: the presence of symptoms does not reliably predict ulcers, nor does the absence of symptoms exclude disease (Fig. 51-2). Patients may present with symptoms of a complication of PUD, such as bleeding (hematemesis, melena), perforation with peritonitis, or gastric outlet obstruction from pyloric channel edema (Fig. 51-3). Rarely, patients may present

with syncope or angina secondary to previously undetected blood loss. Some subjects with PUD, especially those taking NSAIDs, may have no symptoms from the disease.

The clinical signs of PUD are often subtle. Vital signs are usually normal unless significant hemorrhage has occurred. Pain on palpation of the mid or right epigastrium is common, but not diagnostic. Stool test results for fecal occult blood may be positive but are neither sensitive nor specific for PUD.

Differential Diagnosis

An accurate history is essential to discriminate between common and uncommon disorders that imitate PUD. With a detailed history and minimal testing, conditions such as gastroesophageal reflux, gastric adenocarcinoma, biliary tract disease, and pancreatic disease can be excluded. Functional or nonulcer dyspepsia is the most common cause of epigastric pain. This poorly understood entity likely represents several different pathophysiologic processes, only some of which are acid peptic in nature. Functional dyspepsia and irritable bowel syndrome are the most common functional gastrointestinal disorders.

Figure 51-2 Peptic Ulcer Disease: Chronic Gastric Ulcers.

Diagnostic Approach

Older patients presenting with abdominal pain or any patient with alarm symptoms (early satiety, weight loss, bleeding, anemia) should undergo endoscopy for exclusion of gastric adenocarcinoma. In patients younger than 45 years without alarm symptoms, a test-and-treat strategy may be pursued. To test and treat, one obtains a noninvasive measure of *H. pylori* infection such as a serum or breath test and treats to eradicate the organism if it is present.

Endoscopy is the gold standard for the evaluation of PUD (Fig. 51-4). It allows detection of ulcer disease with accuracy and permits biopsy, to exclude carcinoma as well as confirm infection with *H. pylori* by histology or rapid urease testing (e.g., CLOtest). The margins of all gastric ulcers should be examined and undergo biopsy to exclude malignancy.

Upper gastrointestinal radiography for the diagnosis of PUD is largely of historical interest but is an acceptable substitute in areas where endoscopy is not available. Although certain radiographic features suggest benign or malignant disease, the test has insufficient accuracy to rule out malignancy as a cause of ulceration, especially in the case of gastric ulcers.

Management and Therapy

Optimum Treatment

The goals of treatment are fourfold: relief of symptoms, ulcer healing, prevention of complications, and decreasing the risk for recurrent ulceration. Repeat endoscopy has been advocated for gastric ulcer diseases to document

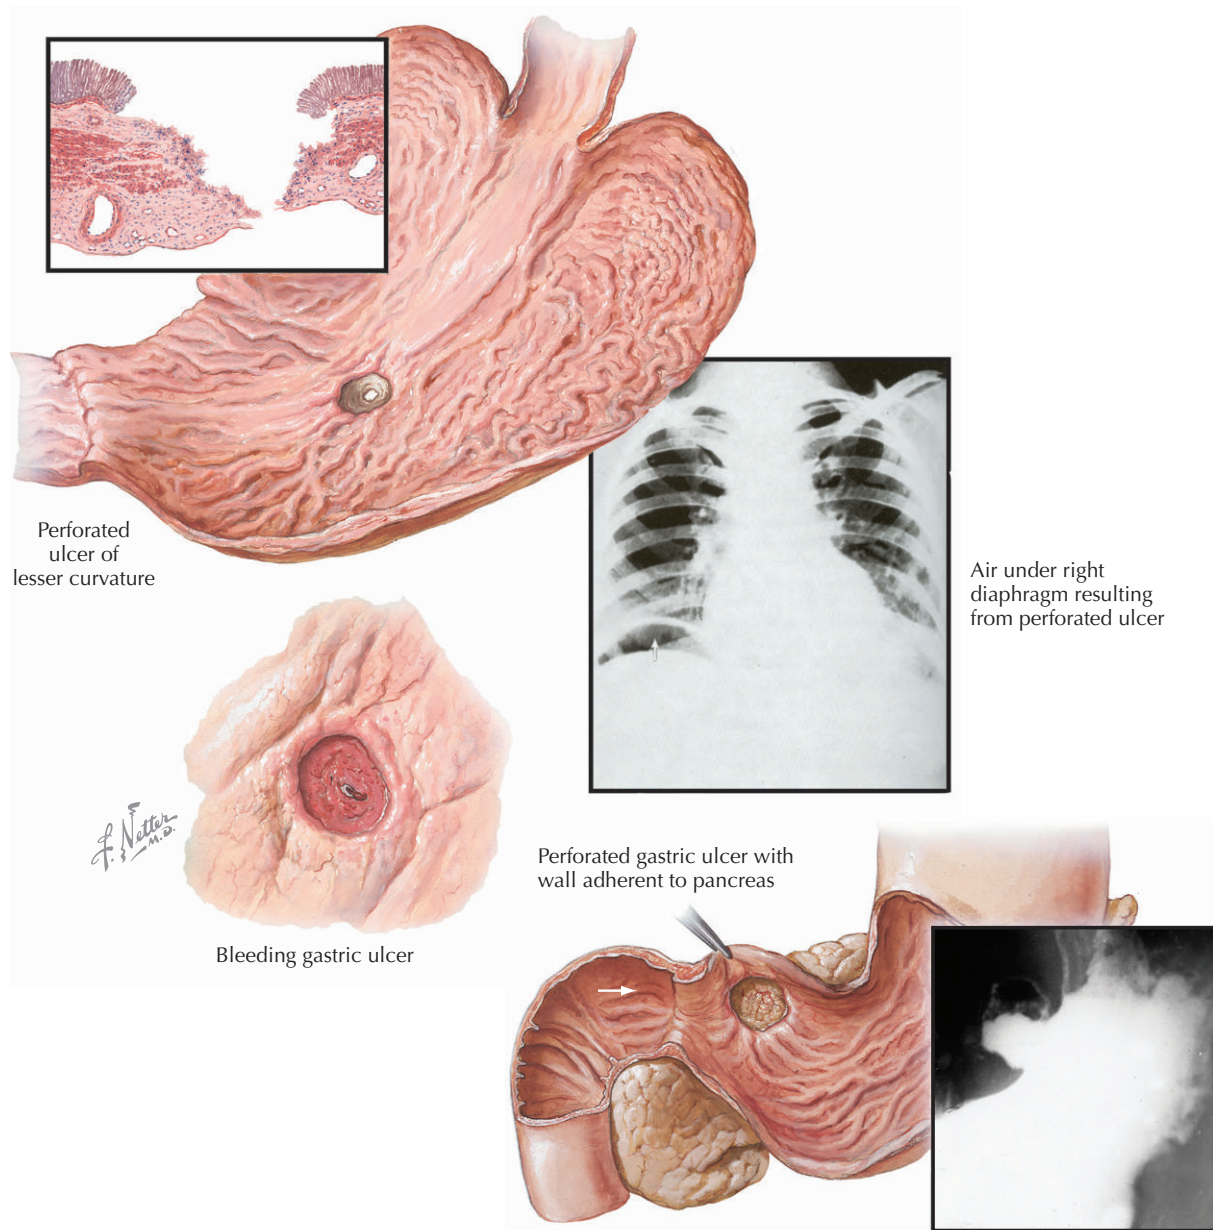

healing and disprove malignancy; however, it is unclear whether this is necessary in all cases.

Multiple forms of therapy (histamine-2 receptor antagonists, proton pump inhibitors [PPI], or misoprostol) are effective for symptom relief and ulcer healing. For an NSAID-associated ulcer, the agent should be discontinued, if possible. If the patient must remain on the NSAID, PPIs achieve superior healing rates and decrease the risk for relapse. Treatment with COX-2 inhibitors appears to lessen the risk for gastrointestinal side effects in patients requiring chronic NSAID use, but the increased risk for cardiovascular and cerebrovascular events has precluded their use in most cases. Surreptitious or inadvertent NSAID use is the most common reason for recurrent ulcer disease.

The role of *H. pylori* in duodenal and gastric ulcer formation is indisputable. If infection is documented, eradication with a standard regimen of a PPI with two antibiotics for 10 to 14 days is important (see Chapter 52). Successful eradication decreases the recurrence of endoscopically diagnosed duodenal ulcers from about 55% to 19% at 6 months. Follow-up testing is performed 4 weeks or more following therapy to ensure eradication in patients with complicated ulcer disease (e.g., bleeding, perforation).

Although many chronic NSAID users are *H. pylori* positive, the incremental benefit of eradicating the infection for all subjects who are *H. pylori* positive and require chronic NSAIDs remains controversial. Smoking cessation should be encouraged in any form of ulcer disease. Universal dietary modifications are not indicated.

Endoscopic therapy is the initial management step for PUD complicated by bleeding (see Fig. 51-4). At the time

Figure 51-3 Peptic Ulcer Disease: Complications of Gastric and Duodenal Ulcers.

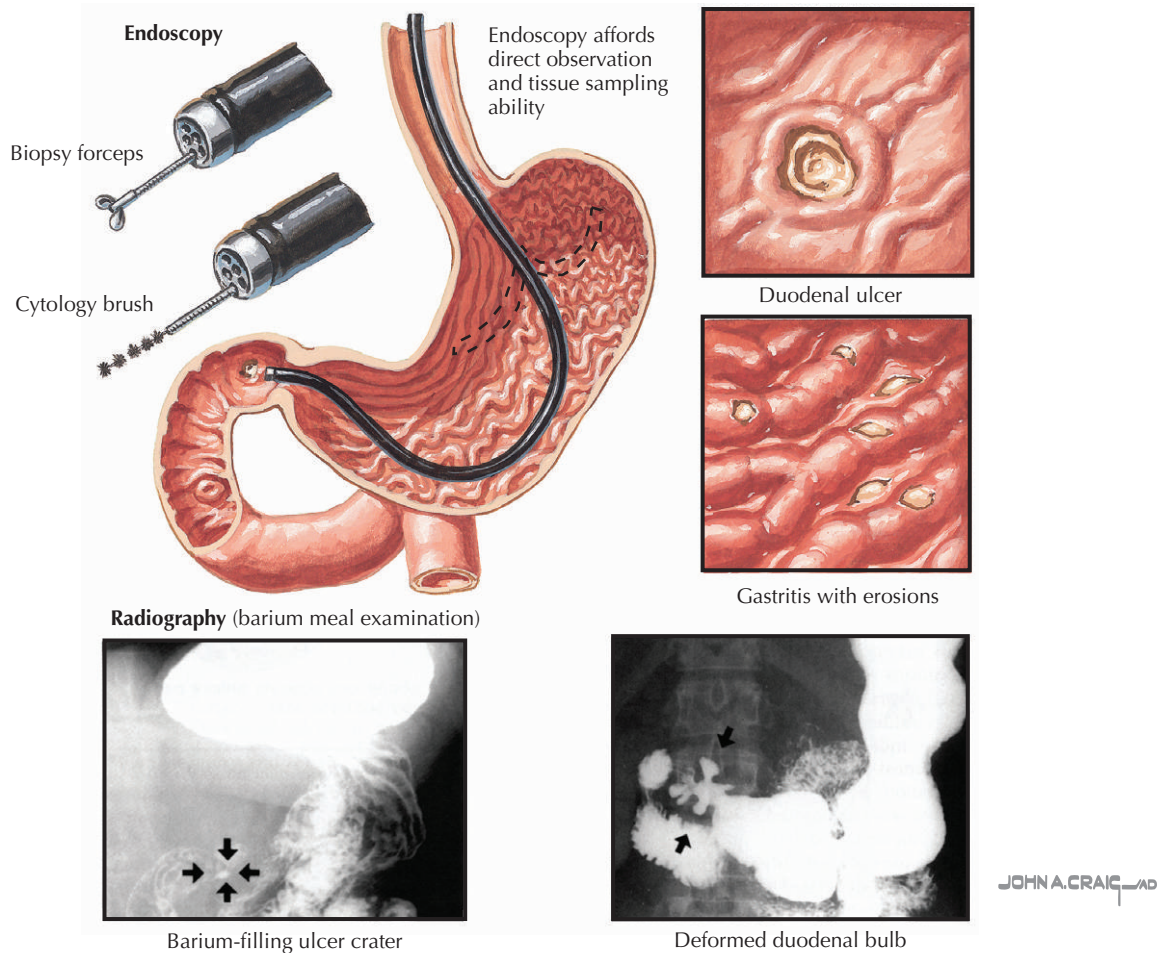

of upper endoscopy, if a visible vessel is seen, either with or without bleeding, treatment can usually be accomplished with various techniques (e.g., cautery, injection, endoclip). Successful endoscopic therapy can also lower the short-term risk for recurrent bleeding as well as the need for surgery. In addition, intravenous PPIs offer the promise of decreasing the acute morbidity and mortality associated with ulcer hemorrhage.

Upper endoscopy can also be useful in gastric outlet obstruction secondary to chronic scarring from PUD because endoscopic balloon dilation may relieve the obstruction, obviating surgery. Generally, ulcers complicated by refractory bleeding may be managed with interventional radiology or surgery. Potent acid suppression

and antimicrobial therapy have lessened the role of surgery in the management of ulcers, and today, surgical intervention is rarely necessary.

Avoiding Treatment Errors

The long-term use of PPI therapy is not indicated for most patients with prior peptic ulcer disease. For *H. pylori*-associated ulcers, antisecretory therapy may be stopped after 3 months. For NSAID-associated ulcers, the patient should be counseled to cease NSAID use, if possible. Lastly, follow-up endoscopy at a 2- to 3-month interval remains warranted for gastric ulcers to exclude malignancy. Definitive studies are needed to facilitate revision of this recommendation.

Figure 51-4 Diagnostic Evaluation.

Future Directions

Although the relative risk for ulcer formation is increased in patients with *H. pylori* infection or NSAID ingestion, the absolute risk is low. Challenges facing investigators include identifying the subsets of these populations who are at higher risk. High-risk patients could be targeted for *H. pylori* testing and eradication. In the case of those requiring chronic NSAID use, prophylactic therapy with PPIs is an option. The epidemiology of PUD is likely to change as the prevalence of *H. pylori* infection in developed nations such as the United States declines; the proportion of *H. pylori*-negative and NSAID-negative ulcers will increase. Thus, investigations aimed at understanding the pathophysiology of ulcer formation and healing will return to center stage.

Helicobacter pylori Infection and Associated Disorders

Introduction

Helicobacter pylori, the most common chronic bacterial infection in the world, is associated with chronic gastritis, peptic ulcer disease, gastric adenocarcinoma, and gastric lymphoma. Phylogenetic analysis suggests that the organism coevolved with humans, dating to the initial human migrations. The pivotal work by Barry Marshall and Robin Warren in the 1980s confirmed the association of *H. pylori* with gastric disease. Their contributions were recognized with the award of the Nobel Prize in Medicine in 2005. The more recent notion that antibiotic therapy with *H. pylori* eradication may prevent gastric adenocarcinoma and cure gastric lymphoma is of equal potential importance.

Nearly half of the world's population is chronically infected with *H. pylori*. *H. pylori* is endemic in most of the developing world, affecting about three fourths of adults, compared with about one third of adults in the developed world. Childhood socioeconomic status is the strongest determinant of the likelihood of infection. Related risk factors include inadequate sanitation, crowded living conditions, and sibling infection. In the United States, there are also significant racial and ethnic differences with respect to infection prevalence (Table 52-1).

Person-to-person transmission, specifically gastro-oral, is the postulated mode of infection. Studies suggest that most infections are acquired in childhood before 5 years of age, with familial clustering. Viable organisms have also been isolated from feces and water supplies, suggesting that low-level sporadic transmission may also occur. Adult infection in the developed world is uncommon, with an estimated rate of less than 1% per annum. Importantly, persistent infection following an antibiotic regimen is likely a result of treatment failure (compliance, resistance) rather than new infection.

The decrease in *H. pylori* infection worldwide resulting from improved socioeconomic conditions has several implications. A cohort effect is observed in developed nations, with older individuals more likely to be infected, which reflects childhood socioeconomic status rather than new adult infection. In part, this explains the decrease in incidence in duodenal ulcers and gastric cancer in the developed world. The prevalence of *H. pylori* infection is likely to decrease further owing to our improved understanding of the role of racial and ethnic differences in infection rates and for treatment—underlining the importance of an individualized approach to dyspepsia.

Etiology and Pathogenesis

H. pylori is a gram-negative spiral-shaped gastric organism. The bacteria inhabit the stomach's mucosal surface without invasion. The usual organism burden in the stomach is 1

billion, with a plethora of quasi-species present within each individual. *H. pylori* infection triggers a robust host immune response, resulting in chronic active gastritis in most infections. The organism uses a novel pH-dependent urea channel (UreI) and urease to generate ammonia and create

Table 52-1 *Helicobacter pylori* Seroprevalence in the United States

Race or Ethnicity	Age (yr)

a buffered microenvironment. The urease enzyme is produced at a higher level by *H. pylori* than by other bacteria and serves as the basis for many of the diagnostic tests.

H. pylori infection is a model for understanding gene-environment interactions that can lead to disease through chronic inflammation. The development of ulcer disease or cancer depends on the complex interaction at the gastric microniche level between host genetics, virulence factors, diet, and the environment. Several virulence factors have been described for the organism, the most important of which is the cytotoxin-associated gene A (*cagA*), which increases the likelihood of both ulcer disease and cancer. Other virulence factors include vacuolization factors (*vacA*) and adhesion factors (*babA*). Proinflammatory cytokine genotypes (e.g., polymorphisms of interleukin [IL]-1 β , IL-10, tumor necrosis factor- α) are associated with gastric adenocarcinoma in *H. pylori*-infected subjects (Box 52-1).

Three patterns of *H. pylori* infection are associated with chronic active gastritis. Most infected persons have a mild gastritis, without clinical manifestations. Second, antral predominant gastritis can be present and is associated with peptic ulcer disease. Third, corpus gastritis is correlated with intestinal metaplasia and gastric adenocarcinoma (Fig. 52-1). Failure to account for the heterogeneity of *H. pylori* infection accounts for much of the discordant literature, particularly in relation to esophageal disease. Lastly, the gene-environment model may vary globally as a result of racial and ethnic differences as well as variance in *H. pylori* virulence factors.

Clinical Presentation

The principal diseases associated with *H. pylori* infection are chronic gastritis, peptic ulcer disease, gastric adenocarcinoma, and low-grade B-cell non-Hodgkin's lymphoma. The *H. pylori*-associated lymphoma is also termed *mucosa-associated lymphoid tissue lymphoma* (MALToma).

Box 52-1 *Helicobacter pylori* Infection and Pathways to Gastric Carcinogenesis

 Gastric dysplasia
 Gastric adenocarcinoma

Most infected persons have an asymptomatic chronic active gastritis. Dyspepsia is the hallmark of symptomatic infection. Initial infection with acute gastritis is self-limited but may cause discomfort, halitosis, nausea, and vomiting. Transient achlorhydria often develops for 1 to 6 months.

H. pylori is the most important cause of peptic ulcer disease and is implicated in 75% of both duodenal and nonsteroidal anti-inflammatory drug (NSAID)-negative gastric ulcers. The lifetime risk for an ulcer with infection is 5% to 20%. Active ulcer disease may cause epigastric pain, nausea, vomiting, and, if complicated, hemorrhage or obstruction. Eradication of *H. pylori* decreases the risk for ulcer recurrence, but less so than initially postulated. A meta-analysis of trials suggested that the duodenal ulcer recurrence rate with successful eradication is 20% at 6 months, versus 56% in untreated patients. Most commonly, the failure of antibiotic therapy is related to an inadequate course of therapy. Infection testing and treatment are strongly recommended for patients with past or current peptic ulcer disease.

The concept of antibiotic therapy for cancer prevention or cure is intriguing. Patients with *H. pylori*-related gastric cancer or MALToma usually have nonspecific symptoms until large tumors are present. Although the etiology of gastric adenocarcinoma is multifactorial, *H. pylori* infection has a proven role, although it is neither necessary nor sufficient. Epidemiologic studies consistently suggest a relative risk increase of 3 to 9 times, similar to the relation between tobacco and lung cancer. A definitive cancer prevention trial has not been performed and probably will not be because a half-million patient-years would be required to prove efficacy. Thus, treatment recommendations are based on cost-effectiveness analyses, and the current recommendation is to screen for *H. pylori* in high-risk patient populations: family history of gastric cancer and immigrants from high incidence regions (e.g., Asia, Latin America).

Most patients with gastric MALToma also have evidence of infection. A number of studies suggest that nearly 80% of patients with low-grade tumors attain remission

Figure 52-1 Etiology and Pathogenesis of *Helicobacter pylori*.

with antibiotic therapy. It must be noted, however, that half of these patients demonstrate a persistent monoclonal B-cell clone.

A number of entities have been less convincingly associated with *H. pylori* infection. These include functional dyspepsia, gastroesophageal reflux disease (GERD), and synergistic effects with NSAIDs and proton pump inhibi-

tors (PPIs). Most randomized controlled trials have shown a borderline benefit of eradication therapy for functional dyspepsia, supporting the notion that it is a functional disease. Some patients may derive benefit from antibiotic therapy, however, suggesting that an individualized approach is appropriate. This has important implications for the approach to uninvestigated dyspepsia.

There may be an additive effect in peptic ulcer disease between *H. pylori* and NSAIDs. The current literature fails to provide a consensus regarding the benefit of testing and eradication before the initiation of chronic NSAID therapy. In the setting of a dual NSAID and *H. pylori* ulcer, eradication is indicated. Continued PPI therapy may be considered if ongoing NSAID use is needed. Subsequent studies have not substantiated the initial report of an increased risk for atrophic gastritis and, by inference, gastric cancer in infected patients treated with chronic PPI therapy. Currently, testing for and treatment of *H. pylori* are not recommended before the initiation of chronic NSAID or PPI therapy.

Postulated extragastric manifestations of disease are tenuous. Studies have yielded discordant results regarding the worsening of GERD and its complications in some patients following *H. pylori* treatment. In the moderate to severe GERD population, the indication for initial testing should be clear, and patients with positive results should be offered treatment. Despite initial reports, there is little evidence for an association with coronary artery disease, iron-deficiency anemia, rosacea, chronic idiopathic urticaria, or growth delay.

Differential Diagnosis

Dyspepsia is broadly defined as the symptom of upper abdominal discomfort and encompasses the clinical entities caused by *H. pylori*. The differential diagnosis for dyspepsia is broad and includes many non-*H. pylori*-related causes: NSAID (and other) peptic ulcer diseases, gastric cancer, esophageal disease and GERD, myocardial ischemia, and hepatobiliary disease. Functional dyspepsia, also known as nonulcer or endoscopy negative dyspepsia, refers to pain in this region without alarm features, laboratory abnormalities, or findings on upper endoscopy. Uninvestigated dyspepsia refers to the initial presentation with epigastric pain or discomfort before clinical evaluation. At upper endoscopy in patients with uninvestigated dyspepsia, about 15% each have ulcer disease, esophageal disease, or gastritis, whereas the remaining 40% to 60% are negative, suggestive of functional or self-limited dyspepsia.

A variety of approaches to uninvestigated dyspepsia have been suggested, including empiric acid suppression, immediate endoscopy, and the test-and-treat and test-and-scope approaches. The latter approaches refer to *H. pylori* testing with either treatment or endoscopy for positive results. The dominant strategy in the United States is test and treat. Patients with new-onset dyspepsia, younger than 45 to 50 years, and without alarm signs or symptoms (vomiting, weight loss, bleeding, anemia) are tested for *H. pylori* infection and treated if results are positive. Persons with persistent symptoms are referred for endoscopy. Recent outcome studies support the efficacy of this approach. The test-and-scope approach is often used in Asia and Latin America where gastric cancer rather than ulcer disease is

the main concern. Some European centers use immediate endoscopy for uninvestigated dyspepsia. Small studies suggest that outcomes and patient satisfaction are slightly better with direct endoscopy. If endoscopy costs in the United States decrease, particularly with the use of unsedated endoscopy, this may become a reasonable approach. Empiric acid suppression for 1 to 2 months has returned to favor with the availability of PPIs. Although the test-and-treat strategy is reasonable for most patients, the approach should be individualized with consideration of test and scope or immediate endoscopy based on symptoms, age, ethnicity, family history, and test availability.

Diagnostic Approach

Testing for *H. pylori* is suggested for those with active or prior peptic ulcer disease, uninvestigated dyspepsia, family history of gastric cancer, moderate-to-severe gastritis diagnosed on upper endoscopy, and gastric cancer or MALToma. All infected patients should be offered treatment.

Diagnostic tests include both noninvasive and invasive approaches (Box 52-2; Fig. 52-2). Serology (enzyme-linked immunosorbent assay detects immunoglobulin G antibodies) can be used to document past or current infection but cannot be used to document successful eradication. The urea breath tests (UBT) and stool antigen assay are active tests, documenting operative infection, and may be used to confirm eradication. For patients undergoing upper endoscopy, gastric biopsy specimens may be submitted for either histology or rapid urease testing (RUT). Histologic studies are the gold standard. Both the UBT and RUT depend on the detection of bacterial urease activity. Culture of *H. pylori* remains difficult and is limited to the research setting.

In low-prevalence populations, such as young whites in the United States, the false-positive rate of serologic testing is unacceptable, and active testing is recommended, particularly for the test-and-treat strategy for uninvestigated dyspepsia. Recent treatment (within 2 to 4 weeks) with any

Serologic testing (ELISA)

Serology testing (ELISA) detects IgG antibodies and documents past or current infection, but not eradication

of the components of *H. pylori* treatment (PPIs, bismuth compounds, and antibiotics) decreases the sensitivity of all nonserologic tests.

In general, documentation of successful eradication is unnecessary. Confirmation of clearance should be considered in patients with complicated peptic ulcer disease, gastric adenocarcinoma, MALToma, or persistent symptoms, and for those requesting such documentation. Active testing or endoscopy is indicated at least 1 month after

treatment to avoid false-negative results in the immediate post-treatment period.

Management and Therapy

Optimum Treatment

Optimal therapy for *H. pylori* infection requires a PPI with two antibiotics for 10 to 14 days (Table 52-2). Treatment

Table 52-2 Standard *H. pylori* Treatment Regimens*

Antibiotic	Proton Pump Inhibitor (PPI) [†]
PAC, twice daily	PPI, clarithromycin (500 mg), amoxicillin (1 g)
PMC, twice daily	PPI, clarithromycin (250-500 mg), metronidazole (250-500 mg)
PBMT, 4 times daily [‡]	PPI (twice daily), bismuth (525 mg), metronidazole (250 mg), tetracycline (500 mg)

*Treatment duration is 10-14 days.

[†]The PPIs (omeprazole, esomeprazole, lansoprazole, pantoprazole, rabeprazole) are equivalent.

[‡]The PBMT regimen is a 4 times daily regimen, except for twice daily PPI administration.

PAC, a PPI, amoxicillin, and clarithromycin; PBMT, a PPI, bismuth, metronidazole, and tetracycline; PMC, a PPI, metronidazole, and clarithromycin.

should be offered to all patients with positive diagnostic test results. The three principal regimens have similar efficacy of 80% to 85%.

The PAC regimen (a PPI, amoxicillin, and clarithromycin) is the most common combination. The PMC combination (a PPI, metronidazole, and clarithromycin) is appropriate for those individuals who have a penicillin allergy. The use of a PPI with the bismuth-based regimen significantly improves its efficacy. No significant difference has been noted between PPIs, although some physicians have preferences, based on their clinical experience in prescribing these agents. Prepackaged or combination products may improve compliance (e.g., PreVPac, Helidac, Pylera). Of note, the efficacy rates of various regimens and shorter treatment durations have largely been based on studies performed elsewhere and often have not been duplicated in the United States.

Avoiding Treatment Errors

Eradication failure is usually due to patient noncompliance or antibiotic resistance. Patients should be advised that completion of therapy is required and that the choice of a 2-week period without competing factors (e.g., travel) is important. There is no significant resistance to either amoxicillin or tetracycline. Primary resistance rates with clarithromycin and metronidazole are 5% to 10% and 25% to 35%, respectively, with age, sex, racial, and regional differences. Higher resistance rates are noted in elderly, female, and African-American patients. Metronidazole resistance may be an in vitro effect and can be overcome with the use of bismuth or PPI. Clarithromycin resistance

markedly decreases efficacy, and in this case PBMT (a PPI, bismuth, metronidazole, and tetracycline) is the principal retreatment regimen (Fig. 52-2). The use of other antibiotics has been reported in small studies for patients who have failed the PAC and PBMT regimens (e.g., rifabutin, furazolidone, levofloxacin, azithromycin).

Future Directions

H. pylori infection suggests a model for gene-environment interactions leading to disease through chronic inflammation, particularly for gastric cancer. Ongoing research should provide insights into the mode of transmission, childhood infection, and immunology. New antibiotic regimens are expected. A vaccine would provide the most cost-effective manner to prevent gastric cancer in high-incidence regions of the developing world, but development has proved difficult owing to the organism's genetic diversity. Because *H. pylori* has coevolved with humans, continued basic and clinical research will likely offer insights into the organism itself, other bacterial infections, and other human diseases.

Gastrointestinal Bleeding

Introduction

Gastrointestinal (GI) bleeding refers to bleeding from a source in the esophagus, stomach, small intestine, colon, anus, or rarely the liver and pancreas. In 2002, there were 116,724 hospital discharges with a principal diagnosis of GI hemorrhage (ICD-9 code 578.9), which was the 51st among all discharge diagnoses, and 74,717 hospital discharges with a principal diagnosis of diverticulosis with hemorrhage (ICD-9 code 562.12). Various descriptors have been used to categorize GI bleeding including the following: acute, chronic, active, occult, and obscure. In addition, GI bleeding is usually classified as upper versus lower. Upper GI bleeding refers to bleeding from a source from the esophagus to the duodenum at the ligament of Treitz. Lower GI bleeding refers to bleeding from the jejunum to the anus. Because of the breadth of this topic, the focus here is primarily on the causes of GI bleeding and the management strategies for acute bleeding.

Etiology and Pathogenesis

There are many different causes of GI bleeding (Fig. 53-1). Several factors can increase an individual's risk for GI bleeding. These include cirrhosis, coagulopathy, the use of aspirin or nonsteroidal anti-inflammatory drugs, and the use of antiplatelet or anticoagulating drugs.

Clinical Presentation

The clinical presentation depends on the rate, source, and volume of blood loss. Upper GI bleeding can present in several ways: hematemesis, vomiting of bright red blood; coffee ground emesis, vomiting of blood that has been digested by gastric acid; and melena, the passage of black tarry stool. Upper GI blood loss can also be occult, with no visible evidence of blood to the naked eye.

Lower GI bleeding can present as hematochezia, the passage of bright red blood per rectum, and less commonly as melena. Lower GI bleeding does stop spontaneously in most cases (about 85%). It can also be occult.

A person who is experiencing a rapid, large-volume GI bleed will manifest hemodynamic instability. Orthostatic blood pressure changes (a decrease in blood pressure of 20 mm Hg systolic or 10 mm Hg diastolic with an associated 20-point rise in heart rate after standing) can be seen with a 15% reduction in blood volume. Hypotension usually occurs with a 20% blood volume reduction.

Slow chronic blood loss can result in a significant reduction in hemoglobin without a change in hemodynamic stability. These patients often present with weakness, fatigue, shortness of breath, or chest pain as a result of anemia.

All patients presenting with GI bleeding should be checked for physical examination findings suggestive of chronic liver disease, including palmar erythema, spider angiomas, splenomegaly, ascites, and scleral icterus. Underlying cirrhosis with portal hypertension is a common cause of upper GI hemorrhage from gastric and esophageal varices.

Some etiologies of GI bleeding are associated with abdominal pain, but many are not. A careful abdominal examination looking for distention, the presence of bowel sounds, and tenderness is a critical step in patient evaluation.

Differential Diagnosis

Numerous lesions can cause upper GI bleeding (Box 53-1) as well as lower GI bleeding (Box 53-2). The following questions yield very important historical information that helps to narrow a very broad differential list of diagnoses:

- Have there been similar prior episodes?
- Did nonbloody emesis precede bloody emesis?
- What medications, both prescription and over the counter, have been taken recently?

Figure 53-1 Gastrointestinal Hemorrhage.

- Is there a history of clotting disorder?
- Is there associated abdominal pain?
- Is there a history of abdominal aortic aneurysm repair?
- Are there risk factors for chronic liver disease?

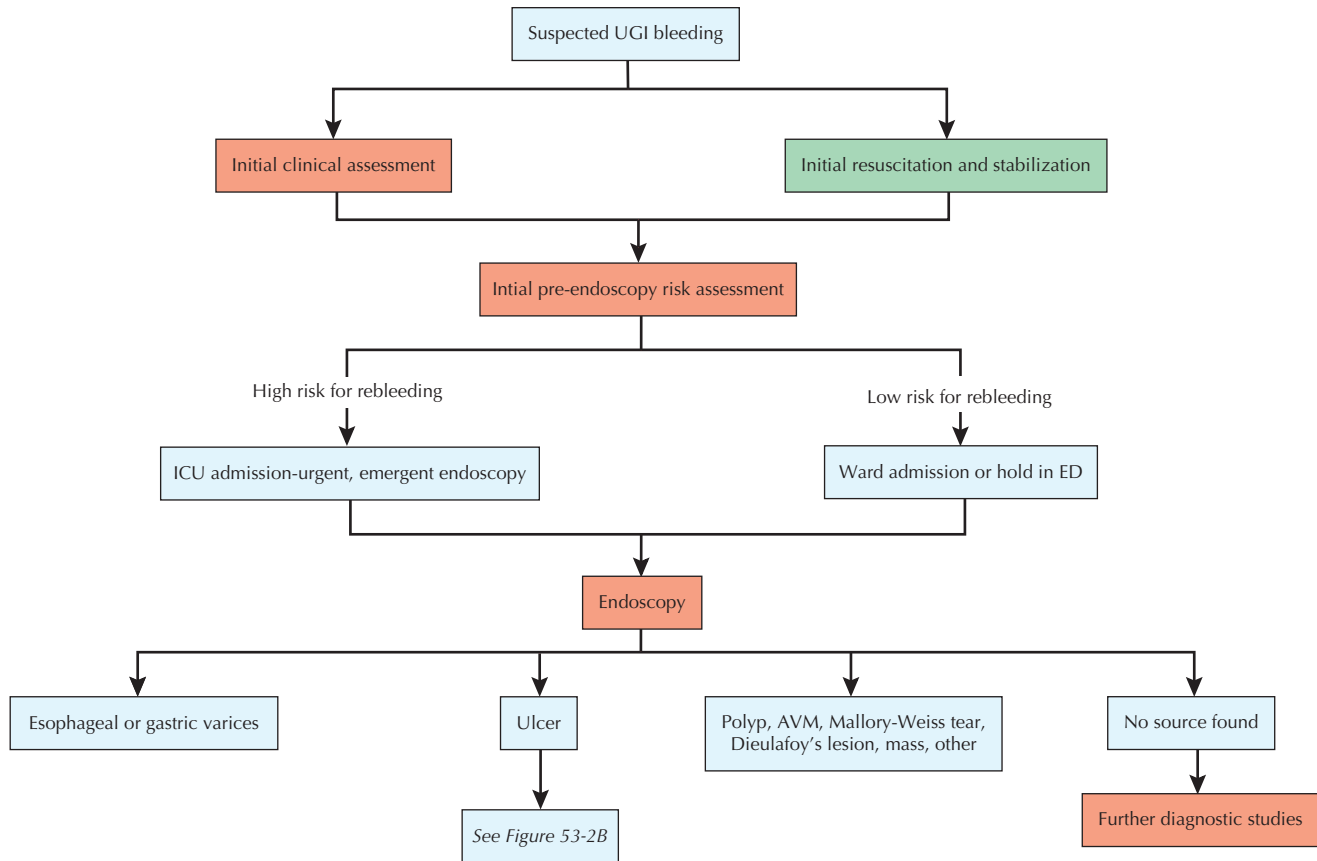

Diagnostic Approach

When a patient presents with GI bleeding, the urgency of evaluation is highly dependent on an initial assessment of

hemodynamic stability and on whether there is significant ongoing bleeding. Monitoring vital signs, obtaining good intravenous access with large-bore intravenous catheters, and ordering a complete blood count, prothrombin time and partial thromboplastin time, and a type and cross-match for blood products should occur early in the evaluation. Hypotension requires aggressive intravenous fluid resuscitation and blood transfusions as indicated. The correction of an underlying coagulopathy is also a key initial therapeutic step. If a patient is having ongoing hematem-

sis, airway protection may require tracheal intubation. The patient should not receive anything by mouth except essential oral medications.

An experienced endoscopist should see the patient as soon as possible, and the medical care team should ask for a surgical consultation if the patient's hemodynamic state remains unstable with evidence of continuing blood loss. If an upper GI bleed is suspected, the patient should have an urgent upper endoscopy. Endoscopy provides diagnos-

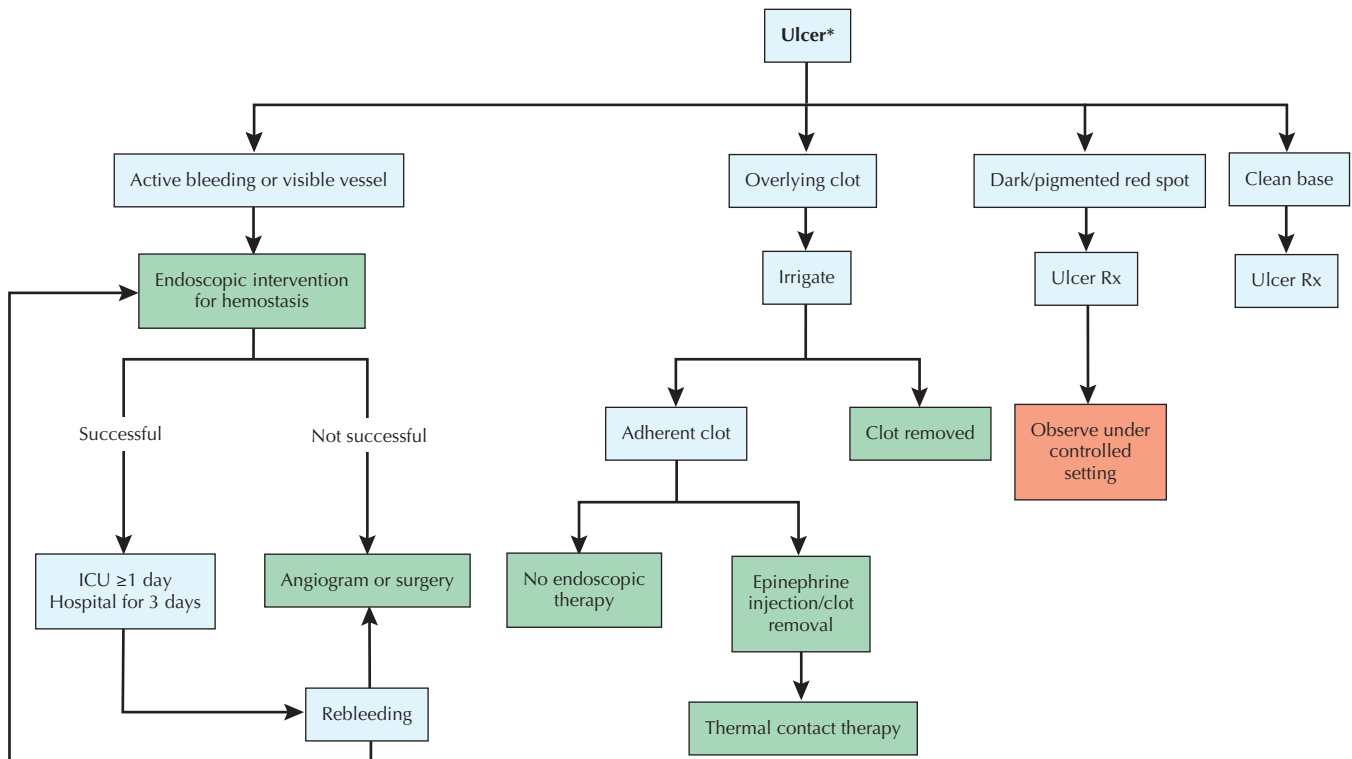

tic and prognostic information and also allows for therapeutic intervention.

If the patient can be stabilized hemodynamically and if it is clear that a lower GI bleed is occurring, a polyethylene glycol purge should be given over 3 to 4 hours.

If the patient presents with evidence of chronic occult GI bleeding and is hemodynamically stable, an outpatient upper and lower endoscopy is a reasonable approach. When there is no definite diagnosis after these studies, the next step is capsule endoscopy of the small bowel or other small bowel imaging modality.

*Continued from Figure 53-2A

Management and Therapy

In 2001, the American Society for Gastrointestinal Endoscopy published algorithmic approaches to upper and acute lower GI bleeding (Figs. 53-2 and 53-3). These approaches remain relevant. A 250-mg dose of intravenous erythromycin is often given before upper endoscopy to help empty blood clots from the stomach. Also, most endoscopists now try to remove all adherent clots and provide endoscopic therapy to the lesions found beneath them, if indicated.

In upper GI bleeding, the following are predictors for rebleeding: older age; shock, hemodynamic instability, and orthostasis; comorbid disease states (e.g., coronary artery disease, congestive heart failure, renal and hepatic diseases, cancer); specific endoscopic diagnosis (e.g., GI malignancy); use of anticoagulants and coagulopathy; and presence of a high-risk lesion (e.g., arterial bleeding or nonbleeding, visible vessel).

Optimum Treatment

For upper GI bleeding, optimum treatment involves a combination of endoscopy and medications. The findings on endoscopy identify lesions at risk for rebleeding, which affect the length of hospitalization. Helpful adjunctive

medications are available. Proton pump inhibitors, given in high-dose oral or intravenous forms, have decreased rebleeding rates and the need for surgery in patients with peptic ulcer disease. Somatostatin or its synthetic analogue octreotide is used to help control variceal bleeding along with the use of endoscopic therapeutic techniques.

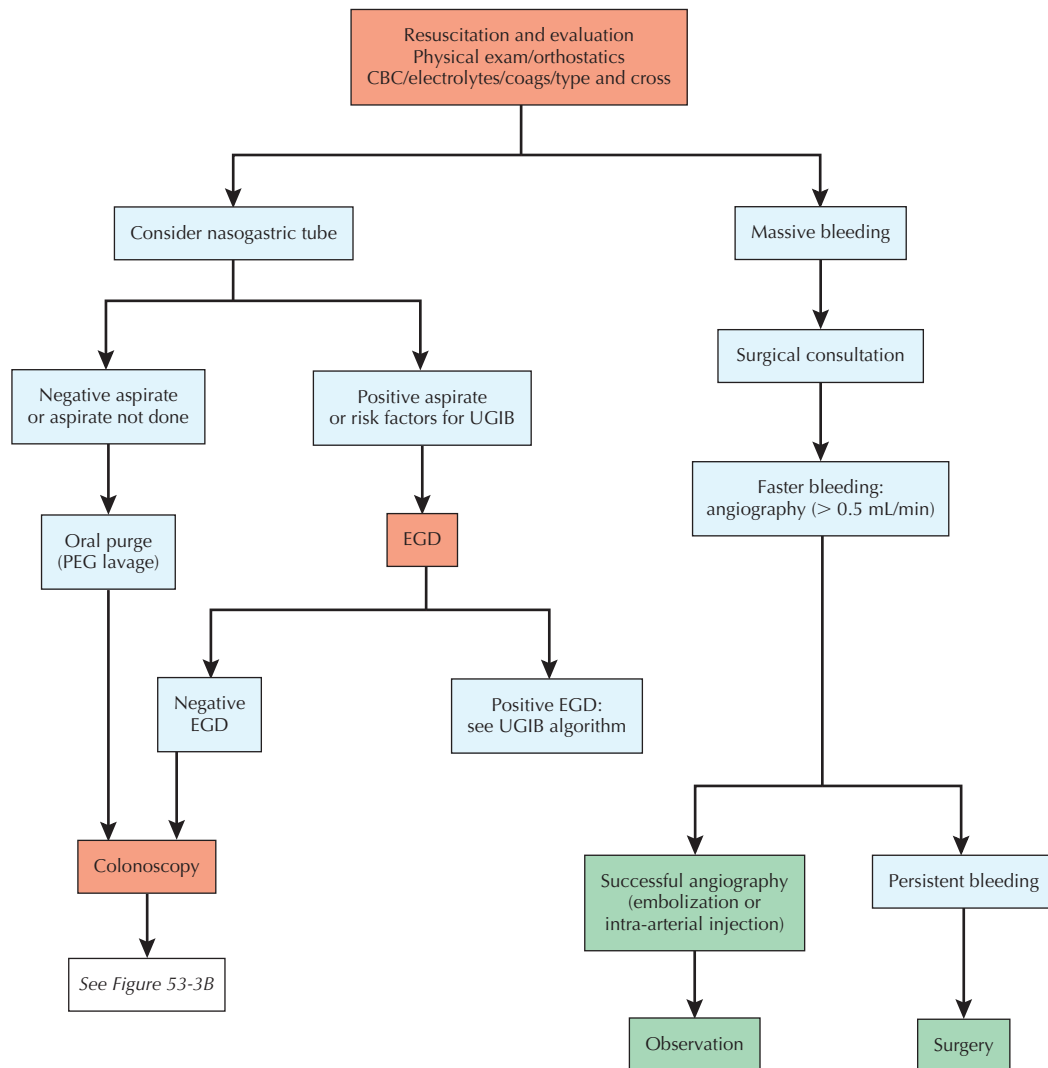

For acute lower GI bleeding, the optimum treatment strategy is shown in the algorithm in Figure 53-3. Stabilization of the patient must be the first priority, followed by evaluation for a specific bleeding source. Some lower GI bleeding lesions are amenable to endoscopic hemostatic therapy, including a culprit diverticulum, arteriovenous malformation, polypectomy sites, and radiation proctitis. Angiography should be reserved for those with massive bleeding that precludes colonoscopy and those in whom colonoscopy was nondiagnostic but bleeding persists. If an extravasation site is identified, arterial embolization is an alternative. Surgery is reserved for those failing endoscopic and angiographic therapy.

Avoiding Treatment Errors

Not paying enough attention to a bleeding patient's hemodynamic stability both at the time of presentation and over

Figure 53-3A Acute Lower Gastrointestinal Bleeding, Part 1.

Coags, coagulation studies including prothrombin time and partial thromboplastin time; CBC, complete blood count; EGD, esophagogastroduodenoscopy; PEG, polyethylene glycol solution; UGIB, upper gastrointestinal bleeding. the ensuing hours of hospitalization is the most important treatment error. These patients must have frequent, if not continuous, monitoring of vital signs, cessation or reversal of anticoagulant therapy, ongoing monitoring of hemato-crits, adequate intravenous access, fluid support, and blood product support.

Future Directions

Capsule technology will continue to evolve and in the future may have a role in diagnosing lower GI bleeding. Device manufacturers will continue to develop tools to aid the endoscopist in achieving hemostasis. Endoscopic suturing devices are being developed.

Cholelithiasis

Introduction

The prevalence of gallstones in the United States increases from about 4% in 20-year-olds to more than 15% in those older than 60 years. Cholecystectomy is the most common abdominal operation performed in this country, with about 750,000 completed each year. The annual cost for the management of gallstones, their complications, and the associated economic losses to society is close to \$5 billion.

Etiology and Pathogenesis

Gallstones are classified according to their composition. They vary in shape, number, size, and consistency; however, these characteristics play little role in whether symptoms develop (Fig. 54-1).

Cholesterol gallstones are the most common type. Three factors are necessary for their formation: supersaturation of gallbladder bile with cholesterol, crystal nucleation, and gallbladder hypomotility (Fig. 54-2). The solubility of cholesterol in bile depends on the incorporation of cholesterol in solubilizing bile acid–lecithin micelles. Alterations in the relative concentrations of cholesterol, bile acids, or lecithin can lead to cholesterol supersaturation. Mucin glycoprotein molecules act as nucleating agents to form gallstones. Cholesterol crystals in the mucin gel, coupled with defective emptying of the gallbladder, lead to the growth and development of stones.

Pigmented stones include black or brown varieties. Black pigmented stones are composed of pure calcium bilirubinate or polymer-like complexes of calcium, copper, and large amounts of glycoproteins. These stones are most common in cirrhosis and chronic hemolytic states. Brown pigmented stones are usually associated with infection. Bacteria present in the biliary system hydrolyze glucuronic acid from conjugated bilirubin. Calcium salts of the now unconjugated bilirubin crystallize and form brown stones.

Most epidemiologic series indicate that the prevalence of gallstones in women varies from 5% to 20% between the ages of 20 and 55 years, and from 25% to 30% after age 50 years. The prevalence for men is about half that

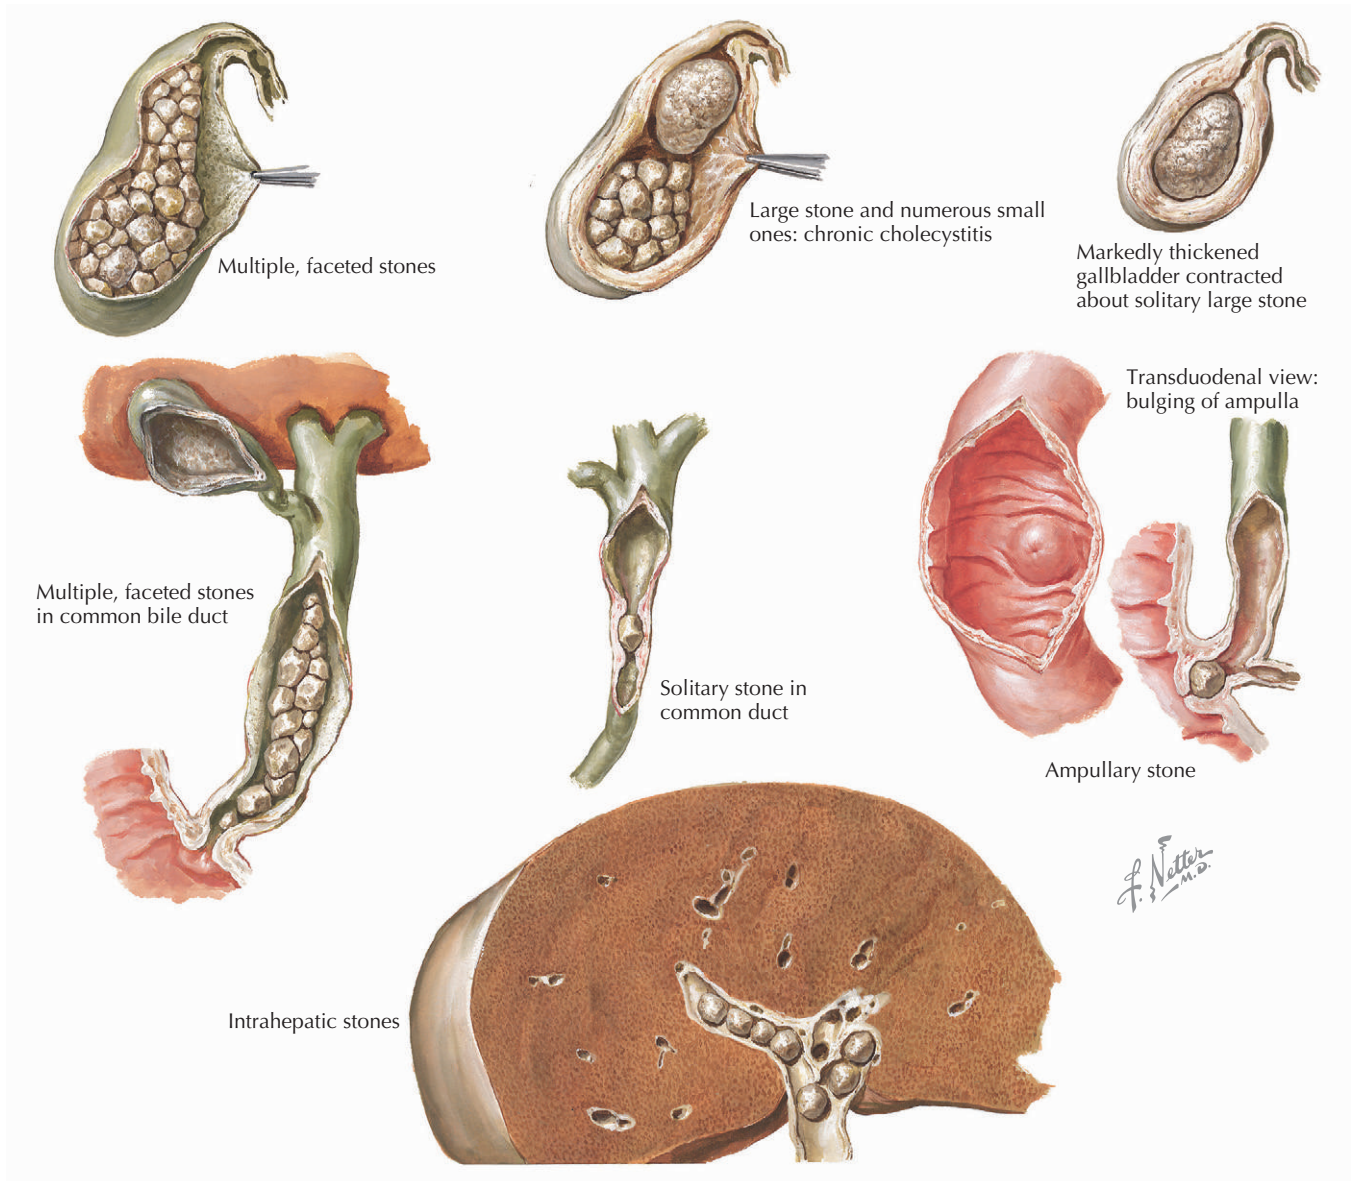

of women at any age. Other risk factors are listed in Box 54-1.

Clinical Presentation

Gallstones cause symptoms by obstruction of the cystic duct, common bile duct, or erosion into neighboring organs (Fig. 54-3). Seventy-five percent of gallstones do not cause symptoms; 20% cause intermittent pain or biliary colic; 10% result in acute cholecystitis; 5% pass into the common duct, causing bile duct obstruction or pancreatitis; and less than 0.1% are associated with fistulas or gallbladder cancer.

Biliary Colic and Chronic Cholecystitis

About 75% of patients with symptomatic cholelithiasis present with biliary colic. Pain results from the intermittent obstruction of the cystic duct by one or more stones. Inflammation is not present, so there are usually few, if any, systemic signs or symptoms. Biliary colic is a visceral pain that is poorly localized but typically felt in the epigastrium, right upper quadrant, or even left upper quadrant. The pain is steady rather than intermittent and lasts 1 to 6 hours. Describing the pain as “colic” is a misnomer. Pain lasting longer than 6 hours is more commonly associated with the onset of inflammation and hence cholecystitis. Physical examination is typically normal, but mild tenderness in the right upper quadrant may be elicited. Laboratory tests are frequently unrevealing. Seventy percent of patients experience recurrent symptoms within 2 years of

Figure 54-1 Cholelithiasis: Pathologic Features, Choledocholithiasis.**Box 54-1 Risk Factors for Gallstone Development**

- Genetic predisposition
- Diseases of the terminal ileum
- Hypertriglyceridemia

the initial attack. Recurrent episodes of biliary colic are referred to as *chronic cholecystitis*.

Acute Cholecystitis

Similar to biliary colic, acute cholecystitis is brought on by impaction of a gallstone or stones in the cystic duct or infundibulum (Fig. 54-4). Prolonged obstruction of the cystic duct leads to stasis of bile within the gallbladder, damage to the gallbladder mucosa, and the consequent release of intracellular enzymes and activation of inflammatory mediators. As concentrations of inflammatory mediators rise within the gallbladder, ongoing inflammation produces increased protein and prostaglandin secre-

Figure 54-2 Pathogenesis of Gallstones.

tion, decreased water absorption, and white blood cell infiltration. Acute cholecystitis is initially a chemically mediated inflammatory process. Enteric bacteria may be cultured from the bile, but they are not responsible for the onset or activation of acute cholecystitis.

Symptoms persist and usually worsen. Over time, inflammation of the gallbladder ensues, and the pain becomes parietal in nature with localization to the right upper quadrant. Radiation of pain to the back or scapular

area is common. Fever is fairly common, but the temperature is usually less than 102° F. Nausea and vomiting may occur. Jaundice may develop in up to 20% of patients, whereas bilirubin levels typically are less than 4 mg/dL. Frequently, white blood cell counts are elevated. Abdominal examination often reveals right subcostal tenderness. A palpable gallbladder occurs in about one third of patients. Murphy's sign, an insensitive but moderately specific finding described as inspiratory arrest during palpation of

Figure 54-3 Cholelithiasis II: Clinical Aspects.

the right subcostal area during deep inspiration, may be detected.

Choledocholithiasis, Cholangitis, and Gallstone Pancreatitis

Gallstones may pass from the gallbladder into the common bile duct and cause pain, obstructive jaundice, cholangitis, or pancreatitis (Fig. 54-5). Five to 15% of patients with

gallstones also have common duct stones. Stones within the common duct cause pain that is colicky, occurring in the epigastrium with radiation to the back. Jaundice is very common because bilirubin levels rise with the degree of obstruction. Elevations in alkaline phosphatase occur frequently.

Of all the complications of gallstones, cholangitis kills most quickly. The usual clinical presentation consists of

Figure 54-4 Mechanisms of Biliary Pain.

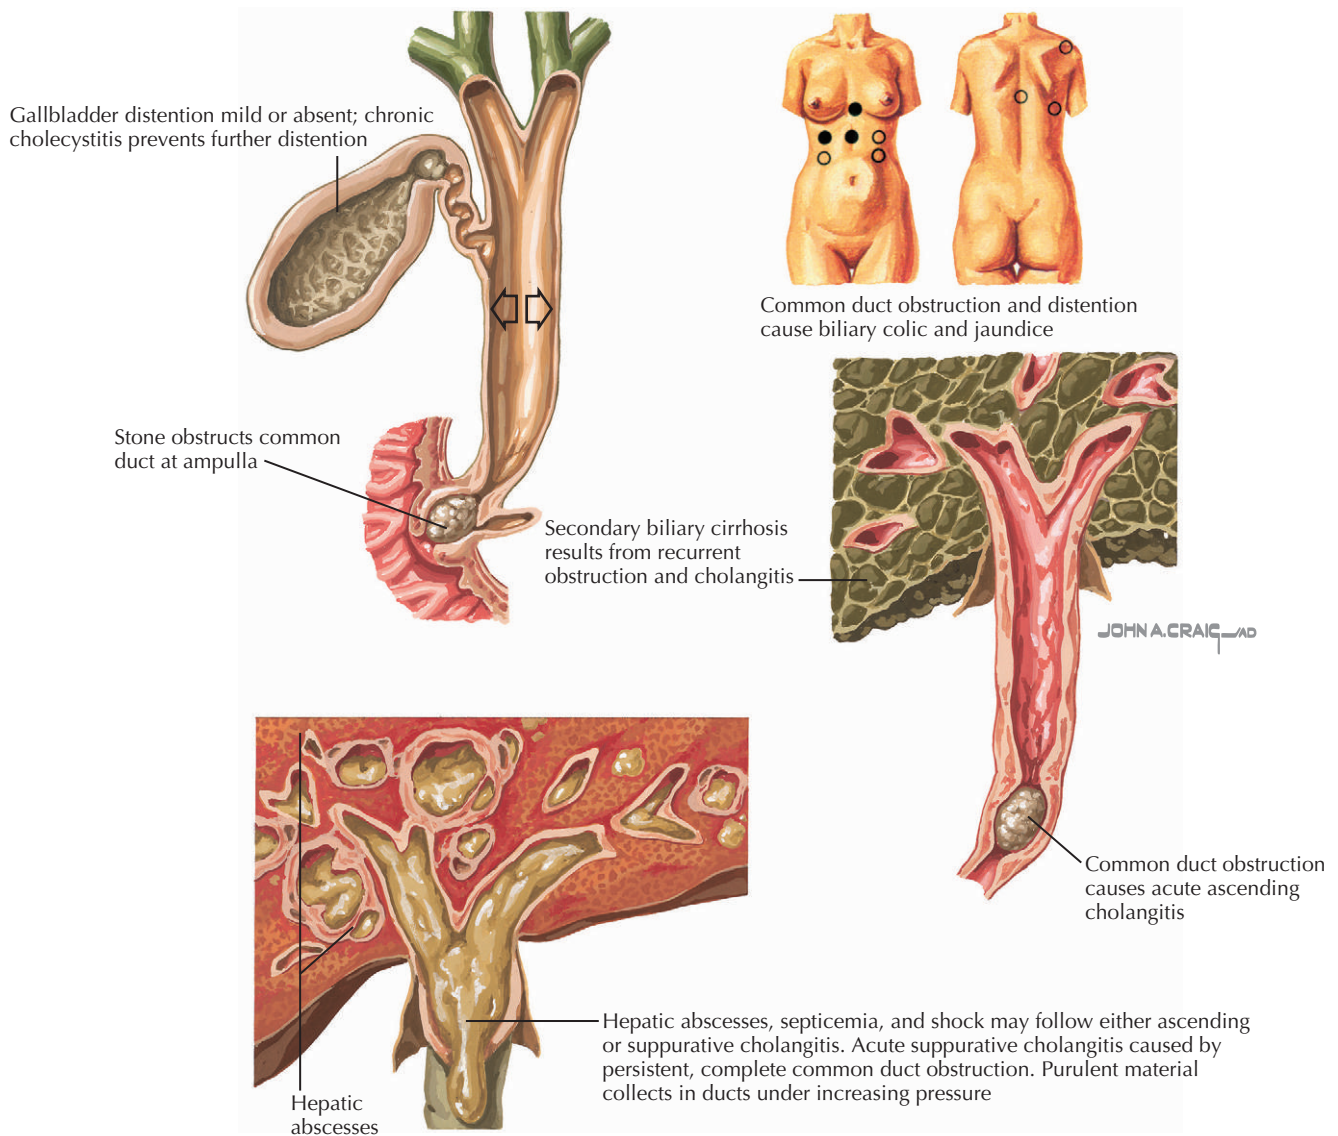

pain, jaundice, and chills (i.e., Charcot's triad). Refractory sepsis characterized by altered mentation, hypotension, with Charcot's triad constitutes Reynold's pentad.

Gallstone pancreatitis occurs when a biliary stone causes a transient or sustained blockage of the ampulla of Vater. Most patients experience a mild, self-limited attack that resolves within several days, characterized by abdominal or back pain and elevated serum amylase and lipase levels. Clinical symptoms and abnormal serum biochemistries resolve slowly during this time. Severe pancreatitis devel-

ops in a finite number of patients, manifested by persistent retroperitoneal inflammation, pseudocyst formation, or pancreatic necrosis with or without peripancreatic sepsis.

Uncommon Complications of Gallstone Disease

Emphysematous cholecystitis occurs when gas-forming organisms infect the gallbladder secondary to acute cholecystitis. Gas pockets present within the gallbladder wall

Figure 54-5 Calculus Obstruction of Common Duct (Choledocholithiasis).

can be detected radiographically. Urgent cholecystectomy is recommended. Cholecystoenteric fistulas occur when a stone erodes through the gallbladder wall into an adjacent viscus. The most common sites include the duodenum, the hepatic flexure of the colon, and the stomach.

Differential Diagnosis

Biliary Colic and Chronic Cholecystitis

Colic and chronic cholecystitis mimic episodic upper abdominal symptoms, including gastroesophageal reflux, peptic ulcer disease, pancreatitis, renal colic, diverticulitis, colon cancer, and angina pectoris. Although complaints of gas, bloating, flatulence, and dyspepsia are frequent in patients with gallstones, these symptoms are nonspecific

and should not be considered characteristic clinical manifestations of gallstone disease.

Acute Cholecystitis

The signs and symptoms of acute cholecystitis mimic those of acute appendicitis, acute pancreatitis, right kidney diseases, pneumonia with pleurisy, acute hepatitis, hepatic abscesses, and gonococcal perihepatitis (Fitzhugh-Curtis syndrome).

Choledocholithiasis and Cholangitis

Because the symptoms associated with cystic and common duct obstruction are so similar, biliary colic and acute

cholecystitis are always in the differential diagnosis. Malignant obstruction of the common bile duct, acute congestion of the liver associated with congestive heart failure, acute viral hepatitis, and the cholangiopathy of AIDS may also mimic choledocholithiasis.

Diagnostic Approach

Laboratory Tests

In uncomplicated biliary colic and chronic cholecystitis, there are usually no accompanying changes in hematologic and biochemical tests. In acute cholecystitis, leukocytosis is usually observed. Serum aminotransferase, alkaline phosphatase, bilirubin, and amylase levels may also increase.

Sonography

Ultrasonography is the modality of choice for examining the biliary tract. Ultrasound can detect gallbladder stones as small as 2 mm in diameter with sensitivity and specificity rates exceeding 95%.

Sonography is also valuable in the diagnosis of acute cholecystitis. Eliciting a sonographic Murphy's sign (focal gallbladder tenderness under the transducer) has a positive predictive value of more than 90% for diagnosis of acute cholecystitis when stones are seen. The presence of pericholecystic fluid in the absence of ascites and gallbladder wall thickening to more than 4 mm are other nonspecific findings suggestive of acute cholecystitis.

Stones in the common bile duct are seen with sonography in only half of cases. Thus, sonography confirms, but does not exclude, common duct stones.

Hepatobiliary Scintigraphy

Hepatobiliary scintigraphy is most useful in evaluating patients with suspected acute cholecystitis. A normal hepatobiliary scan represents a patent cystic duct and virtually rules out acute cholecystitis in patients who present with abdominal pain. The sensitivity of the test is about 95%, and the specificity is 90%. False-positive results occur primarily in fasting or critically ill patients.

Endoscopic Retrograde Cholangiopancreatography

Endoscopic retrograde cholangiopancreatography (ERCP) is the standard for evaluating common duct stones and pathology. Endoscopic therapeutic applications have revolutionized the treatment of common duct stones and other biliary tract disorders.

Computed Tomography and Magnetic Resonance Imaging

Although not well suited for the evaluation of uncomplicated stones, standard computed tomography (CT) is an excellent test to detect complications such as abscess formation, perforation of the gallbladder or common bile duct, or pancreatitis. Spiral CT and magnetic resonance cholangiography may prove useful as a noninvasive means of excluding common bile duct stones.

Management and Therapy

Optimum Treatment

Cholecystectomy remains the mainstay of treatment of symptomatic gallstones.

Asymptomatic Cholelithiasis

Because up to 80% of all gallstones are asymptomatic and the risk for developing symptoms or complications is low, adult patients with silent or incidental gallstones should be observed and treated expectantly.

Biliary Colic and Chronic Cholecystitis

The natural history of biliary colic is such that recurrent biliary pain occurs in about 38% to 50% of patients per year. The risk for serious biliary complications is relatively low, estimated at 1% to 2% per year. A reasonable approach is to offer cholecystectomy to those with recurring episodes of biliary colic. The laparoscopic approach to gallbladder removal is the treatment of choice for symptomatic gallstones. Laparoscopy, unlike the traditional open operation, allows the surgery to be performed on an outpatient basis with a marked reduction in postoperative pain and a more rapid return to work and usual activities. Conversion to open cholecystectomy is uncommon, averaging less than 3% in most institutions. The incidence of bile duct injury associated with laparoscopic cholecystectomy has decreased to less than 0.5%, and mortality rates are less than 0.1%.

Acute Cholecystitis

If acute cholecystitis is suspected, the patient should be hospitalized for evaluation and treatment. Antibiotics may be withheld in uncomplicated cases but are indicated in toxic-appearing patients or when complications such as perforation or emphysematous cholecystitis are suspected. Definitive therapy is cholecystectomy performed within 24 to 48 hours of the onset of symptoms. Delaying the procedure potentially increases the difficulty in performing surgery, the complication rate, and the need to convert to an open operation. Percutaneous cholecystostomy or transpapillary endoscopic cholecystostomy can be used to drain the inflamed gallbladder for patients deemed to be at high risk for surgery.

Choledocholithiasis

The optimal treatment for common duct stones depends on the level of local expertise in endoscopy and surgery. In general, the presence of obstructive jaundice with a dilated common bile duct should lead promptly to preoperative ERCP with sphincterotomy and stone extraction. Once the bile duct has been cleared, the patient can undergo a routine laparoscopic cholecystectomy within 1 or 2 days.

Cholangitis

The management of sepsis in cholangitis is of paramount importance. Drainage or decompression of the biliary system is definitive. ERCP with stone extraction or at least bile duct decompression with a stent is the treatment of choice. Alternatively, access to the obstructed biliary tract through percutaneous transhepatic cholangiography with drainage catheter placement can temporize by draining the infected obstructed bile duct. Once the patient has recuperated from the infectious insult, elective laparoscopic cholecystectomy can be undertaken.

Gallstone Pancreatitis

For more than three fourths of patients, gallstone pancreatitis is mild, is self-limited, and resolves with conservative management. Cholecystectomy should be performed during the initial admission when the pancreatitis has resolved. Delaying surgery increases the risk for recurrent symptoms and further complications. An evaluation of the biliary system for retained stones should be performed with either a preoperative ERCP or intraoperative cholangiography. For patients with severe biliary pancreatitis, early ERCP with sphincterotomy, if indicated, can be beneficial.

Avoiding Treatment Errors

The widespread use of CT, ultrasound, and nuclear scintigraphy have greatly aided in the diagnosis of cholecystitis and its complications. A team approach in its management is always indicated because coordination of care among primary care physicians, radiologists, gastroenterologists, and surgeons is essential to ensure optimal patient care.

Future Directions

In light of the significant public health impact of gallstones, ongoing research continues to focus on finding the

medical means to prevent gallstone formation. Further advances in nonsurgical therapy are expected. Perhaps the most exciting developments will occur in biliary tract imaging techniques with the application of improved resolution ultrasound, endoscopic ultrasound, magnetic resonance imaging, and cholangiography.

Clinical trials comparing early versus late cholecystectomy for acute cholecystitis are included in this analysis. Early laparoscopic cholecystectomy during acute cholecystitis seems safe and shortens hospital stay.

2. Keus F, de Jong JA, Gooszen HG, van Laarhoven CJ: Laparoscopic versus open cholecystectomy for patients with symptomatic cholelithiasis. *Cochrane Database Syst Rev* 4:CD006231, 2006.

Thirty-eight trials randomized 2338 patients. Meta-analysis suggests less overall complications in the laparoscopic group with a shorter hospital stay and convalescence.

3. Urbach DR, Stukel TA: Rate of elective cholecystectomy and the incidence of severe gallstone disease. *CMAJ* 172:1015-1019, 2005.

Did the increase in the performance of elective cholecystectomies that occurred after the introduction of laparoscopic cholecystectomy in 1991 result in a reduction in complications of gallstone disease? This study concludes that, as a result of more elective cholecystectomies being performed, there has been an overall reduction in the incidence of severe gallstone disease that is entirely attributable to a reduction in the incidence of acute cholecystitis.

Pancreatitis

Introduction

Pancreatitis is a general term that encompasses a broad spectrum of pathophysiologic disorders and clinical manifestations. Acute pancreatitis (AP) may range in severity from simple interstitial edema to extensive necrotizing pancreatitis with multisystem organ failure (Fig. 55-1). Most episodes of AP are mild, with an excellent prognosis for complete recovery. However, pancreatic necrosis develops in about 20% of patients, which markedly increases the risk for severe complications and death. The mortality rate for patients with sterile necrosis is 10%, but mortality can exceed 25% in patients with infected pancreatic necrosis. Chronic pancreatitis (CP) refers to irreversible fibrosis and atrophy of the gland, often with a chronic inflammatory cell infiltrate, and progressive loss of exocrine and endocrine function (Fig. 55-2).

Etiology and Pathogenesis

The most common causes of pancreatitis in developed countries are gallstones (45%) and alcohol (35%). About 10% of cases result from miscellaneous causes, whereas another 10% remain unexplained (Box 55-1).

CP can result from recurrent AP; however, it often develops insidiously. Most patients presenting with an initial attack of alcoholic pancreatitis, for instance, already have morphologic changes of CP. Risk factors for CP are listed in Box 55-2.

Clinical Presentation

AP presents with severe epigastric pain of sudden onset, frequently with radiation to the back, nausea, and vomiting (see Fig. 55-1). The pain typically reaches maximal intensity within 30 minutes and persists for hours without relief. Fever, tachycardia, and leukocytosis may be present.

CP may initially present with an attack resembling AP, but it often progresses to a pattern of recurrent inflammatory flares or chronic persistent pain (see Fig. 55-2). Subsequently, malabsorption and diabetes mellitus may develop.

Differential Diagnosis

AP can mimic many causes of an acute abdomen, such as biliary colic, perforated ulcer, mesenteric ischemia or

infarction, bowel obstruction, inferior wall myocardial infarction, or ectopic pregnancy. CP can resemble ulcer disease, biliary disorders, gastrointestinal malignancies, malabsorption syndromes, or chronic functional abdominal pain.

Diagnostic Approach

Serum amylase or lipase elevations exceeding 3 times normal are characteristic of acute pancreatitis. Lesser elevations can occur in other conditions. Lipase values are slightly more accurate, especially when the presentation is delayed. An elevation of alanine aminotransferase more than 3 times the upper limit of normal is specific for a gallstone etiology, with a positive predictive value of 95%, in patients without a history of alcohol use. Abdominal computed tomography (CT) detects the presence or absence of pancreatitis in all but the mildest cases and is useful in excluding other conditions having a similar presentation.

The diagnosis of CP requires either evidence of characteristic morphologic abnormalities of the gland or a combination of typical clinical features and abnormal pancreatic functional studies. Pancreatic calcifications on plain radiography or CT represent intraductal stones, which are pathognomonic for CP. Stones may also be seen on transabdominal ultrasonography. Endoscopic retrograde cholangiopancreatography (ERCP) and magnetic resonance

Figure 55-1 Acute Pancreatitis.

cholangiopancreatography can provide fine detail of the ductal anatomy, such as irregular dilation of the pancreatic duct, strictures, or ductal filling defects. Endoscopic ultrasonography is the most sensitive means for detecting subtle pancreatic parenchymal changes, although the clinical significance of such findings is uncertain.

The secretin test is the gold standard for documenting pancreatic insufficiency, but it is cumbersome and not widely available. The qualitative fecal fat stain is a simple test to document fat malabsorption, which, in a patient

with suspected CP, implies loss of 90% of exocrine function.

Management and Therapy

Acute Pancreatitis

Optimum Treatment

Management of AP should focus on rapid treatment and early identification of patients at risk for severe AP. All

Figure 55-2 Chronic (Relapsing) Pancreatitis.

patients should receive aggressive fluid replacement, pain management, and careful observation for signs of respiratory insufficiency or significant third-space fluid losses (hemoconcentration, oliguria, hypotension, tachycardia, or azotemia). To promptly identify individuals at risk for severe pancreatitis, the Acute Physiology and Chronic Health Evaluation (APACHE II) score should be calculated on the day of admission. Early predictors of severity include an APACHE II score of 6 or above, obesity (body mass index >30), or pleural effusions. Severe AP is defined

as an APACHE II score of 8 or more; a Ranson score of 3 or more; organ failure (shock, pulmonary insufficiency, renal failure, or gastrointestinal bleeding); or local complications, including necrosis, abscess, or pseudocyst. Abdominal ultrasound is indicated to screen for gallstones or biliary ductal dilation. Patients with severe AP and suspected biliary obstruction should undergo urgent ERCP (within 72 hours) to remove bile duct stones. Patients with severe pancreatitis should be transferred to an intensive care setting and undergo dynamic contrast-enhanced CT

Box 55-1 Causes of Acute Pancreatitis and Recurrent Acute Pancreatitis**Common**

Gallstones—microlithiasis
Alcohol abuse
Idiopathic causes

Uncommon

Endoscopic retrograde pancreatography
Metabolic: hypertriglyceridemia, hypercalcemia
Obstructive: sphincter of Oddi dysfunction, pancreatic ductal lesions (tumor, stricture)
Duodenal or periampullary lesions: Crohn's disease, blind loop obstruction
Congenital: annular pancreas, pancreas divisum
Trauma
Medications (e.g., azathioprine, 6-mercaptopurine, corticosteroids, dideoxyinosine, estrogens, furosemide, metronidazole, pentamidine, sulfonamides, tetracycline, thiazides, valproic acid)
Toxins
Infections: tuberculosis, cytomegalovirus, mumps, Coxsackie virus, mycoplasma, parasites
Vascular: vasculitis, embolism, hypotension
Autoimmune
Hereditary: hereditary pancreatitis, cystic fibrosis gene mutations

(ideally after 72 hours) to identify pancreatic necrosis. Oral intake is typically withheld while pain persists. Nasogastric suction is indicated for ileus or for refractory nausea and vomiting. In the absence of ileus, early jejunal feeding is safe and may reduce the risk for complications. Prophylactic antibiotics are widely used in patients with necrotizing pancreatitis (e.g., imipenem-cilastatin for 2 to 4 weeks), although the data and recommendations regarding this practice are conflicting. Patients with necrotizing pancreatitis and clinical deterioration or signs of infection should undergo guided, percutaneous fine-needle aspiration for bacteriology studies. Aggressive surgical débridement is the standard treatment for infected necrosis, which is otherwise uniformly fatal.

Avoiding Treatment Errors

Common errors in the initial management of acute pancreatitis involve the failure to provide adequate fluid resuscitation and the failure to recognize the potential severity of the disease, especially in the first few days of illness. Although most cases of pancreatitis are mild, the full severity of the disease may not be evident in the first several days, during which time patients require close attention for early signs of organ failure. Severity scoring systems, although less than perfect, are valuable clinical tools for predicting complications and mortality, yet they are often not employed in routine practice.

Adapted from Etemad B, Whitcomb DC: Chronic pancreatitis: Diagnosis, classification, and new genetic developments. *Gastroenterology* 120(3):691, 2001.

Acute fluid collections are common in acute pancreatitis. Most of these resolve spontaneously with no intervention. They should not be referred to as *pseudocysts* until they have been present for at least 4 weeks because this label tends to invite an unnecessary therapeutic intervention. Percutaneous drainage of acute fluid collections increases the risk for infecting an otherwise sterile environment.

Chronic Pancreatitis**Optimum Treatment**

Therapy is directed at managing pain and fat malabsorption primarily. A low-fat diet, non-narcotic analgesics, and abstinence from alcohol are recommended. Narcotics may be required for severe pain. For persistent pain, high protease pancreatic enzyme replacement should be prescribed for at least 8 weeks. Microencapsulated enzyme preparations with high lipase content are useful for treatment of steatorrhea. Treatable problems should be sought, such as pseudocysts or stenosis of the duodenum or intrapancreatic common bile duct. Patients with refractory pain and pancreatic duct strictures or stones may benefit from endoscopic therapy. Those with intractable pain and a dilated

main pancreatic duct often respond to surgical decompression (i.e., lateral pancreaticojejunostomy). Treatments of last resort for pain in patients with nondilated ducts include nerve blocks and pancreatic resection.

Avoiding Treatment Errors

Fluid collections and cystic lesions in the pancreas should be accurately characterized before contemplating a plan of treatment. This may require multiple imaging modalities, including endoscopic ultrasonography. In a patient presenting with a pancreatic cystic lesion in the absence of an antecedent diagnosis of pancreatic disease, the possibility of a cystic neoplasm should be strongly considered. Patients with diffuse dilation of the pancreatic duct are occasionally given an incorrect diagnosis of chronic pancreatitis when the underlying disease is in fact an intraductal mucinous papillary neoplasm. Pancreatic pseudocysts and duct disruptions are increasingly managed by endoscopic means, thereby avoiding prolonged hospitalizations associated with parenteral feeding, percutaneous drainage, or postoperative recovery.

Future Directions

Newer diagnostic tests for pancreatitis (e.g., urinary trypsinogen-2) and biochemical markers of severity (e.g., urinary trypsinogen activation peptide, serum interleukin-6 and -8) may improve current practice. Novel therapies for severe AP will target inhibition of the systemic inflammatory response associated with this disease. The role of genetic factors in the development of pancreatic diseases will remain a major research focus.

Alanine aminotransferase elevations of more than threefold are highly predictive of a gallstone etiology of acute pancreatitis.

Diarrhea: Acute and Chronic

Introduction

Diarrhea is defined as increased stool output. The increased fecal output may represent increased stool frequency, increased stool fluidity, or a combination of both. Objectively, diarrhea is defined as a stool weight in excess of 200 g in 24 hours. Diarrhea is classified as acute or chronic, depending on the duration of symptoms. Acute diarrhea lasts no longer than 6 to 8 weeks, with most cases resolving in 2 to 3 weeks. Cases lasting longer than 8 weeks are deemed chronic. Most cases of diarrhea in the United States are acute and self-limited; nevertheless, diarrheal illnesses remain a major cause of morbidity and mortality worldwide.

Etiology and Pathogenesis

Diarrhea occurs because of abnormal fluid and electrolyte transport and altered intestinal motility. The major pathogenic mechanisms include the presence of unusual amounts of poorly absorbable intraluminal solute with associated osmotic diarrhea, abnormal ion absorption or ion secretion that causes secretory diarrhea, inflammatory processes of the mucosa and bowel wall, and abnormal intestinal motility (Fig. 56-1).

In the normal state, in a 24-hour period, about 8 to 10 liters of fluid enters the duodenum from a combination of dietary intake and gut secretions. Two thirds of the fluid is reabsorbed in the duodenum, with one third entering the proximal jejunum. Of the 10 liters of fluid entering the small intestine, only a volume of 1500 mL is presented to the colon. The small intestine has a chloride (Cl^-) and bicarbonate (HCO_3^-) transport mechanism that reduces the concentration of Cl^- and increases the concentration of HCO_3^- such that the concentrations reflect the plasma concentrations. The colon absorbs most of the fluid, excreting only 100 mL in a 24-hour period. The colon's very efficient active transport mechanisms extract sodium (Na^+) and fluid and secrete potassium (K^+). Magnesium (Mg^{2+}) and calcium (Ca^{2+}) are poorly absorbed in the colon. The excreted stool contains 3 millimoles (mmol) of Na^+ , 8 mmol of K^+ , and 2 mmol of chloride.

Osmotic diarrhea is the result of osmotically active, nonabsorbable solutes accumulating in the gut lumen with resulting intraluminal salt and water retention. A classic feature of osmotic diarrhea is cessation of the symptoms with fasting or after the patient stops ingesting the osmotically active agent. The electrolyte content of the excreted stool is normal in osmotic diarrhea and does not account for the total fecal osmolality. The difference between the measured osmolality and that accounted for by the electrolyte content is termed the *osmotic gap*. The osmotic gap is calculated by doubling the fecal sodium and potassium concentrations and subtracting the value from the stool osmolality or expressed as a formula: $\text{osmotic gap} = 290 \text{ mOsm/L} - [2 \times (\text{fecal Na}^+ + \text{K}^+)]$.

The normal stool osmotic gap is less than 125 and is usually less than 60. A fecal osmotic gap greater than 60 is suggestive of an osmotic diarrhea, a condition in which the osmotic gap is, in fact, usually more than 125. In contrast to osmotic diarrhea, secretory diarrhea does not abate with fasting. There may be a decrease in the stool volume and stool weight, an observation that should not be mistaken for osmotic diarrhea. There is a net luminal secretion of water and electrolytes into the gut, and the osmotic gap is less than 60.

Inflammatory diarrhea is characterized by exudation of blood, mucus, pus, or serum proteins in the stool. This results in increased stool weight and diarrhea.

Figure 56-1 Diarrhea.

Abnormal intestinal motility may cause diarrhea secondary to rapid intestinal transit or by slow intestinal transit with stasis and resultant bacterial overgrowth.

Clinical Presentation

Individuals who present with diarrhea usually complain of frequent loose, watery stools. Medical attention is often sought because of accompanying dehydration, abdominal discomfort, fever, vomiting, gastrointestinal bleeding, pus in the stool, or chronicity of symptoms. It is crucial to characterize the patient's stool pattern and associated symptoms in order to guide the diagnostic approach.

Differential Diagnosis

The differential diagnoses for both acute and chronic diarrhea is extensive. Either may be caused by infectious agents. Pathogens commonly associated with acute infectious diarrhea include *Salmonella*, *Shigella*, enterohemorrhagic *Escherichia coli*, *Campylobacter*, rotaviruses, and Norwalk agent. *Vibrio cholera* and *Cyclospora* species are less frequent causes of acute diarrhea. Microsporidium and cryptosporidium can cause acute diarrhea and are more likely to affect immunocompromised individuals. *Clostridium difficile* is the agent most frequently associated with nosocomial diarrhea and with antibiotic-associated diarrhea. Common infections associated with chronic

diarrhea include giardiasis, strongyloidiasis, and amebiasis.

Ischemic colitis is a noninfectious cause of acute diarrhea that occurs more frequently in middle-aged and elderly patients with significant peripheral vascular disease or atherosclerotic heart disease. Several medications, including nonsteroidal anti-inflammatory agents, digitalis, vasopressin, and diuretics, have been associated with ischemic colitis.

Osmotic diarrhea with carbohydrate malabsorption from lactase deficiency is seen in lactose intolerance, excessive sorbitol intake, lactulose use, fructose intake, ingestion of magnesium-containing compounds (laxatives, antacids, or supplements), and intestinal mucosal disease such as celiac sprue or gluten intolerance.

A variety of toxin-producing infections cause secretory diarrhea. These include *E. coli* enterotoxin and *V. cholerae* enterotoxin. Senna-containing laxatives, bisacodyl-containing laxatives, vasoactive intestinal peptide, calcitonin, substance P, gastrin, serotonin, and prostaglandins also produce secretory diarrhea. Parasitic infections, including giardiasis, strongyloidosis, and amebiasis, can cause secretory diarrhea. Congenital chloridorrhea is caused by a secretory stimulus from a mucosal ion transport defect. Bile acid malabsorption, microscopic colitis, collagenous colitis, hyperthyroidism, medullary carcinoma of the thyroid, and collagen vascular diseases such as systemic lupus erythematosus and scleroderma are additional causes of secretory diarrhea.

Inflammatory bowel disease secondary to Crohn's disease, ulcerative colitis, and Behçet's disease produces exudative or inflammatory diarrhea. Chemotherapeutic agents, radiation enteritis, microscopic colitis, collagenous colitis, and graft-versus-host disease can also produce inflammatory diarrhea. Parasitic infections, viral agents, and bacterial pathogens may cause inflammatory diarrhea.

Abnormal intestinal motility underlies the functional diarrhea experienced in irritable bowel syndrome (IBS). Constipation may alternate with the diarrhea of IBS. Typically, the diarrhea of IBS is associated with mucus production with absence of inflammatory markers. The nocturnal diarrhea experienced by some patients with advanced diabetes is caused by deranged intestinal motility.

Diagnostic Approach

The initial evaluation of patients with both acute and chronic diarrhea should include a detailed history that includes the duration of symptoms, hydration status, severity of illness, travel history, exposure to potentially contaminated food or water, sick contacts, recent use of antibiotics, medication use, and the immune status of the individual.

A complete physical examination should include careful assessment for evidence of dehydration such as orthostasis, dry mucous membranes, and poor skin turgor. The abdom-

inal exam should include a careful evaluation for peritoneal signs, which are associated with enteroinvasive infectious agents. A rectal exam should include an assessment for fistulas and abscesses.

The diagnostic evaluation of acute diarrhea should include fecal leukocytes and fecal occult blood testing. Routine stool cultures are of little value in healthy individuals who lack fecal leukocytes and fecal occult blood. Also, stool cultures are thought to be of little benefit in cases of nosocomial diarrhea. *C. difficile* is the most likely offending agent and is effectively diagnosed with enzyme-linked immunosorbent assays for toxin A. Stool cultures should be obtained from immunocompromised individuals and from persons with known Crohn's disease or ulcerative colitis. Infectious agents can cause an acute exacerbation of diarrhea in the setting of inflammatory bowel disease. The role of endoscopy is limited. Flexible sigmoidoscopy is helpful if ischemic colitis is suspected. Demonstration of pseudomembranes on endoscopic exam is diagnostic of *C. difficile* colitis and may be beneficial in individuals who are toxic.

Recommended laboratory testing for chronic diarrhea includes a complete blood count to evaluate for inflammation and serum electrolytes for information regarding fluid status. Stool analysis for fecal leukocytes may be helpful in differentiating inflammatory from noninflammatory diarrhea. Calculation of the stool osmotic gap helps to characterize osmotic diarrhea from secretory diarrhea. Fecal occult blood testing is also indicated. Positive fecal occult blood testing is suggestive of an inflammatory process. Stool analysis for excess fecal fat helps to differentiate malabsorption. Stool can be evaluated for fecal fat by a Sudan stain or by quantitatively measuring the fat content of the stool in a 72-hour period. A fecal fat concentration greater than 7 g per 24 hours is consistent with a malabsorptive process. Measuring the stool pH may also be beneficial in differentiating carbohydrate malabsorption—pH usually less than 5.6. Endoscopy has a greater role in chronic diarrhea than in acute diarrhea (Fig. 56-2). Lower endoscopy, flexible sigmoidoscopy, or colonoscopy with biopsies can be helpful with the diagnosis of Crohn's disease, ulcerative colitis, microscopic colitis, and collagenous colitis. Upper endoscopy, esophagogastroduodenoscopy, with biopsy samples taken from the proximal duodenum, is the gold standard for confirming celiac disease or gluten intolerance. In the setting of chronic diarrhea, if the evaluation has been extensive and a diagnosis has not been established, factitious diarrhea should be considered, and the stool should be analyzed for laxative use.

Management and Therapy

Optimum Treatment

The management and therapy of diarrhea depend on the etiology of the disease. Most cases of acute diarrhea are

Figure 56-2 Bacillary Dysentery.

self-limited and do not require therapy beyond supportive care with attention to fluid intake to prevent dehydration. Oral rehydration solutions consisting of sodium chloride, sodium bicarbonate, potassium chloride and sucrose or glucose are designed to use the intestinal sodium-glucose transport system to promote water absorption to decrease the risk for dehydration. Symptomatic therapy with loperamide or diphenoxylate warrants consideration for acute diarrhea if the stool is nonbloody and there is no fever. In general, empiric antibiotic therapy has not been shown to significantly alter the course of acute diarrhea. Empiric antibiotics are generally reserved for patients with bloody diarrhea, fever, and fecal leukocytes who are dehydrated and may require hospitalization and who have been symptomatic for about 1 week. Antibiotic therapy should also be considered in immunocompromised hosts. Probiotics are beneficial in reestablishing the intestinal flora with nonpathogenic microorganisms and in shortening the length of diarrhea in traveler's diarrhea and *C. difficile* infection.

The treatment of chronic diarrhea is guided by the etiology of the disease or disorder and the symptoms. Cases of chronic diarrhea of unknown etiology are often challenging. Long-term use of loperamide is acceptable in

selected cases for symptomatic relief. The long-term use of diphenoxylate, codeine, and tincture of opium requires caution because dependency may develop. Fiber supplementation or bulking agents such as polycarbophil can be beneficial for decreasing the stool fluidity. Alosetron is a highly selective 5-HT₃ antagonist that slows transit and reduces stool frequency. Alosetron is approved for use in diarrhea-predominant IBS when prescribed by practitioners knowledgeable of the side-effect profile with close patient monitoring as recommended by the manufacturer. Rifaximin is an antibiotic that inhibits bacterial RNA synthesis by binding DNA-dependent RNA polymerase. It is approved by the U.S. Food and Drug Administration for treatment of travelers' diarrhea caused by noninvasive strains of *E. coli*.

Avoiding Treatment Errors

Treatment of diarrhea, whether acute or chronic, depends on careful evaluation of the stool pattern and associated symptoms. Successful treatment requires proper identification of the underlying cause. A detailed history, including information about travel, dietary intake, and exposure to sick contacts, helps to provide clues about potential

infectious agents or dietary factors causing diarrhea. Careful monitoring of fluid and electrolyte status with replacement of both as necessary is essential because dehydration and electrolyte abnormalities are a major source of morbidity and mortality in diarrheal illnesses.

Future Directions

Current research includes the clinical investigation of serotonin 5-HT₃ antagonists for the management of diarrhea-predominant IBS. Studies include trials to optimize dosing for alosetron. Ramosetron is a selective 5-HT₃ receptor antagonist shown in animal studies to have more potent effects on abnormal colonic function than alosetron. Continued evaluation of ramosetron may provide additional treatment modalities for functional diarrhea. Other investigations include the evaluation of rifaximin in managing the diarrhea associated with small bowel bacterial overgrowth.

Constipation

Introduction

Constipation refers to specific symptoms associated with impaired defecation, including abnormal stool frequency, straining with defecation, passage of hard stool, and a sense of incomplete evacuation. It is very common and affects persons of all ages. An individual with constipation may experience one or more of the symptoms. Millions of dollars are spent annually on over-the-counter laxatives, physician visits, and pharmacologic agents to control the symptoms. The true prevalence is not known because many of those affected do not seek medical care. Reported prevalence rates range from 2% to 20%. The Rome III consensus criteria for constipation include two or more of the following: straining during at least 25% of defecations, lumpy or hard stools in at least 25% of defecations, sensation of anorectal obstruction or blockage during at least 25% of defecations, manual maneuvers to facilitate at least 25% of defecations, and fewer than three defecations per week along with rare loose stools and insufficient criteria for diagnosis of irritable bowel syndrome. The symptoms should be present for the past 3 months with onset of symptoms at least 6 months before diagnosis. It is important to define the patient's specific symptoms to determine the most appropriate and cost-effective diagnostic and therapeutic approach.

Etiology and Pathogenesis

Most individuals are toilet trained and able to control defecation by 4 years of age. Successful continent evacuation requires a degree of mental functioning to be able to respond to cues indicating the need to evacuate, normal intestinal motility, proper internal and external anal sphincter function, and coordination of the puborectalis muscle. The rectum is a compliance reservoir with stretch or mechanoreceptors located in the rectal wall. The urge to defecate is experienced once stool is propelled from the distal sigmoid colon into the rectum, activating the mechanoreceptors. Defecation is initiated by sitting and straining to perform a series of maneuvers that increase the intra-abdominal pressure, decrease the resting tone of the internal anal sphincter, straighten the angle of the puborectalis muscle, relax the external anal sphincter, and allow expulsion of the fecal bolus. These maneuvers occur almost simultaneously, and abnormality in any one of the steps can result in constipation.

The causes of constipation are broad and can be divided into metabolic, neurogenic, and idiopathic causes (Fig. 57-1). In addition, numerous drugs are associated with constipation. *Common metabolic or endocrine causes* include

hypothyroidism, diabetes mellitus, pregnancy, hypercalcemia, hypokalemia, uremia, glucagonoma, and porphyria. *Neurogenic disorders* include peripheral neuropathy, Hirschsprung's disease, autonomic neuropathy, neurofibromatosis, Chagas' disease, and intestinal pseudo-obstruction. *Central nervous system disorders* include multiple sclerosis, Parkinson's disease, cerebrovascular accident, and spinal cord injury. *Categories of medications* that can cause constipation include narcotic analgesics, anticholinergic drugs, antidepressants, antihypertensives, diuretics, nonsteroidal anti-inflammatory medications, antacids containing aluminum or calcium salts, antihistamines, and antiparkinson agents. *Idiopathic causes* include slow transit-type constipation or colonic inertia, pelvic floor dyssynergia, constipation-predominant irritable bowel syndrome, megacolon, and megarectum.

Clinical Presentation

Individuals who present with complaints of constipation may describe infrequent bowel movements; excessive straining with defecation; inability to evacuate the rectum after experiencing an urge; a desire to have a bowel move-

Figure 57-1 Causes of Constipation.

ment but with lack of an urge to defecate; evacuation of small, hard or dry stools; digital manipulation to achieve evacuation; or a sense of incomplete evacuation. The diagnostic approach depends on what the patient describes as constipation in order to guide the selection of diagnostic tests.

Differential Diagnosis

Most causes of constipation are not life threatening and are of a functional rather than an organic nature. Functional causes of constipation include insufficient fluid and fiber intake as well as physical inactivity. Organic conditions that may cause constipation must be considered.

These include colorectal tumors, hernias, strictures, chronic intermittent volvulus, endometriosis, rectocele, rectal prolapse, and anal stricture.

Diagnostic Approach

Taking a detailed history is the most important factor when evaluating an individual with a complaint of constipation. Information obtained during the history guides selection of appropriate testing. The number of bowel movements in a 7-day period should be documented along with the appearance of the stool. Infrequent stools may reflect slow transit of fecal material through the colon. Small, hard, lumpy stool may reflect inadequate fiber and

Figure 57-2 Diagnosis and Management of Constipation.

fluid intake. Long, small-caliber or long, flat stools can be seen with inappropriate relaxation of the puborectalis muscle and external anal sphincter during evacuation. Small-caliber stool can also be associated with tumors, and endoscopic evaluation with colonoscopy should be performed to exclude malignancy.

Standard diagnostic testing includes the balloon expulsion test, colonic transit study, anorectal manometry, and defecography (Fig. 57-2). Other studies such as pelvic floor

electromyography, colonic motility testing, and pudendal nerve latency testing are not available at all testing centers; adequate diagnostic information can usually be obtained without these studies.

The *balloon expulsion study* is a simple test that determines whether the patient can evacuate a 50-mL air- or water-filled balloon. Some advocate balloon expulsion testing as a screening study for pelvic floor dysfunction. Inability to expel the balloon may reflect inability to appro-

priately relax the pelvic floor to allow defecation, as seen with pelvic floor dyssynergia or paradoxical contraction of the pelvic floor in response to straining.

Colonic transit testing evaluates the time required for material to move through the colon. The most cost-effective method to determine the colonic transit time is by ingestion of radiopaque markers in conjunction with having one or more abdominal x-rays obtained several days after ingestion. The number of retained radiopaque markers is used to determine the colonic transit time. There are several protocols for colonic transit marker studies, and the various protocols correlate well with each other. The colonic transit time can also be determined by radionuclide gamma scintigraphic studies. Radionuclide scintigraphic assessment of colon transit is not readily available, but it, too, correlates well with determination of colon transit time when compared with radiopaque markers.

Anorectal manometry testing provides useful information about rectal sensation, internal anal sphincter relaxation, rectal compliance, and pelvic floor responses to straining. Anorectal manometry testing is performed by placing pressure-recording catheters across the anal sphincters. Measurements are obtained by introducing increments of air into a balloon attached to the tip of the catheter. Balloon expulsion testing is often done in conjunction with anorectal manometry. Surface electromyography can be done with skin pads or anal plugs and is often done at the time of anorectal manometry to evaluate for external anal sphincter and puborectalis dysfunction such as paradoxical pelvic floor motions that hinder evacuation. It is very helpful if there is a history of childhood constipation. Screening for Hirschsprung's disease is easily done with manometry. Hirschsprung's disease is excluded by demonstrating appropriate relaxation of the internal anal sphincter in response to balloon distention.

Defecography involves introducing soft barium paste into the rectum and then having the patient evacuate during fluoroscopic exam. It can provide information about the anorectal angle, pelvic floor descent, retentive rectoceles, intussusception, and rectal prolapse.

Management and Therapy

Optimum Treatment

Initial management should include counseling regarding adequate fiber intake, sufficient fluid intake, and physical activity. Most Western diets do not provide the minimum recommended daily requirement of dietary fiber. If the fiber content is deficient, the patient should be instructed to gradually increase the fiber intake to 20 to 35 g daily. Psyllium supplements are effective in increasing fiber intake (Fig. 57-2). Any increase in daily dietary fiber content should occur over a period of days because high dietary fiber is often associated with abdominal bloating

and increased flatulence, and individuals with constipation often experience bloating. Fiber should be avoided if there is concern of colonic blockage or stricture because an impaction may develop proximal to the stricture. Patients should drink a minimum of six glasses of fluid, preferably water and fruit juices, daily. Physical limitations often restrict activity, especially in older individuals; nonetheless, the patient should be strongly encouraged to undertake physical activity. Often with attention to fiber, water, and physical activity, the symptoms of constipation improve. If there is still inadequate relief after these initial steps, the history should guide further testing.

Patients with infrequent bowel movements without excessive straining may benefit from stool softening agents such as docusate. Determination of the colonic transit time is indicated if there is inadequate symptom relief despite compliance with basic management. Documented slow colon transit or colonic inertia may be managed with laxatives. If long-term laxative use is required, bulk-forming agents (psyllium), hyperosmolar laxatives (polyethylene glycol, lactulose and sorbitol), and saline laxatives (magnesium sulfate, magnesium citrate, and magnesium phosphate) are preferred to stimulant laxatives. Stimulant laxatives are not recommended for long-term use because they may cause degeneration of the enteric nerve plexus, in turn exacerbating the symptoms of constipation. Common stimulant laxatives include bisacodyl, senna, and cascara. Lubiprostone is a novel type 2 chloride channel activator used to treat chronic constipation by increasing the number of spontaneous bowel movements, improving the stool consistency, and decreasing straining associated with constipation.

Anorectal manometry testing is indicated if there is concern about Hirschsprung's disease and sensory perception or pelvic floor dysfunction. Balloon expulsion testing is often done at the time of anorectal manometry testing. If pelvic floor dysfunction is identified, pelvic floor retraining with biofeedback may be beneficial. Patients are taught to relax, instead of contract, the pelvic floor musculature when attempting to evacuate.

Subtotal colectomy with ileorectal anastomosis is reserved for individuals with constipation that does not respond to conservative measures and to laxative therapy and who do not have pelvic floor dysfunction, including pelvic floor dyssynergia or outlet obstruction. These individuals should have demonstrated normal small bowel neuromuscular function because small bowel neuropathy and small bowel myopathy can contribute to constipation.

Avoiding Treatment Errors

Successful treatment of constipation requires taking a detailed history and tailoring the evaluation to the patient's symptoms. In simple cases, increasing fluid intake along with fiber supplementation and increased activity may provide significant improvement. Diagnostic testing should

be reserved for individuals who have failed simple measures, including management of any organic condition that may be contributing to the symptoms.

Future Directions

Tergaserod is a highly selective, partial 5-HT₄ receptor agonist with prokinetic properties that increase gastrointestinal transit. Recently, tergaserod was withdrawn from the market under advice from the U.S. Food and Drug Administration secondary to an increased number of cardiovascular events noted in patients taking the drug as part of a treatment study when compared with patients receiving a placebo. In the future, tergaserod may become commercially available for selected patients without significant cardiovascular risks. Recent research includes the clinical investigation of methylnaltrexone for opioid-induced constipation in individuals with advanced illness requiring narcotic analgesics. Methylnaltrexone is derived from naloxone and is a quaternary methyl agent that does not cross the blood-brain barrier. Clinical trials have shown that methylnaltrexone reduces the symptoms of constipation without clinical evidence of loss of analgesia or withdrawal.

This medication may prove useful in narcotic-induced constipation.

Common Anorectal Disorders and Colonic Diseases

Introduction

Anorectal disorders, which often present as pain on defecation, are common and can pose very serious problems for patients. The three most frequent causes of pain on defecation are thrombosed hemorrhoids, fissure in ano, and perirectal abscess. In evaluating these patients, it is important to obtain a thorough history concentrating on the events leading up to the problem and on the aspects of defecation that are troublesome. General physical examination includes an anorectal examination concentrating on external inspection, digital examination, and anoscopy, which allows direct visualization of the anal canal. The pain is often too severe to allow a good anoscopic examination without anesthesia, and some patients may need a general anesthetic to facilitate the diagnosis.

The two most common diseases that afflict the colon relate to the appendix (appendicitis) and diverticuli (diverticulitis). Each presents with somewhat typical signs and symptoms, yet commonly poses challenges in diagnosis and management.

THROMBOSED HEMORRHOIDS

Etiology and Pathogenesis

Hemorrhoids are protrusions of the submucosal veins into the anal canal (Fig. 58-1). External hemorrhoids arise from the inferior hemorrhoidal plexus, occur below the dentate line, and are covered by squamous epithelium. Internal hemorrhoids arise from the superior hemorrhoidal plexus above the dentate line and are covered by rectal mucosa. Mixed hemorrhoids are a combination of both the internal and external varieties. Hemorrhoids are usually caused by constipation with repeated straining to pass hard stool, leading to stretching of the anal mucosa, engorgement, and possible prolapse. If prolapsed hemorrhoids remain out and are not reduced, stasis leads to thrombosis.

Clinical Presentation

The most common symptom of patients with hemorrhoids is bleeding occurring during or after defecation, exacerb-

bated by straining. Pain usually does not occur unless the hemorrhoid is thrombosed or ulcerated. A prolapsed thrombosed hemorrhoid appears blue or purplish on physical examination. Many patients have edematous tissue around the thrombosed hemorrhoid. The area is usually tender because of stretching of the anoderm.

Differential Diagnosis

Prolapsed hemorrhoids that are not thrombosed, anal condylomata, epidermal inclusion cysts, true rectal prolapse, and sentinel pile (associated with a fissure) deserve consideration. Other causal associations include pregnancy, which can cause increased venous pressure in the hemorrhoidal plexus, or the presence of cirrhosis with portal hypertension.

Diagnostic Approach

Generally, the diagnosis is obvious based on direct physical examination of the external anal canal. Occasionally,

Figure 58-1 Hemorrhoids.

optimal visualization may require examination under local or general anesthesia, especially when the patient is experiencing severe pain. Anoscopy is rarely indicated.

Management and Therapy

Optimum Treatment

Therapy is generally surgical. Incision and drainage of the clot may be adequate, but the excision of the thrombosed hemorrhoid itself is preferable because it allows the tissue to reduce and speeds recovery. Patients can have a local anesthetic with both procedures. Less severe cases can be treated with sitz baths, local steroid creams, and bulk-forming agents. Altering diet, stool consistency, and bowel habits is critical for the long-term treatment of these patients.

Avoiding Treatment Errors

The importance of avoiding errors in diagnosis that lead to a delay in therapy deserves special emphasis. Trials of topical steroids or anesthetics only “prolong the agony” for these patients, whereas timely surgical intervention results in almost immediate relief.

FISSURE IN ANO

Etiology and Pathogenesis

Fissure in ano is a superficial laceration or tear in the anoderm occurring just below the dentate line. The combination of constipation with hard stools and sphincter spasm causes the patient to strain against a spastic sphincter and, as a result, causes the anoderm to give or tear. The skin

in this area is richly innervated by sensory fibers, and the patient is enveloped in a cycle of pain, inflammation, spasm, and more pain. As the patient defecates, the area stretches again, leading to pain that can last several hours. Often, patients will resist having a bowel movement, making the subsequent passage of hard stool even more painful.

Clinical Presentation

The patient presents usually with an acute event or tear causing a cycle of pain and spasm. The physical finding that is pathognomonic in this entity is a sentinel pile or skin tag (Fig. 58-2). This occurs in the posterior midline in 90% of adults. In children, 15% to 20% of lesions can be seen anteriorly. In general, having the patient lie in the lateral decubitus position and spreading the buttocks and asking the patient to strain allows the fissure to be seen. The anoderm will evert out, and the fissure can usually be seen underneath the sentinel pile. Digital examination should be avoided because the area is usually extremely tender. If the diagnosis is suspected and a fissure cannot actually be seen, it may be necessary to perform an examination with the patient under general anesthesia.

Differential Diagnosis

Some patients can sustain tears in this area from physical trauma. Patients with ulcerative colitis commonly have fissures. Various infectious lesions can cause fissures (e.g., amebiasis and tuberculosis), but these are generally quite rare.

Diagnostic Approach

A good history and physical examination are essential to diagnosis. Occasionally, anoscopy with the patient under general anesthesia is necessary.

Management and Therapy

Optimum Treatment

The goal of therapy is to break the spasm of the internal sphincter, so as to reduce pain and improve blood flow to the healing ulcer. Initial therapy for an anal fissure is medical in nature because more than 80% of acute anal fissures resolve without further therapy. First-line therapy includes stool softeners, fiber supplements, and sitz baths for symptomatic relief of pain; they are effective in perhaps 35% of patients.

Nitroglycerin and calcium channel blocker ointments have enjoyed widespread use as second-line therapy. Both serve to relax the internal sphincter muscle and have been met with variable success, 45% to 68% initial healing with up to 35% recurrence rates. Noncompliance with the use of nitroglycerin is common because significant headaches occur in up to 50% of patients.

The injection of botulinum toxin A (BTX) into the internal anal sphincter produces, in effect, a chemical sphincterotomy that lasts up to 3 months. Healing rates up to 90% occur with BTX therapy, with very low recurrence rates.

The gold standard treatment is a lateral anal sphincterotomy, performed by incising the inferior 1 cm of the internal anal sphincter with either an open or closed approach. Complications include bleeding and, rarely, abscess formation and fistula. Incontinence, the most feared complication, occurs when the sphincterotomy performed is too large. This is avoidable with careful surgical technique. Although patients often achieve prompt relief with this procedure, those with chronic fissures may take longer to heal and should be advised accordingly. Comparison of botulinum toxin with lateral internal sphincterotomy showed that at 1 year, more fissures were healed after surgery (94%) than with the injection (75%).

Avoiding Treatment Errors

The timely diagnosis of an anal fissure cannot be over-emphasized. Referral to a specialist should not be unduly delayed because therapy results in nearly immediate improvement in a patient's symptoms.

PERIRECTAL ABSCESS

Etiology and Pathogenesis

Almost all anorectal suppurative disease results from infection of the anal glands that extend from the anal crypts, located along the dentate line at the base of the columns of Morgagni. This leads to crypt abscesses, which then penetrate through the wall of the rectum into the perirectal space. Nearly all the anal glands terminate in the intersphincteric plane; therefore, abscesses tend to originate there, and then can travel up, down, or circumferentially around the anus (Fig. 58-3). Perirectal abscesses are classified according to where they are located: perianal, ischio-rectal, intersphincteric, or supralelevator. Perianal abscesses are the most common, occurring about 50% of the time, whereas the least common type is the supralelevator abscess, about 5%.

Clinical Presentation

Patients with perirectal abscesses present with swelling, throbbing, and continuous pain. The onset of pain is usually slower than a fissure and can be more diffuse. On physical examination, there may be edema, induration, or erythema overlying the abscess. Because of the thick fascial bands around the anus, fluctuance is a relatively late sign. Digital examination may be rather painful. If the patient is able to tolerate it, the digital examination can show boggy.

Figure 58-2 Anal Fissure.

Differential Diagnosis

Very few entities are included in the differential diagnosis of perirectal abscess. Chronic perirectal abscesses with fistula formation are well-known complications of Crohn's disease. Rarely, patients with tuberculosis and actinomycosis present with abscesses in the perirectal area. A localized soft tissue infection from chronic bedsores, as seen in paraplegic patients, can lead to diagnostic confusion.

Diagnostic Approach

The diagnosis is usually made by careful physical examination, looking for induration and occasionally boggy on the rectal examination. Some clinicians have advocated a computed tomography (CT) scan in difficult patients.

Examination with the patient under anesthesia, with aspiration of the suspected area, may be necessary. Where the perirectal abscess should be drained is obvious in many cases. Newer adjuncts, such as endorectal ultrasound, are helpful in selected patients but generally are not necessary.

Management and Therapy

Optimum Treatment

The critical approach to perirectal abscess is incision and drainage. Antibiotics are also important but are not adequate alone. Localized perianal abscesses can be drained under local anesthesia. Patients with more complicated abscesses require examination in the operating room under

Figure 58-3 Surgical Management of Anorectal Abscess.

anesthesia. A circumanal incision in the inner sphincteric groove is the safest incision to avoid damage to the sphincters (see Fig. 58-3). If the offending crypt can be identified, then a radial incision can be used to connect it in a submucosal fashion to allow better drainage. Fistula in ano occurs in about 10% to 15% of cases, and these usually drain into the rectum into an area in which the offending crypt has not been identified. Patients with fistula in ano should be referred to a surgeon because of the complexity of management.

Avoiding Treatment Errors

The most common pitfall in the management of perirectal abscesses is over-reliance on antibiotics. Perirectal abscess is a surgical disease, and timely operative intervention is imperative.

DIVERTICULAR DISEASE

Diverticular disease, which includes diverticulosis and diverticulitis, is very common in Western populations.

Some estimates place the incidence of diverticular disease at 10% per decade of life. Most patients with diverticulosis remain symptom free; however, 10% to 30% develop complications, with diverticulitis being the most common. Diverticulitis accounts for more than 200,000 hospitalizations annually and health care costs of more than \$300 million (Fig. 58-4).

Etiology and Pathogenesis

Colonic diverticula are actually pseudodiverticula, out-pouching of the mucosa through weak areas of the muscularis where blood vessels penetrate. The relatively lower fiber content of Western diets leads to firmer, less bulky stools that require higher intramural pressures within the colon to propel them. The increased pressures then lead to the formation of diverticula at the areas of relative weakness within the colonic wall. Diverticula occur mainly in the left colon, with up to 90% of patients having involvement of the sigmoid colon and only 15% having right-sided disease. They can number from one to hundreds, with the typical size being less than 10 mm, but they can also be as large 2 cm in diameter.

Diverticulitis is characterized as inflammation, infection, or both associated with diverticula. It occurs as the result of perforation of a single diverticulum. Uncomplicated diverticulitis results in a localized phlegmon. Complicated diverticulitis is associated with abscess formation, free perforation with peritonitis, fistula to adjacent viscera, or obstruction. Lower gastrointestinal bleeding may also occur with diverticulosis.

Clinical Presentation

Abdominal pain, typically in the left lower quadrant, is the most common presenting symptom of diverticulitis. The pain may be intermittent or constant. It is frequently associated with a change in bowel habits, either diarrhea or constipation. Anorexia, nausea, and vomiting also may occur, as well as fever. Dysuria and urinary frequency can result from bladder irritation by the adjacent inflamed sigmoid colon.

Differential Diagnosis

The differential diagnosis for diverticulitis is vast. Acute appendicitis is perhaps the most common misdiagnosis that is made. Other diagnoses to be considered are inflammatory bowel disease, ischemic or infectious colitis, peptic ulcer disease, colorectal cancer, and gynecologic abnormalities.

Diagnostic Approach

The diagnosis of acute diverticulitis is commonly made on clinical grounds based on the patient's history, signs, and symptoms and physical exam. Radiologic imaging is the

most common modality used not only to confirm the diagnosis but also to assess its severity and the presence of complications.

Plain abdominal and chest films are typically done in the initial evaluation of patients with abdominal pain. Free intraperitoneal air is detected in about 10% of patients with acute diverticulitis. More commonly, nonspecific findings such as ileus are apparent.

Contrast studies such as barium or water-soluble contrast enemas had been the gold standard in diagnosing diverticulitis. These have been supplanted by cross-sectional imaging studies such as CT, magnetic resonance imaging, and ultrasound to a lesser extent.

CT scanning has a sensitivity approaching 98% in diagnosing diverticulitis. It also provides imaging of adjacent structures and the ability to determine the severity of the disease. Mild disease is characterized by bowel wall thickening and pericolic fat stranding. In moderate diverticulitis, the bowel wall thickening is greater than 3 mm with a phlegmon or small abscess. In severe diverticulitis, there is an abscess greater than 5 cm with or without local or free perforation with free intraperitoneal air (Fig. 58-5).

Management and Therapy

Optimum Treatment

Patients with mild diverticulitis (no peritoneal signs and the ability to take fluids) can be treated as an outpatient with close follow-up. Oral antibiotics directed toward gram-negative and anaerobic organisms should be administered for 7 to 10 days.

Patients with moderate to severe disease, complications, or comorbidities require hospitalization. Broad-spectrum antibiotics should be started with the expectation that clinical improvement should occur within 2 to 3 days. About 75% of these patients respond, and the remaining patients come to surgical intervention.

Patients with small, localized, pericolic abscesses can be managed medically with antibiotics. Larger abscesses are best treated with CT-guided drainage, which has been proved very successful in managing these collections because it allows the patient to undergo an elective, less risky surgical resection at a later date after the localized sepsis has resolved.

Indications for immediate surgical intervention include pneumoperitoneum, peritonitis, sepsis, inability to drain the abscess percutaneously, and failure of medical management. The indications for elective surgery are not as well defined. The risk for developing recurrent diverticulitis after an initial episode that responded to medical treatment is about 30%. After a second episode, the chance of a third episode is more than 50%. Because recurrent episodes are less likely to respond to medical management, surgical resection of the involved area should be considered for the second episode of documented uncomplicated diverticulitis.

Figure 58-4 Diverticular Disease.

The surgical options that are available in the management of diverticulitis traditionally differ for emergent versus nonemergent, elective operations. In the emergency setting where free perforation with fecal contamination, peritonitis with abscess formation, or systemic sepsis is present, there is a significant risk for anastomotic dehiscence and its associated morbidity if a resection with primary anastomosis is performed. Hence, in these instances, the strategy is to manage the patient in a two-stage manner. At the time of the initial operation, the

affected bowel, usually the sigmoid colon, is resected. A colostomy is created of the proximal colon and the site of distal transection (distal sigmoid-proximal rectum) is left within the pelvis as a closed off stump. It is estimated that 50,000 colostomies are created in this country per year under this circumstance. After the patient has recuperated from this initial procedure, the option exists for the second stage, namely takedown of the colostomy with reanastomosis. About 60% of these patients do elect to have their colostomy reversed.

Figure 58-5 Diverticular Disease, with Computed Tomography Scans Showing a Thickened Wall and Diverticula.

CT scan of the abdomen. Arrows indicate the sigmoid wall, which is thickened and associated with diverticula.

Abdominal CT scan. Arrows indicate a large phlegmonous area associated with the descending colon, which has numerous diverticula.

In the elective setting when the patient is otherwise healthy and local inflammation and infection have resolved, primary resection of the involved bowel with immediate anastomosis is the procedure of choice.

Avoiding Treatment Errors

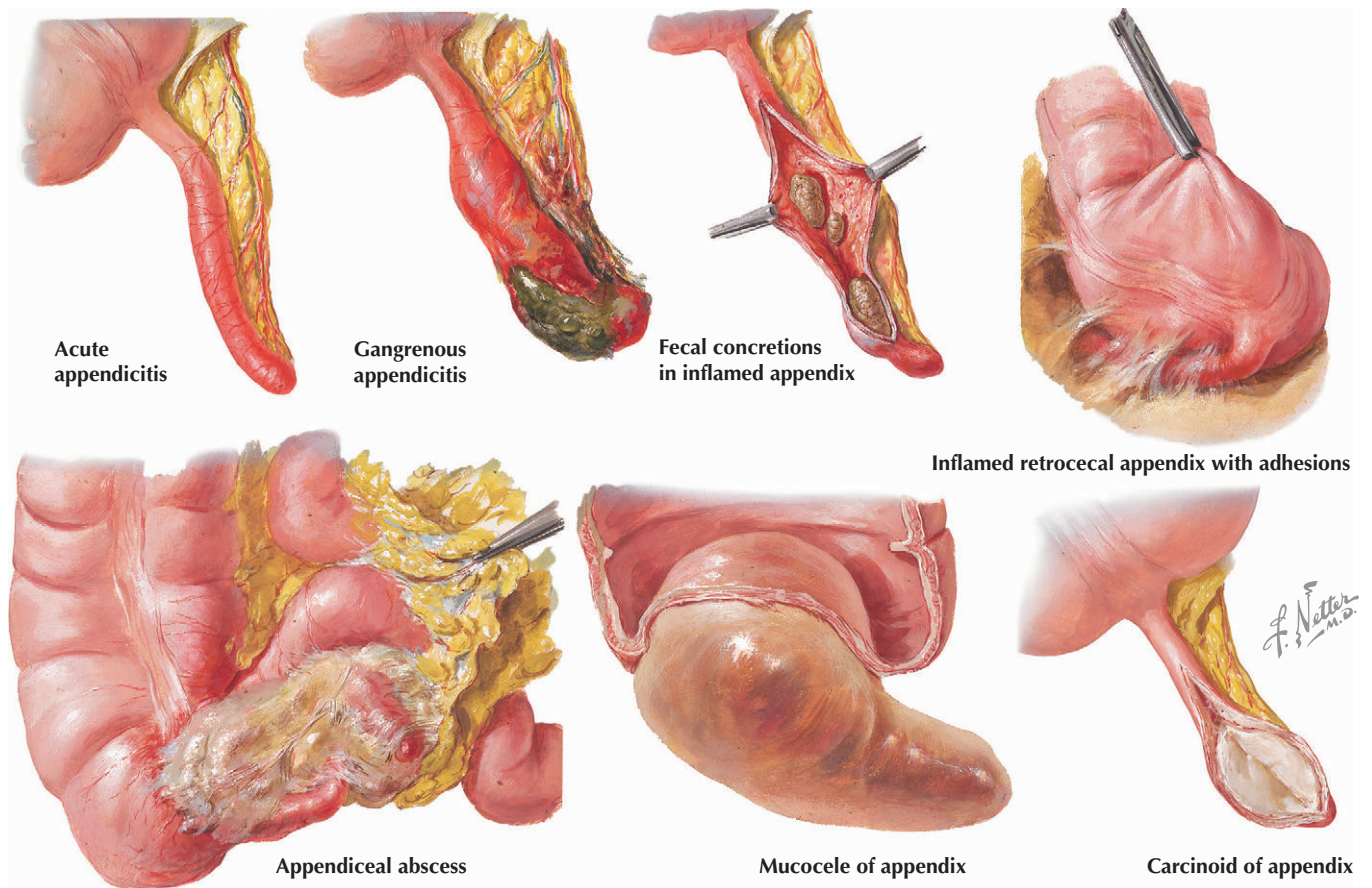

The widespread use of CT and magnetic resonance imaging have greatly aided in the diagnosis of diverticulitis and its complications. A team approach in its management is frequently indicated because coordination of care among primary care physicians, radiologists, gastroenterologists, and surgeons is essential to ensure optimal patient outcomes.

Future Directions

Whether the far-reaching beneficial effects of increasing the amount of fiber in Western diets will have an effect on the future incidence of diverticular disease and its complications remains in question.

The application of laparoscopic surgery in the management of diverticular disease is becoming more the norm than the exception. It has a low complication rate (<10%) and has shortened hospital stays (2 to 5 days) in most series.

Although the two-stage surgical approach in the management of patients with complications of diverticulitis had been considered the safest alternative, the second stage

Figure 58-6 Progressive Inflammation of the Appendix with Fecaliths.

of the procedure, colostomy takedown, is not without morbidity. Anastomotic dehiscence rates for this operation average 4%; wound infections are 4%; and mortality approaches 1%. In light of these complication rates, there are recent reports that even in the presence of abscesses or localized sepsis, resection with primary anastomosis can be performed with satisfactory results.

The traditional acceptance of surgery after two episodes of uncomplicated diverticulitis has been brought into question. Recent analysis supports performing colectomy after the fourth rather than the second episode in patients older than 50 years. This practice resulted in 0.5% fewer deaths, 0.7% fewer colostomies, and saved \$1,035 per patient.

APPENDICITIS

Leonardo da Vinci was the first to make anatomic mention of the appendix in the 15th century, and the German surgeon Lorentz Heister first recognized appendicitis in a case report in 1711. The lifetime risk for developing appendicitis is about 8%. Appendectomy is the most common emergency operation performed in the world, with more than 250,000 procedures performed in the United States per year.

Etiology and Pathogenesis

Appendicitis occurs when the appendiceal lumen becomes obstructed (Fig. 58-6). The cause of obstruction can be a fecalith, tumor, foreign body, or hypertrophied lymphatic tissue. Luminal obstruction then produces an increase in intraluminal pressure, which in turn results in venous hypertension, ischemia of the appendiceal wall, and subsequent bacterial invasion of the appendix with necrosis and perforation.

Clinical Presentation

Early on in the progression of appendicitis, distention of the appendiceal lumen typically results in dull, poorly characterized viscerally mediated pain located in the peri-umbilical area. As the inflammatory process progresses to involve the serosal surface, parietal irritation localizes pain to the right lower quadrant, associated with the location of the appendix. Further progression may then lead to perforation with potential abscess formation. Many patients report anorexia and low-grade temperatures.

Differential Diagnosis

Many, if not most, abdominal pathologic processes may mimic appendicitis. These include bacterial or viral enteri-

tis, mesenteric adenitis, pyelonephritis, renal colic, acute pancreatitis, Crohn's disease, cecal or sigmoid diverticulitis, small bowel obstruction, ectopic pregnancy, ruptured ovarian cyst, ovarian torsion, and acute salpingitis or tubo-ovarian abscess.

Diagnostic Approach

Appendicitis can be a diagnostic challenge because there is no single symptom, finding, or laboratory test that is completely sensitive or specific for the diagnosis. A detailed history and physical exam are the cornerstones in making the diagnosis. Patients with early appendicitis typically appear slightly ill and may manifest low-grade temperature. Localized peritoneal irritation can be detected with localized tenderness in the right lower quadrant as well as the presence of guarding, cough tenderness, or associated Rovsing, psoas, or obturator signs. Elevated white blood cell counts commonly are in the 11,000 to 17,000/mm³. Abdominal CT scans are considered the imaging study of choice in nonclassic cases of appendicitis but are increasingly used in more routine cases.

Management and Therapy

Optimum Treatment

Since its introduction in 1894 by McBurney, appendectomy is the treatment of choice for acute appendicitis, and the technique has remained nearly unchanged. Appendectomies are now commonly performed by the laparoscopic approach. The advantage of laparoscopy over open appendectomy relates to quicker and less painful recovery, fewer complications, and better cosmesis.

Avoiding Treatment Errors

As with most surgical diseases, making the correct diagnosis is key. Conventional wisdom has taught that a negative appendectomy rate (no appendicitis at the time of surgery) should be on the order of 10%. Delaying surgery until the diagnosis is more certain may lead to an increased rate of perforation and other potential complications.

Future Directions

In many instances, the diagnosis of appendicitis can be made on clinical grounds alone. With the development of rapid helical and multidetector CT scanners, CT imaging increasingly is used as the first test to evaluate patients with acute abdominal pain. Clearly, many CT scans are performed unnecessarily in the evaluation of the patient with appendicitis. The proper role of imaging in diagnosing appendicitis has yet to be determined.

EVIDENCE

1. Brisinda G, Cadeddu F, Brandara F, et al: Randomized clinical trial comparing botulinum toxin injections with 0.2 percent nitroglycerin ointment for chronic anal fissure. *Br J Surg* 94:162-167, 2007.

One hundred patients were randomized to receive either nitroglycerin or BTX for chronic anal fissure. Although treatment with either agent is effective as an alternative to surgery, Botox is the more effective agent.

2. Lan P, Wu X, Zhou X, et al: The safety and efficacy of stapled hemorrhoidectomy in the treatment of hemorrhoids: A systematic review and meta-analysis of ten randomized control trials. *Int J Colorectal Dis* 21:172-178, 2006.

A meta-analysis includes 10 randomized controlled studies that evaluated the safety and efficacy of PPH compared with open hemorrhoidectomy. Stapled hemorrhoidectomy may be as safe as traditional open hemorrhoidectomy.

3. Menten BB, Irkorucu O, Akin M, et al: Comparison of botulinum toxin injection and lateral internal sphincterotomy for the treatment of chronic anal fissure. *Dis Colon Rectum* 46(2):232-237, 2003.

The healing rate of chronic anal fissure is high with Botox; the procedure allows an earlier recovery and fewer complications when compared with sphincterotomy. It occasionally requires repeat injection, and the healing rate is lower in this circumstance.

4. Salem L, Veenstra DL, Sullivan SD, Flum DR: The timing of elective colectomy in diverticulitis: A decision analysis. *J Am Coll Surg* 199(6):904-912, 2004.

Decision and cost analysis simulated clinical and economic outcomes after recovery from diverticulitis. This study suggested that the expectant management is associated with lower rates of death and colostomy and is cost-saving for both younger and older patients.

5. Sauerland S, Lefering R, Neugebauer EA: Laparoscopic versus open surgery for suspected appendicitis (review). *Cochrane Database Syst Rev* 4:CD001546, 2004.

Fifty-four studies that compared open versus laparoscopic appendectomies were reviewed. Recommendations are to use laparoscopy and laparoscopic appendectomy in patients with suspected appendicitis unless laparoscopy is contraindicated or not feasible. Especially young, female, obese and employed patients appear to benefit.

Irritable Bowel Syndrome

Introduction

Irritable bowel syndrome (IBS), the most common functional gastrointestinal (GI) disorder, is defined as a combination of chronic or recurrent gastrointestinal symptoms not explained by structural or biochemical abnormalities. Studies show that 8% to 23% of adults in the Western world have IBS of varying severity. It accounts for 12% of primary care and 28% of gastroenterologic practice visits yearly.

IBS affects both genders and all ages and demographic groups. Prevalence is higher in females (female-to-male ratio, 2 : 1 in the community setting) and decreases with age. Patients with IBS report lower health-related quality of life as compared with patients who have other chronic GI and non-GI disorders, or healthy controls. IBS poses a considerable socioeconomic burden in terms of health care utilization and costs. On average, patients with IBS miss 3 times more workdays and have significantly more health care and physician visits annually than people without bowel symptoms. The cost of health services for patients with IBS is significantly higher than that for controls. The estimated annual direct cost in the United States is more than \$2 billion, and the calculated indirect costs are as high as \$20 billion.

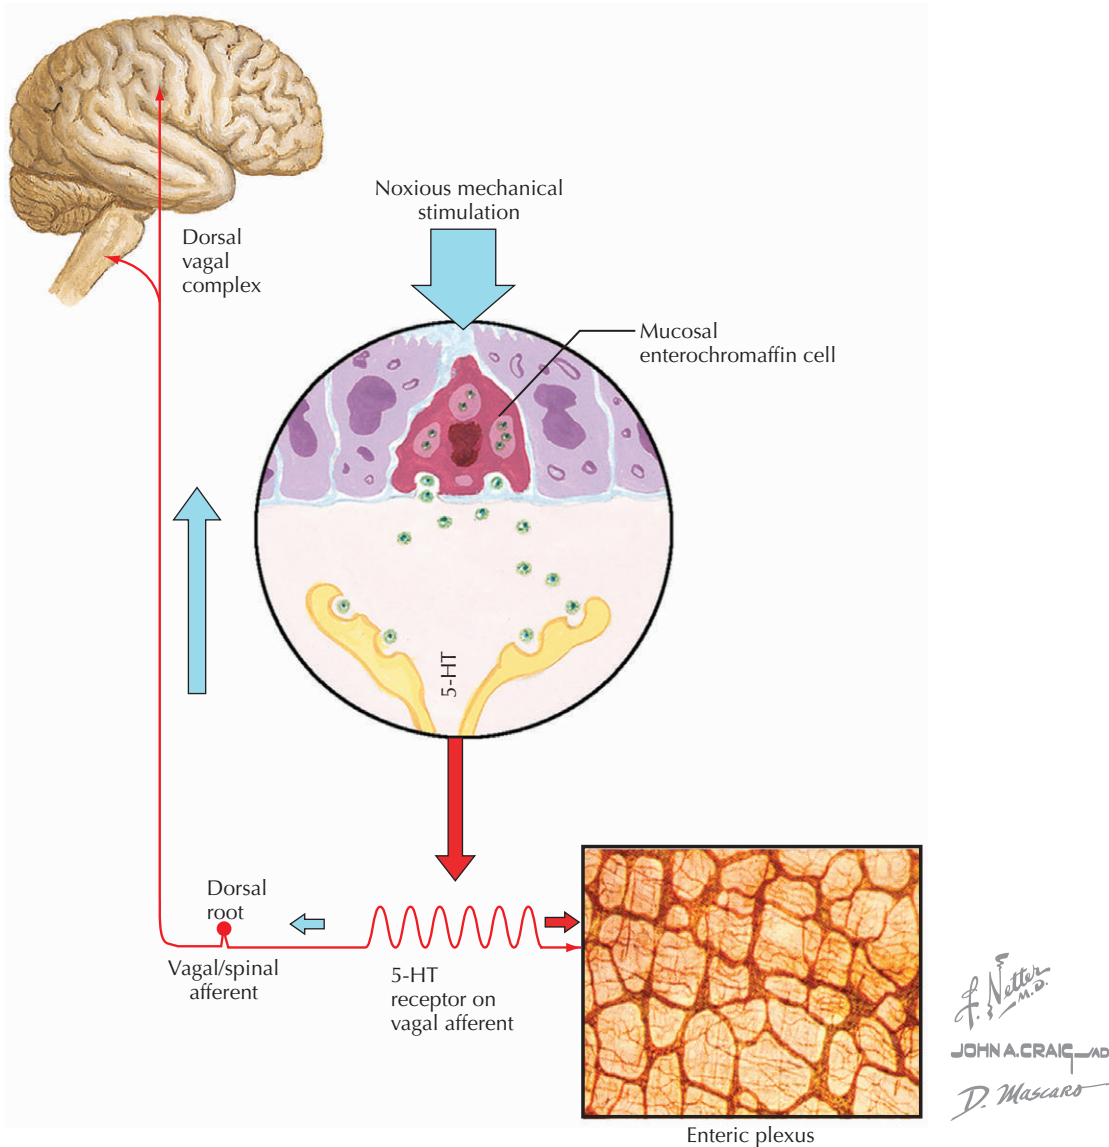

Etiology and Pathogenesis

There is no unique pathophysiologic mechanism that explains the symptoms of IBS. It is best understood as an integration of several contributing features. Patients may have exaggerated intestinal motor activity in response to intrinsic (e.g., meals, intraluminal balloon distention) or environmental (e.g., psychological stress) stimuli. However, although certain motility abnormalities have been described, they are not unique or well correlated with pain or with the discomfort that characterize IBS. Patients can also exhibit lower pain thresholds to intestinal or rectal distention (i.e., visceral hypersensitivity and altered pain perception).

The pathophysiologic mechanisms by which visceral hypersensitivity and altered perception are induced or modulated are incompletely understood. Recent studies show that the autonomic nervous system, the neuroendocrine system, and the central nervous system (CNS) have a major role in processing and modulating afferent visceral information from the gut and influencing the conscious experience of visceral sensations and pain through activation of 5-HT afferent receptors (Fig. 59-1). Thus, the experience of IBS symptoms can result from dysfunction

at the level of the gut (i.e., abnormal intestinal motor or sensory function) or from dysfunction at any level of neural control of the gut, including the autonomic nervous system, spinal pathways, and CNS (i.e., the brain-gut axis). Figure 59-2 describes the physiologic interactions between brain and gut as well as the visceral pain modulation system.

Considerable attention has been given to potential links between IBS and several predisposing genetic and environmental factors. Recent genetic studies have shown that IBS is twice as prevalent in monozygotic as in dizygotic twins and suggested an association between IBS and several possible gene pleomorphisms (e.g., serotonin reuptake transporter, interleukin-10, and GNB3 protein). The role of intestinal inflammation and activation of the mucosal immune system in the pathophysiology of IBS, as well as in the mechanisms responsible for intestinal dysmotility and visceral hypersensitivity, has also been investigated. Epidemiologic studies have shown that IBS can occur in up to 30% of patients recovering from acute bacterial gastroenteritis, leading to identifying acute GI infections as the greatest single risk factor for IBS. Other studies reported a clinical association between IBS and inflammatory conditions (e.g., inflammatory bowel diseases) and

Figure 59-1 Irritable Bowel Syndrome: Serotonin (5-HT) Receptors on Sensory Afferent Nerves.

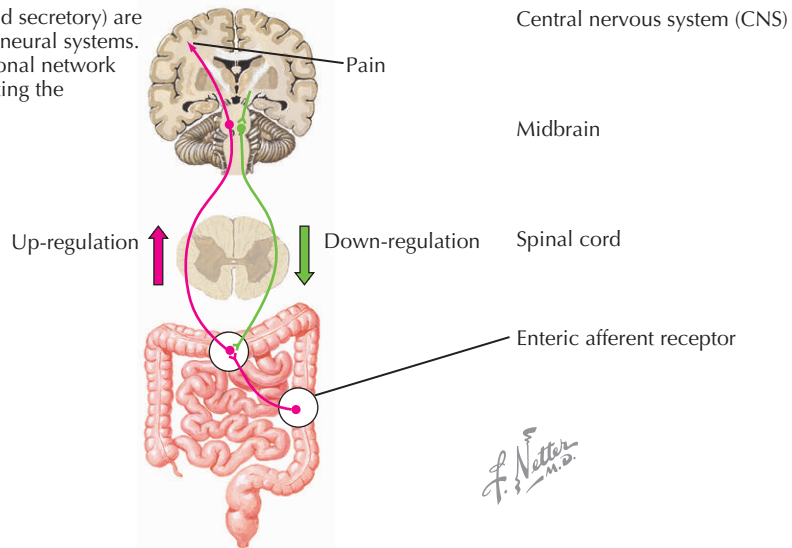

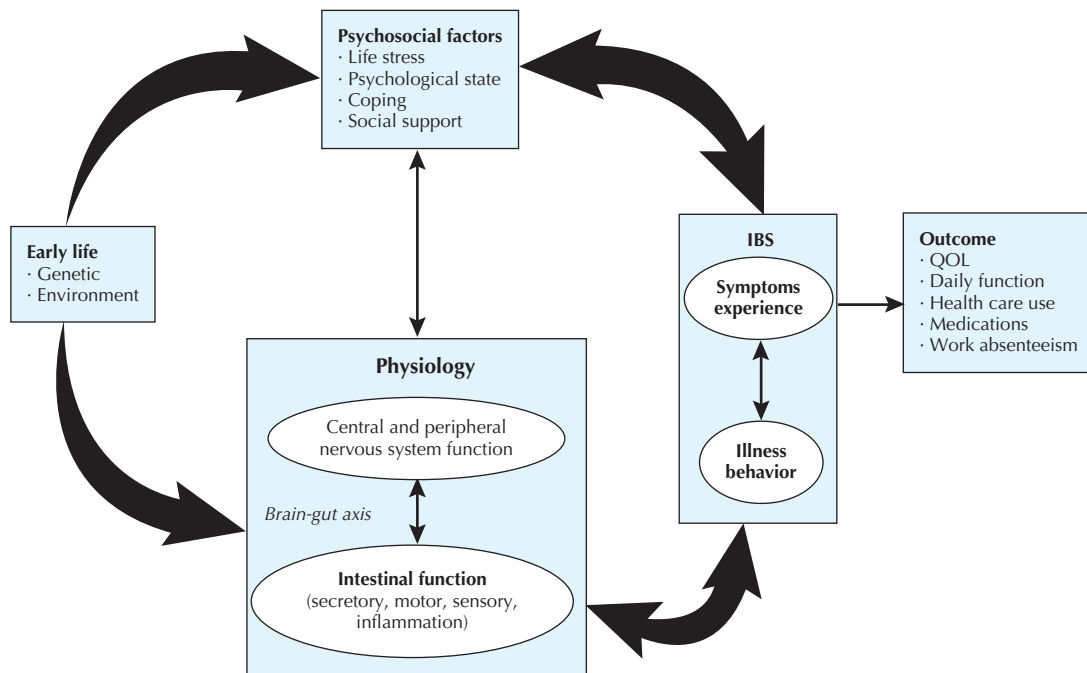

documented increased infiltration of chronic inflammatory and activated immunocompetent cells (e.g., intraepithelial lymphocytes and mast cells) in the intestinal mucosa of patients with IBS, suggesting a possible etiologic role for structural or functional changes following acute inflammation or low-grade subclinical inflammation in the pathophysiology of the disorder.

Psychological factors, through their effects on the CNS (e.g., brain cognitive and affective centers) or through autonomic nervous system and neuroendocrine (e.g., hypothalamic-pituitary-adrenal axis) pathways, also influence symptom perception as well as behavioral and emotional responses. Psychological distress affects intestinal motor function and reduces the intestinal sensation threshold, leading to increased gastrointestinal perception.

Because both physiologic and psychological factors contribute to the patient's symptoms and illness, a biopsychosocial model of illness and disease is used for IBS (Fig. 59-3). The biopsychosocial model of illness and disease integrates the physiologic, psychological, behavioral, and environmental factors that contribute to clinical presentation and outcome. Consistent with this model, all these factors interact simultaneously at multiple levels to define illness experience and outcome. The relative contribution and importance of each factor vary among patients and in an individual patient over time. Thus, the clinical presentation, the severity of the symptoms, and the outcome are determined by interaction of all these factors. This complexity carries important implications for establishing a comprehensive and effective diagnosis and treatment plan for patients with IBS.

Figure 59-2 Irritable Bowel Syndrome: Brain-Gut Axis.

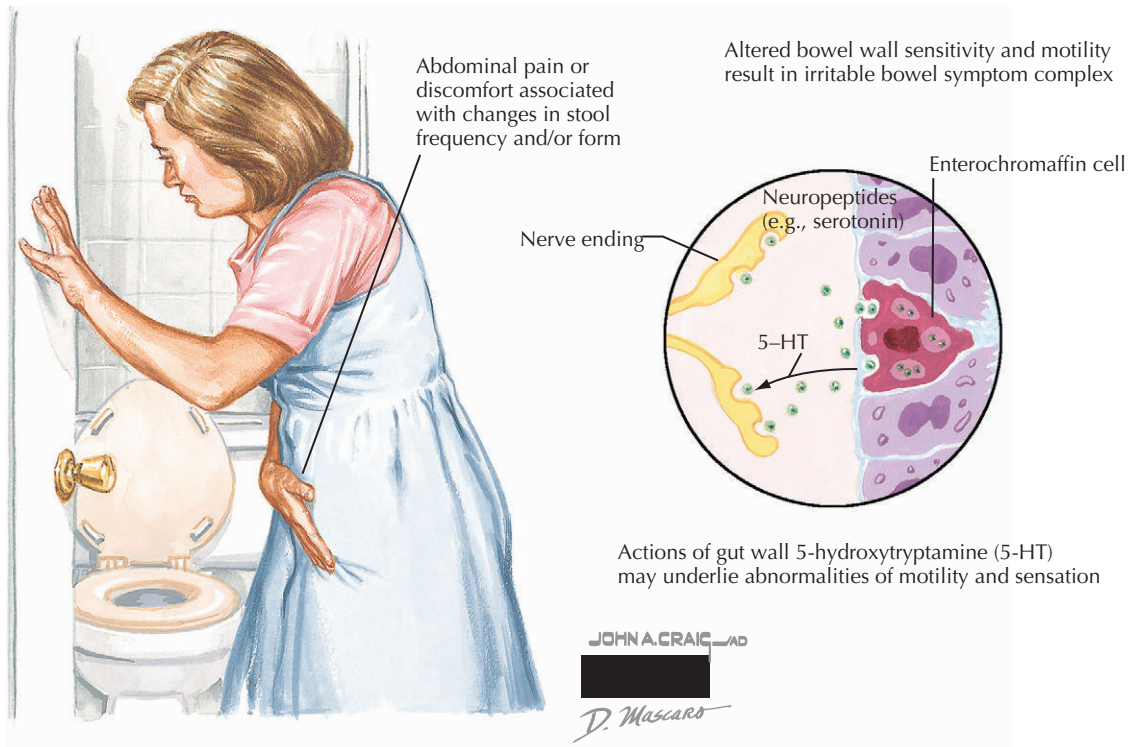

All gut functions (motor, sensory, and secretory) are controlled by intrinsic and extrinsic neural systems. These systems interact in a bidirectional network between the brain and the gut, creating the brain-gut axis.

**Figure 59-3 Conceptual (Biopsychosocial) Model for Irritable Bowel Syndrome.**

Clinical Presentation

Abdominal pain or discomfort is the most frequently reported symptom in IBS (Fig. 59-4). It is often poorly localized, variable in nature, and usually relieved with defecation. Pain or discomfort is also associated with altered bowel habits (e.g., diarrhea, constipation, or combination of both at times) and with a change in the consistency or frequency of stools. Associated symptoms include bloating, urgency, and a feeling of incomplete evacuation. Although

symptoms tend to occur in clusters, individual symptoms may also occur sequentially and may vary in type, location, and severity over time. In addition, some patients may complain about other (i.e., noncolonic) GI symptoms, such as heartburn and dyspepsia including nausea and early satiety; or non-GI (i.e., extraintestinal) symptoms, including musculoskeletal symptoms (e.g., fibromyalgia), headache, genitourinary symptoms, sexual dysfunction, sleep disturbances, and chronic fatigue. In addition, patients with more severe IBS are more likely to have an increased

Figure 59-4 Irritable Bowel Syndrome.

prevalence of comorbid psychosocial disturbances (e.g., anxiety, depression, life stressors, trauma, and a history of abuse). The presence of these psychosocial disturbances is usually associated with an increase in symptom reporting, poorer health status, and poorer outcome.

IBS is classified as diarrhea predominant, constipation predominant, or mixed (combination of both), depending on the most prevalent bowel pattern. This subclassification is determined by stool frequency, form, and passage. However, because the predominant symptom often changes over time, it is not uncommon for a patient to alternate between these IBS subgroups or even between different functional disorders such as IBS and dyspepsia.

As noted, IBS symptoms are heterogeneous in their expression, may overlap other functional GI disorders (e.g., dyspepsia, functional heartburn), or may coexist with other disorders (e.g., ulcerative colitis, Crohn's disease). In these patients, treatment of both disorders is necessary for symptom control and prevention of long-term adverse outcomes. Although symptoms may help direct diagnostic and treatment approaches, they are not sufficient to make a diagnosis.

Differential Diagnosis

The differential diagnosis is broad for IBS (Box 59-1). It includes lactase deficiency; bacterial overgrowth; GI malignancy (e.g., colon or rectal cancer); drugs such as laxative-cathartics or antacids containing magnesium; infection due

to *Salmonella* species, *Campylobacter jejuni*, *Yersinia enterocolitica*, *Clostridium difficile*, *Giardia lamblia*, *Entamoeba histolytica*; and opportunistic infections in an immunocompromised host. IBS can mimic inflammatory bowel disease (i.e., Crohn's disease, ulcerative colitis); chronic pancreatitis; celiac sprue; metabolic disorders such as diabetes mellitus and thyrotoxicosis; endocrine tumors such as gastrinoma, carcinoid, and vipoma; psychiatric illnesses including depression and somatization disorders; intestinal

pseudo-obstruction due to primary visceral myopathy and neuropathy or secondary myopathy and neuropathy (e.g., scleroderma, diabetes mellitus). Other colonic diseases in the differential diagnosis include microscopic and collagenous colitis and villous adenoma.

Diagnostic Approach

Because there are no biologic markers for IBS, it is diagnosed by identifying a cluster of clinical symptoms that are consistent with the disorder, excluding other conditions by looking for clinical alert signs (Box 59-2), and performing limited diagnostic testing.

The use of symptom-based diagnostic criteria is standard for IBS. A widely accepted set of diagnostic criteria was developed by multinational working teams known as the Rome Committees. By using the clinical diagnostic criteria, the physician can make a positive diagnosis of IBS, thereby reducing the need for excess diagnostic tests to exclude other conditions.

To meet the Rome III criteria, patients must have abdominal pain or discomfort associated with bowel symptoms. These may include improvement with defecation, changes in bowel frequency, or changes in stool form. The Rome III Committees suggest subtyping of IBS by the predominant stool pattern (hard or lumpy, loose/mushy or watery). Abnormal stool passage (straining, urgency, or feeling of incomplete evacuation), passage of mucus, and bloating or abdominal distention are not essential, but when present, they increase diagnostic confidence and may be used to identify additional subgroups of IBS.

Obtaining the history of the patient's symptoms involves a careful inquiry about the pain or discomfort and its relation to bowel habits and stool characteristics. To meet the IBS criteria, the pain or discomfort must have begun at least 6 months earlier and meet the following criteria for at least 3 days per month for the last 3 months: associated with at least two of the three criteria linking pain to a change in bowel habit (Box 59-3). Initial screening should include blood tests (blood cell count, sedimentation rate, chemistries), stool tests (for ova, parasites, and blood), and sigmoidoscopy to rule out other potential diagnoses. Other studies such as colonoscopy, barium enema, ultrasound, or CT depend on the presence of alarm signs such as symp-

 Improvement with defecation
 Onset associated with a change in frequency of stool
 Onset associated with a change in form (appearance) of stool

*Criteria fulfilled for the last 3 months with symptom onset at least 6 months before diagnosis.

toms that awaken the patient from sleep, initial presentation at an older (>50 years) age; evidence for GI bleeding, weight loss, fever, or a family history of colon cancer or IBD; an abnormal finding on physical examination; or abnormal initial laboratory tests. In addition, specific studies to exclude other conditions such as lactose intolerance, small intestine bacterial overgrowth, thyroid malfunction, or celiac sprue should be considered depending on features in the history or from screening studies that point to other diagnoses. If the initial screening is normal, further diagnostic studies may be withheld, and treatment can be started with a follow-up visit within 4 to 6 weeks. Any changes in the clinical status may lead to further investigation.

Because physiologic and psychological factors influence the presentation of IBS, it is important to consider both in planning the diagnostic approach. Clinicians should evaluate patients for comorbid disorders (e.g., anxiety, panic disorders, depressive disorders, post-traumatic stress disorder, and somatization disorders), personality disturbances, a history of sexual or physical abuse, recent stressful life events, early life experiences, family dysfunction, and maladaptive coping strategies. Understanding the patient's psychosocial status helps to determine an appropriate diagnostic plan while minimizing investigative studies.

Management and Therapy

Optimum Treatment

An effective physician-patient relationship is essential to any treatment plan. This includes appropriate reassurance and education about the condition, its natural history, and its consequences. The patient's understanding of the relevance of physiologic and psychosocial factors to the symptoms, and the acceptance of the need to address both in diagnosis and treatment, is desired but not always achieved.

Given limited understanding and the complexity of the pathophysiologic determinants, the current treatment primarily targets the patient's symptoms and overall well-

being rather than a specific underlying etiologic mechanism. The treatment approach depends on the type of the symptoms, severity of the disorder, presence of other aggravating conditions (e.g., obstructed defecation, fecal incontinence, hemorrhoids), and impact of symptoms on the patient's overall well-being and psychological status. Treatment for symptoms is determined by whether pain, diarrhea, or constipation is predominant. The severity of the symptoms is determined by their intensity and constancy, the degree of psychosocial difficulties, and the frequency of health care utilization. Most patients with IBS symptoms do not see physicians for their symptoms and are usually referred to as *IBS nonpatients*; most patients (about 70%) who do see physicians have mild and infrequent symptoms associated with little disability. These patients usually require only reassurance, education, recommendations for dietary and lifestyle changes, and encouragement for health-promoting behaviors. Short-term medication treatment can be prescribed during exacerbations. Another 25% of patients have moderate symptoms that occasionally interfere with daily activities (e.g., missing school, work, or social functions). These patients may require additional pharmacologic or behavioral treatments. Only a small proportion of patients with IBS (about 5%) have severe symptoms that considerably affect their daily activities and quality of life. These patients usually require psychopharmacologic (e.g., antidepressants) or psychological (e.g., cognitive-behavioral) treatments. In rare cases, referral to tertiary care centers may be needed.

Drug Therapy

Medications directed at the gut can be used to relieve specific GI symptoms. Examples are anticholinergic agents for pain and diarrhea; loperamide for diarrhea; and laxatives such as sorbitol or polyethylene glycol (PEG) solution for constipation. Some new serotonin-receptor acting agents have been recently introduced for use in patients with IBS. These serotonergic medications are directed to reduce gut sensitivity and improve bowel dysfunction. Alosetron, a 5-hydroxytryptamine-3 (5HT₃) antagonist, is suggested for female patients with severe diarrhea-predominant IBS who do not respond to other treatments, and a 5HT₃ agonist (tegaserod) is suggested for female patients with constipation-predominant IBS. Both of these serotonergic medications are currently under restricted use in the United States due to serious adverse events (ischemic colitis and severe constipation with alosetron and cardiovascular effects with tegaserod). Other medications (e.g., κ -opioid active agents for pain) are currently in clinical trials.

Medications with central or psychotropic effects (e.g., antidepressants) can be used to treat comorbid affective or psychiatric disorders (e.g., depression, anxiety). However, low doses of antidepressants also have analgesic

properties that are independent of their psychotropic effects. Tricyclic agents such as desipramine (50 to 150 mg) or amitriptyline (25 to 100 mg) appear to be effective in controlling IBS symptoms. Serotonin reuptake inhibitors are used primarily for reduction of associated anxiety and depression but are not as effective for pain control. Newer serotonin norepinephrine reuptake inhibitors such as duloxetine can provide pain relief without the side effects of the tricyclic agents. Consistent with the biopsychosocial model, it is important to view medication therapy as part of a more comprehensive management plan. More recently, there is increasing interest in the use of probiotics because they appear to reduce inflammation in the gut, which may in part be responsible for the visceral hypersensitivity.

Psychological Treatments

Several psychological treatments are used for IBS, including cognitive-behavioral therapy, dynamic or interpersonal therapy, and more passive treatments (e.g., progressive muscle relaxation, hypnosis). Psychological treatments appear superior to conventional medical treatment in reducing psychological distress, improving coping, and reducing some bowel symptoms. However, no one specific treatment is found to be superior. Psychological treatments are recommended for patients with frequent or disabling symptoms, associated psychiatric disorders, history of abuse with maladjustment to the current illness, and somatization with multiple consultations across specialties.

Avoiding Treatment Errors

Chronic use of opioid pain medications should be avoided in patients with IBS. The beneficial effects of these agents are usually short lived, and patients often develop tolerance and sometimes addiction. Chronic use of opioid medications also alter intestinal function and may lead to worsening of constipation and bloating and produce nausea and vomiting. In addition, there is the potential for the development of narcotic bowel syndrome when the chronic use of narcotics prescribed for pain paradoxically produces increased pain, which may lead to escalating dosages in an effort to reduce the pain. Treatment of this condition requires withdrawal of the narcotics. Prescribing of anticholinergic-antispasmodic agents (e.g., hyoscyamine, dicyclomine) or medications with anticholinergic effects (e.g., tricyclic antidepressants) should be done with caution and consideration of bowel habits pattern because these agents decrease intestinal motility and their use may result in worsening of constipation. Similar consideration should be taken with serotonin reuptake inhibitors because many of them have diarrhea as a side effect and therefore may worsen symptoms in patients with diarrhea.

Future Directions

Significant advances in our understanding of functional gastrointestinal disorders and IBS have occurred during the past decade; however, the diagnosis and management of these difficult yet common disorders are still a challenge in clinical practice. Hopefully, the growing interest and recent advances in the multidisciplinary research of these disorders will contribute to the development of novel and more effective diagnostic and treatment approaches.

Inflammatory Diseases of the Gastrointestinal Tract

Introduction

Inflammation of the gastrointestinal (GI) tract may occur as a result of infection, physical damage (radiation exposure and ischemia), or an idiopathic, chronic relapsing process commonly referred to as inflammatory bowel disease (IBD). IBD includes Crohn's disease and ulcerative colitis. The pathogenesis, clinical features, and treatments overlap. *Clostridium difficile* colitis is an important nosocomial infection of the colon that is increasingly complicating the course of the hospitalized patient. This chapter reviews the pathogenesis, clinical presentation, diagnostic testing, and treatment for Crohn's disease, ulcerative colitis, and *C. difficile* colitis.

Inflammatory Bowel Disease

Both ulcerative colitis and Crohn's disease are more common in individuals of Northern European origin, with incidence rates from 5 to 12 per 100,000. The incidence of ulcerative colitis has remained fairly constant over the past 50 years. In contrast, the incidence of Crohn's disease is increasing globally, with the most marked changes from 1960 to 1987, followed by a recent plateau. The sex distribution is equal in ulcerative colitis; there is a slight female predominance in Crohn's disease. These diseases are more common in white, and Jewish, populations than in other groups. Both diseases show increased incidence in families, with 6% to 20% of patients having a positive family history of IBD. There is a high concordance of disease among monozygotic twins. As compared with a nondiseased population, patients with Crohn's disease have a higher prevalence of smokers, whereas those with ulcerative colitis are more likely to be nonsmokers. Environmental factors such as infections, toxin or drug exposure, and diet may play a permissive role in the development of disease. Specific agents such as nonsteroidal anti-inflammatory drugs and oral contraceptives have been implicated in Crohn's disease.

Etiology and Pathogenesis

The etiology of ulcerative colitis and Crohn's disease is unknown. Studies indicate an interaction between genetic

susceptibility, the host's immune response, and environmental influences. Once inflammation is initiated, there is a failure to down-regulate the immune response. Disordered immunoregulation is thought to occur in part through T-cell responses. Bacteria and bacterial cell products have been implicated in pathogenesis. Genetic variants involving the innate immune system and response to bacteria such as the *NOD2* mutation and toll-like receptor 4 (*TLR4*) have been described in association with Crohn's disease. Certain disease phenotypes have higher associations with these mutations such as early-onset, small bowel disease with the *NOD2* variant in Crohn's disease. Currently, there is an intense effort to identify genes that may play a role in both ulcerative colitis and Crohn's disease, as well as phenotypic associations.

Ulcerative colitis is a mucosal disease limited to the colon. It begins in the rectum and is contiguous throughout the bowel. There may be a sharp cutoff of normal and abnormal mucosa in the distal bowel, or the entire colon may be involved (pancolitis). The ileum is involved in 10% of patients with pancolitis (backwash ileitis). There are no skip lesions, although occasionally there will be a patch of inflammation in the cecum in patients with left-sided ulcerative colitis. Histologically, there is a neutrophilic infiltration with crypt abscess formation and crypt distortion. The inflammation is limited to the mucosal surface. There is foreshortening of the intestine and the development of pseudopolyps with healing.

Figure 60-1 Regional Enteritis (Crohn's Disease).

In Crohn's disease, the inflammatory process may involve any part of the luminal GI tract from the mouth to the anus (Fig. 60-1). The terminal ileum is affected in 70% to 80% of patients, either alone or in combination with colonic involvement. The inflammation is transmural and characterized by infiltration of the bowel wall with neutrophils, followed by mononuclear-type cells and fibrous tissue. With chronicity, there is architectural dis-

ortion. In 60% of cases, noncaseating granulomas may be seen. Small aphthous ulcerations evolve into deep linear ulcerations and fissuring. Mucosal and submucosal fibrosis may lead to stricture formation. The disease is characterized by skip lesions with normal intervening mucosa. The serosa and mesentery exhibit reactive changes with thickening and fibrosis. Grossly, "creeping fat" is noted along the serosal surface. The transmural nature of the disease,

along with the deep ulcerations and fissures, leads to the complications of abscess, fistula formation, and obstruction.

Clinical Presentation

Ulcerative Colitis

Patients typically present with bloody diarrhea and tenesmus. With rectal involvement, presenting complaints include bleeding and constipation. Systemic symptoms are not infrequent and include anorexia, weight loss, and fever; localized abdominal cramping may occur with bowel movements. Steady constant pain in the absence of bowel movements suggests severe disease. In toxic dilation, there are decreased bowel sounds and abdominal distention. Long-standing disease may present with a colonic malignancy. After 10 years of pancolonic disease, the incidence of colon cancer increases by about 0.5% to 1% per year.

Crohn's Disease

The presentation of Crohn's disease depends on the affected location. Gastroduodenal disease presents with signs and symptoms that mimic peptic ulcer disease, including midepigastic pain and nausea. In small bowel disease, pain is common; narrowing of the small bowel lumen may lead to obstructive symptoms such as nausea, vomiting, abdominal distention, and pain. In ileal disease, nonbloody diarrhea occurs; patients with substantial ileal disease may have vitamin B₁₂ deficiency or bile salt diarrhea. Weight loss and nutrient malabsorption are common. Systemic symptoms such as weight loss and fever and laboratory abnormalities such as anemia and thrombocytosis are more common than in ulcerative colitis. Growth retardation in children may be the presenting complaint.

Complications include abscess formation, enterocutaneous fistulas, and obstruction. Extraintestinal manifestations include axial or central and peripheral arthritis, pyoderma gangrenosum, erythema nodosum, iritis, episcleritis, sclerosing cholangitis, aphthous stomatitis, amyloidosis, gallstones, and kidney stones (Figs. 60-2 and 60-3). The extraintestinal manifestations are seen both in Crohn's disease and ulcerative colitis.

Differential Diagnosis

The differential diagnosis (Box 60-1) of ulcerative colitis covers a wide range of bacterial and parasitic infections of the colon as well as direct damage to the bowel from radiation or ischemia. The patient's history is very important in narrowing the diagnostic list. Potential pathogen exposure, vascular risk factors, a history of radiation exposure, and medication history are important components of the history. If a patient presents with only lower GI bleeding, hemorrhoids, colonic polyps, arteriovenous malformation, and malignancy are in the differential diagnosis.

Endometriosis

The differential diagnosis for Crohn's disease of the colon is similar to that of ulcerative colitis. In patients who present with small bowel symptoms, disease processes that affect the small bowel must be considered. These include infections, inflammatory processes of other intra-abdominal organs, and other idiopathic inflammatory diseases of the small bowel (see Box 60-1).

Diagnostic Approach

The clinical presentation dictates the types and timing of diagnostic testing. A stool specimen should be examined in patients presenting with a diarrheal illness. White blood cells and blood are seen in ulcerative colitis and infectious colitis. Stool culture for bacterial pathogens, *C. difficile* toxin, and stool prep for parasites will help rule out infectious etiologies. Of note, *C. difficile* infection has been shown to precipitate flares of ulcerative colitis. Compre-

Figure 60-2 Regional Enteritis (Crohn's Disease).

hensive parasitic screening tests are required in anyone with a travel history or potential parasitic exposure. A qualitative stool fat helps to identify a malabsorptive diarrhea.

Hematologic studies should include hemoglobin, white blood cell count, erythrocyte sedimentation rate, C-reactive protein, and albumin to help define the severity of disease. Serologic testing for antineutrophilic cytoplasmic antibody and anti-*Saccharomyces cerevisiae* antibody has limited diagnostic usefulness. Other serologic markers, such as the antiglycan antibodies laminaribioside and chitobioside, may have a higher specificity

for Crohn's disease but primarily remain research tools at this time.

Sigmoidoscopy, colonoscopy, or both are useful in the diagnosis of colitis (Fig. 60-4). Endoscopic evaluation can help determine the extent and severity of disease. Small bowel radiologic studies help with the diagnosis of small intestinal Crohn's disease demonstrating such findings as luminal narrowing, mucosal irregularity, and internal fistulous disease. They also document the extent of small bowel involvement. In colitis, barium studies of the colon may show a shortened contracted bowel with a loss of bowel wall markings.

Figure 60-3 Extraintestinal Manifestations of Inflammatory Bowel Disease.

Management and Therapy

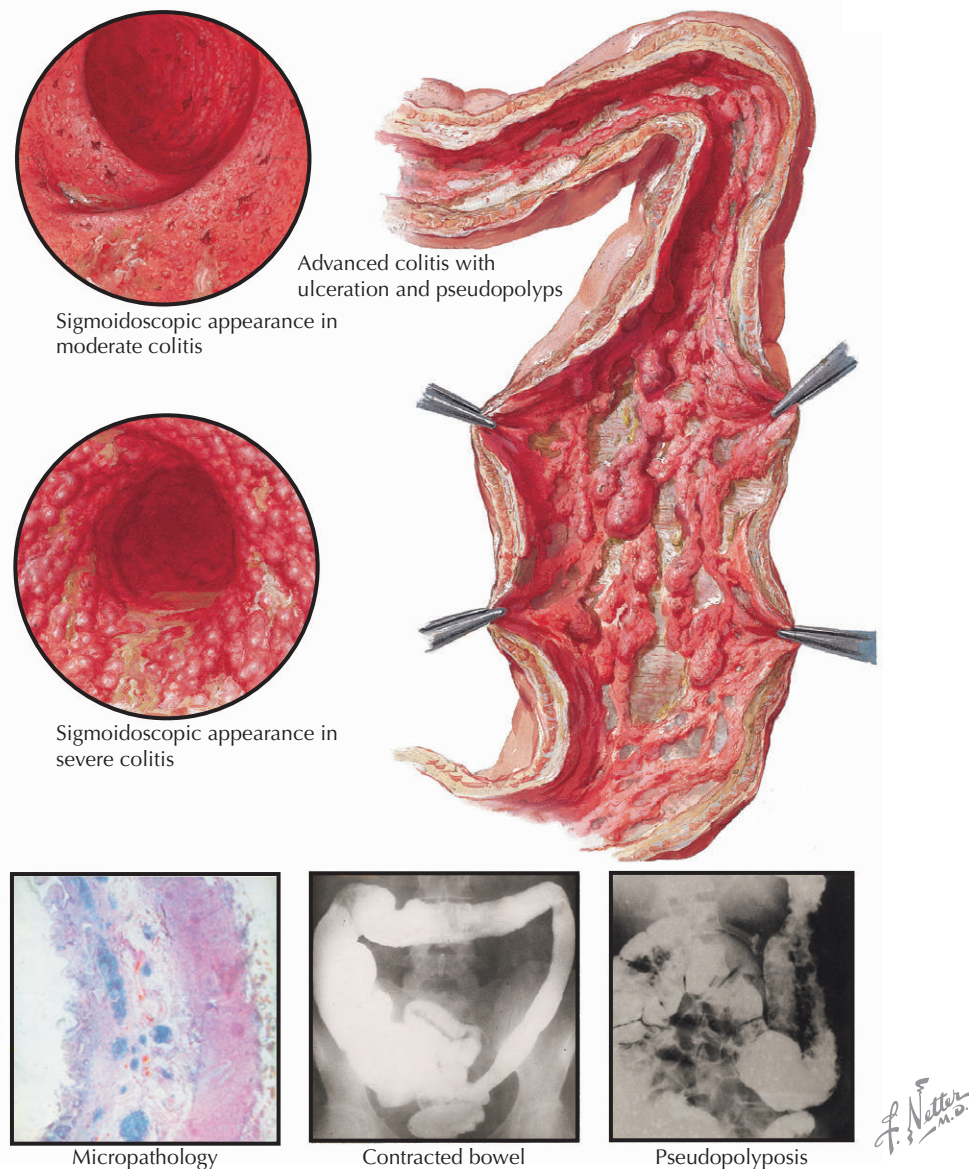

Principles of Therapy

The treatment of ulcerative colitis or Crohn’s disease depends on disease location, extent of disease, and severity. Severe disease exacerbations may require inpatient hospitalization. Symptomatic and supportive treatment includes antidiarrheal agents, antispasmodic drugs, hydration, and nutritional support. The history and physical examination should determine whether there are signs and symptoms

of toxicity or development of complications, such as toxic dilation, perforation, or abscess formation.

Optimum Treatment

The goals of drug therapy are to use the least toxic drugs first, to reduce long-term steroid use, and to induce remission. Over the past several years, alternative strategies have been proposed that include aggressive, immune active therapy at disease diagnosis in attempts to prevent the

Figure 60-4 Inflammatory Bowel Disease: Colitis.

long-term development of disease complications. This has been called the top-down approach. It is not clear whether either approach is beneficial for all patients, and attempts are being made to identify the patients who should receive more aggressive initial therapy.

5-Aminosalicylates (5-ASAs) are the first-line therapy in ulcerative colitis. There is controversy about the effectiveness of this class of drugs in Crohn's disease. There are few consistent controlled data to suggest benefit in induction and maintenance of remission with 5-ASAs in Crohn's disease. 5-ASAs are useful in the maintenance of remission in ulcerative colitis. The 5-ASAs differ in the site and mechanism of release. Their activity is dose dependent, and dosage escalation may enhance response.

Sulfasalazine is a 5-ASA bound to sulfapyridine by a diazo bond. Sulfapyridine is a carrier that prevents small bowel absorption. The diazo bond is broken down by bacteria in the colon, releasing 5-ASA and sulfapyridine. Side effects include nausea, vomiting, malaise, sun sensitivity, and rash, which may be caused by the sulfa component. Patients can be desensitized to some of these side effects. Male patients may experience a reduction in sperm count with decreased fertility. Agranulocytosis has also been described. Despite these potential problems, sulfasalazine is a very useful drug and may have benefit for arthritis in patients with both bowel disease and arthritis.

Olsalazine is a 5-ASA dimer in which the 5-ASAs are linked by a diazo bond, which is broken down by bacteria

in the colon releasing the 5-ASAs. Up to 20% of patients may experience a secretory diarrhea, which limits its usefulness in treating colitis.

Balsalazide is a 5-ASA with a diazo bond to an inert carrier, 4-aminobenzoyl-beta-alanine. Delivery to the colon is similar to that of sulfasalazine but without the sulfa side effects. Standard dosing is 6.75 g/day.

Oral mesalamine is available in a pH-dependent release form and a delayed release form. The delayed release form is delivered into the terminal ileum and colon. When the capsule opens in the ileum or colon, the drug is released. Standard dosing ranges from 2.4 to 4.8 g/day. The pH-dependent form relies on diffusion of water into an ethyl cellulose granule and displacement of the drug out of the granule. The drug is released in the duodenum. It can be used for disease involving the small bowel or the colon. Standard dosing is 4 g/day.

Topical mesalamine is available in enema and suppository forms. The suppositories (500 and 1,000 mg) are useful for the topical therapy of rectal disease. The enema form, dosed at 4 g, can be used for colonic disease to the splenic flexure; it does not require release from a carrier as with the oral agents.

Steroids are used for more severe ulcerative colitis or Crohn's disease. Corticosteroids can be used topically, orally, or intravenously. Prednisone is the most commonly used oral steroid. Budesonide is available in an ileal release preparation. It has the advantage of a rapid first-pass metabolism and, theoretically, a lower steroid side-effect profile. Orally, the prednisone dosage range is typically 40 to 60 mg/day for 3 weeks, with a variable slow taper if there is a response; there is no benefit to using doses higher than this. Intravenous steroids may be given as a bolus or a continuous infusion. There are anecdotal reports suggesting that continuous corticosteroid infusion is better than bolus infusion. Budesonide is available in 3-mg capsules. Standard therapy starts at 9 mg/day and is tapered by 3 mg/day at varying intervals. Short-term side effects of systemic steroids include glucose intolerance, acne, mood swings, sleep disturbances, and weight gain. Long-term side effects include osteoporosis and cataracts. These agents have no maintenance benefit and should be used for acute disease therapy. Topical steroids are available in suppository, foam, and enema preparations. Foam and suppositories are used in rectal disease. Enemas may be used for left-sided colonic disease. All patients on steroids should be followed closely for the development of steroid-induced osteopenia. Calcium and vitamin D supplementation are important. The development of osteopenia or osteoporosis requires more aggressive management of bone health.

Antibiotics have been shown to have a role in colonic disease, perineal disease, small bowel bacterial overgrowth, and infectious complications such as abscess formation and pouchitis. Metronidazole at 10 to 20 mg/kg is the first-line antibiotic. Unfortunately, it is poorly tolerated by many

patients because of nausea and taste disturbances. Peripheral neuropathy may occur with long-term use, and paresthesias are often an early sign of this side effect. Metronidazole should be discontinued if any paresthesias occur because neuropathy is progressive and can be irreversible. Other antibiotics that have been used with some success are ciprofloxacin and clarithromycin. Rifaximin, a nonsystemically absorbed antibiotic, has the theoretical advantage that its activity is limited to the intraluminal GI tract. It is currently in trial in Crohn's disease.

Immunosuppressive agents such as azathioprine and 6-mercaptopurine are used for medically refractory bowel disease, steroid-dependent disease, and perineal disease. These agents are most commonly used in Crohn's disease, but are increasingly used in ulcerative colitis. The white blood cell count should be carefully monitored for evidence of bone marrow suppression. Measurement of metabolites may play a role in determining therapeutic efficacy and potential for toxicity. These agents have a delayed onset of action and should be used for 3 to 6 months before making decisions on lack of efficacy. Other side effects include pancreatitis and cholestasis. Long-term neoplasia risk is not clear.

Parenteral methotrexate has been shown to be of benefit in active Crohn's disease as well as for maintenance therapy. Dosages range from 15 to 25 mg intramuscularly or subcutaneously once per week. Signs of toxicity include liver abnormalities and pulmonary fibrosis. It is absolutely contraindicated in pregnancy, and caution should be used in women of childbearing age.

Cyclosporine is used in severe, acute colitis. It has a limited role in the treatment of Crohn's disease. In fulminant colitis, intravenous dosing has been shown to prevent or delay colectomy. Cyclosporine has a narrow therapeutic window; side effects include renal toxicity, hypertension, hirsutism, and seizures. A surgeon should be closely involved and follow the patient's course, helping to observe for signs and symptoms that indicate the need for an urgent colectomy. Despite the encouraging short-term success of cyclosporine, over the long-term, many patients who were initial responders have a relapse that leads to colectomy.

Infliximab, a chimeric antibody to tumor necrosis factor- α is used to treat Crohn's fistulous disease as well as to induce remission and decrease steroid requirements in patients with luminal disease. It has also been approved for use in the induction and maintenance of remission in ulcerative colitis. The drug is given as a 5 mg/kg IV infusion over 2 hours. The average duration of response is 8 weeks. An induction course of therapy at 0, 2, and 6 weeks is commonly employed with subsequent maintenance dosing every 8 weeks. Potential side effects include infusion reactions, infections, arthritis or arthralgias, and malignancy. Development of antibodies to infliximab may lead to increased infusion reactions and decreased efficacy of drug therapy. Premedication with intravenous hydro-

cortisone and concomitant alternative immunosuppression with antimetabolites or methotrexate are strategies that have been employed in attempts to decrease antibody formation. Adalimumab and certolizumab are alternative anti-tumor necrosis factor agents that may be used in patients who have developed antibodies to infliximab.

Avoiding Treatment Errors

In the therapy of inflammatory bowel disease, there are multiple potential treatment errors that can be predicted and avoided. Both Crohn's disease and ulcerative colitis are characterized by disease exacerbations and remissions. With the treatment of an exacerbation, it is important to make sure that the symptoms are due to recurrent IBD. Enteric infections, bowel ischemia, and functional bowel disease can mimic the symptoms of active inflammatory bowel disease. Escalation of disease therapy for IBD may be harmful if the bowel symptoms are not due to worsening of the IBD. With each change in IBD therapy, reconsider the differential diagnosis with physical examination, endoscopic evaluation, stool examination, and laboratory testing as indicated.

All the therapies used in the treatment of IBD have potential side effects that require vigilance to allow for early detection of complications. The clinician should be familiar with the common side effects of these medications and institute appropriate monitoring procedures.

This is especially important with the immune active agents because complications such as infection from profound immunosuppression may occur. Suggested monitoring for 6-mercaptopurine and azathioprine includes a complete blood count (CBC), aspartate transaminase (AST), alanine transaminase (ALT), alkaline phosphatase, total bilirubin, and when appropriate, lipase and amylase. Before starting 6-mercaptopurine and azathioprine, check the patient's thiopurine methyl transferase (TPMT) phenotype and genotype to detect patients with low enzyme activity. Individuals with low TPMT activity are susceptible to profound early immunosuppression and should be started on lower initial 6-mercaptopurine and azathioprine doses with more frequent initial monitoring.

Suggested monitoring for methotrexate includes CBC, AST, ALT, alkaline phosphatase, total bilirubin, and monitoring of respiratory function. For cyclosporine, monitoring includes CBC, creatinine, AST, ALT, alkaline phosphatase, total bilirubin, and monitoring of blood pressure.

Future Directions

There has been an explosion of knowledge regarding important factors in the pathophysiology of inflammatory bowel disease. This is reflected in how we consider and treat Crohn's disease and ulcerative colitis. As we move forward into a new era of treatment, clinical and genetic phenotyping of disease may allow for more specific thera-

peutic regimens. Advances are being made in the use of biologics in the treatment of IBD, and we are likely to see drug regimens that include growth factors, antibodies to different components of immune active cells, and drugs that stimulate certain classes of white blood cells. The recognition that gut bacterial flora may play a role in disease activity will likely lead to increased manipulation of the gut flora with both probiotics and antibiotics. With these new therapies, attempts will be made to develop therapeutic regimens to avoid steroid exposure and allow for early intervention that may change the disease course.

Clostridium difficile Colitis

C. difficile was first shown to play a causative role in the development of pseudomembranous colitis associated with antibiotic usage in 1978. It has become a more and more important nosocomial pathogen, complicating hospital stays, precipitating inflammatory bowel disease, and causing significant morbidity and increasing mortality in affected patients. The asymptomatic colonization rate of hospitalized patients with *C. difficile* is as high as 20%, compared with a less than 5% colonization rate in the community. In approximately one third of patients colonized, a toxin is produced that leads to diarrhea.

Etiology and Pathogenesis

C. difficile is an anaerobic, gram-positive, spore-forming bacterium. It is spread by the fecal-oral route, often by spores that are left on surfaces. Handwashing helps prevent spread. In colonized patients who receive antibiotics, *C. difficile*, which is resistant to many antibiotics, proliferates in the environment of decreased normal colonic flora. *C. difficile* produces toxins that cause diarrhea in affected patients. If the organism carries the gene for toxin production, disease develops. There are two major toxins: the A and B toxins. Toxin B is more cytotoxic than toxin A. The toxin binds to a receptor on the colonocyte and is incorporated into the cell, which then leads to a loss of polarity of the cell and ultimately cell death. This process leads to a colitis and often pseudomembrane formation. A particularly virulent strain of *C. difficile*—the NAP1/027 strain—has been recently associated with widespread outbreaks in Canada and the United States. This strain produces much larger quantities of toxin than strains previously isolated.

Clinical Presentation

Patients typically present with diarrhea during or immediately after antibiotic exposure. Factors that increase the risk for infection include increasing age, severe comorbid disease, patients on an antisecretory medicine such as proton pump inhibitors, multiple antibiotics, hospitaliza-

tion (particularly in the intensive care unit), patients with nasogastric tubes, and patients who have a long duration of antibiotic therapy. Stools are typically watery and liquid in consistency. Occasionally, the stool is bloody. Patients may have abdominal pain. In more severe cases, patients have systemic symptoms of fever, malaise, dehydration, and delirium.

Differential Diagnosis and Diagnostic Approach

The approach to diagnosis is similar in all patients presenting with diarrhea. The historical information of prior antibiotic exposure should place *C. difficile* infection high in the differential diagnosis. The differential diagnosis for *C. difficile* colitis is nearly the same as that for ulcerative colitis (see Box 60-1). Diagnostic studies include stool culture and stool testing for *C. difficile* toxin. Complete blood count and albumin measurements help with assessment of severity of the ongoing infection. Endoscopic evaluation with a sigmoidoscopy and biopsy may identify pseudomembranes (Fig. 60-5).

Management and Therapy

Optimum Treatment

First-line therapy for *C. difficile* colitis is metronidazole, 500 mg three times daily, based on cost and efficacy. In early studies, up to 90% of patients were cured of infection with metronidazole; however, the response rate appears to be decreasing, with a recent study demonstrating only a 50% relapse-free response rate. Intravenous metronida-

zole is excreted in the bile and may be used for treatment in patients who cannot tolerate oral medication. Oral vancomycin is also effective for treatment of *C. difficile* colitis, with an initial dose of 125 mg four times a day, increasing to 250 mg four times a day for more severe disease. A vancomycin taper is used in relapsing disease. Intravenous vancomycin is not excreted into the lumen of the GI tract and is ineffective for treatment. Nitazoxanide at 500 mg twice a day for 7 days appears to be as effective as metronidazole in the treatment of this disease entity. Repopulating the colon with nonpathogenic bacteria (probiotics) is one proposed therapeutic option in *C. difficile* colitis. *Saccharomyces boulardii* does appear to play a role in decreasing recurrent *C. difficile* colitis. The standard dosage is one 500 mg capsule twice a day for 4 weeks. For symptomatic control of diarrhea, cholestyramine has been used to bind the toxin produced by *C. difficile*. If a patient becomes increasingly toxic despite medical therapy, colectomy should be considered.

Prevention should also be considered as an important therapeutic maneuver in colitis related to *C. difficile* infection. Hospitalized patients with *C. difficile* infections should be placed on contact precautions with handwashing, gloves, and gowns during contact with the patient. The patient should have a dedicated stethoscope and thermometer available in the room. There should be monitoring and surveillance activity by infection control on the hospital floor units and intensive care units.

Avoiding Treatment Errors

In treating *C. difficile* colitis, it is important to recognize that the antibiotics must reach the lumen of the gastrointestinal tract to be effective. Oral vancomycin is effective, whereas intravenous vancomycin is not effective. Both intravenous and oral metronidazole can be used for therapy. *C. difficile* can complicate other forms of inflammatory bowel disease. If a patient is not responding to therapy, it is important to reassess the disease process and treat coexistent disease appropriately.

Future Directions

There are multiple newer antibiotics that are thought to have a role in the treatment of *C. difficile* colitis. In addition to nitazoxanide as mentioned, other antibiotics include ramoplanin, rifaximin, rifalazil, and OPT-80. Both passive and active immunization strategies are being assessed for disease prevention. The vaccines in trial include those directed against the A and B toxin (active immunization) and MDX-066, which is a monoclonal antibody to toxin A.

Esophageal Disorders: Dysphagia

Introduction

Dysphagia, or difficulty swallowing, is among the most common gastrointestinal symptoms experienced by the general population. More than one fourth of elderly patients experience dysphagia at least intermittently. The causes of this symptom are diverse, ranging from the benign to dreaded malignancies such as esophageal cancer. This chapter reviews the etiologies, presentation, diagnostic workup, and treatment of this condition.

Etiology and Pathogenesis

Dysphagia has a myriad of causes that require careful assessment. To understand the etiology and pathogenesis, it is helpful to use the anatomic location of the sensation of dysphagia. Patients who complain of difficulty initiating swallowing, with frequent sensations of choking or suffocation, are said to have *transfer dysphagia*, or difficulty transferring the food bolus from the oropharynx into the upper esophagus. Subjects localizing the sensation of dysphagia to the neck area have *cervical dysphagia*, whereas those who experience lodging of food, pills, or fluid in the chest have *thoracic dysphagia*.

The etiology of dysphagia differs based on the localization of symptoms (Box 61-1). Subjects who complain of transfer dysphagia may have underlying neurologic damage secondary to a cerebrovascular accident (CVA) or multiple sclerosis. Oropharyngeal malignancies also warrant consideration. In patients with cervical dysphagia, cervical spine osteophytes, esophageal webs, squamous cell carcinoma of the esophagus, and esophageal strictures predominate. In subjects with thoracic dysphagia, gastroesophageal reflux disease (GERD), esophageal stricture (Fig. 61-1), Schatzki's ring (a benign ring at the gastroesophageal junction), motility disorders such as achalasia, and esophageal cancer of either squamous or adenomatous histology (Fig. 61-2) are common diagnoses. Extrinsic compression of the esophagus by any structure in the neck or thorax may lead to symptoms referable to the location of the compression.

The pathogenesis of aerodigestive malignancies commonly causing dysphagia differs by location and histology. The main risk factors for cancers of the tongue, pharynx, and larynx, as well as squamous cell cancers of the esophagus, are tobacco use, alcohol consumption, and African American race. Conversely, the pathogenesis of esophageal adenocarcinoma appears to involve chronic inflammation of the distal esophagus by acid reflux (see Chapter 50). This cancer occurs in increased frequency in white males.

Clinical Presentation

The defining characteristic of dysphagia is the sensation of blockage to the passage of solid or liquid contents, or both. Subjects may describe a gradual course, with escalating symptoms initially to only bulky solids such as meats or breads, progressing to dysphagia to substances of a pudding-like consistency, and culminating in complete intolerance to solids. Such a crescendo pattern of symptoms is suggestive of a worsening mechanical obstruction, such as esophageal cancer, or a tightening esophageal peptic stricture. Alternatively, the patient may describe dysphagia to liquids and solids equally, with no crescendo pattern. Such a history is more suggestive of a motor abnormality, such as achalasia or diffuse esophageal spasm. The latter is especially suggested when substances of an especially hot or cold temperature precipitate symptoms. Long-term, nonprogressive problems with intermittent dysphagia to bulky solids is suggestive of the presence of Schatzki's ring (Fig. 61-3).

Profound weight loss may be seen with almost all the causes of dysphagia listed in Box 61-1; however, in elderly patients, this alarm feature is especially concerning for esophageal cancer. Close examination of the patient with dysphagia may yield additional clues as to the pathogenesis of the symptoms. For instance, patients with motility disorders secondary to systemic sclerosis may manifest characteristic changes of the skin of the fingers (sclerodactyly) (see Chapter 154). Those with CREST (calcinosis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia) syndrome may demonstrate several of the cutaneous manifestations of the disorder, so a thorough dermatologic evaluation should be performed.

Differential Diagnosis

As noted in Box 61-1, the differential diagnosis of the symptom of dysphagia is broad. It is important to clarify the patient's symptom complex. Patients may complain of trouble swallowing when they are really experiencing odynophagia, or pain on swallowing. Additionally, severe erosive esophagitis may have a degree of dysphagia as a component of its presentation due to edema of the esophageal wall from inflammation.

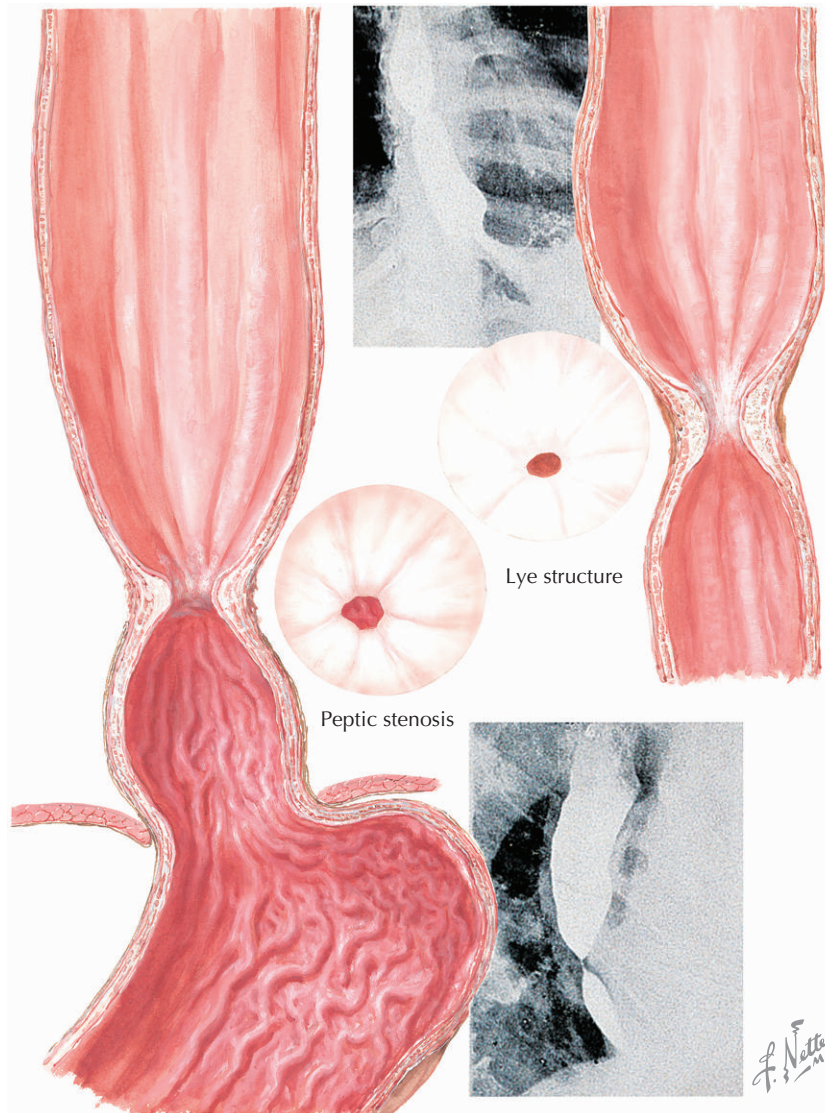

Diagnostic Approach

Because of the specter of possible malignancy, as well as the progressive and destructive nature of many of the etiologies of the symptom, dysphagia generally demands immediate attention and a prompt workup. Dysphagia is one of the alarm symptoms of GERD, and dysphagia in the setting of heartburn mandates diagnostic testing.

The diagnostic measures of choice depend on the character of the dysphagia. Subjects with transfer dysphagia should have a good examination of the oropharynx and neck. Depending on the patient profile, if this examination fails to demonstrate an etiology of the symptoms, further testing with either modified barium swallow (contrast radiography concentrating on the swallowing mechanism and the proximal esophagus) or a fiberoptic endoscopic evaluation of swallowing (FEES) study may be indicated. In a FEES study, the subject is asked to ingest foods of varying consistency while a speech pathologist observes the swallowing mechanism through a fiberoptic scope passed through the nose and positioned in the nasopharynx above the vocal cords. Both the barium study and the FEES study allow evaluation of bolus formation, movement of the epiglottis, and detection of aspiration of even minute amounts of material. The choice between the two modalities may depend on local expertise and availability. Further workup, such as brain imaging studies to assess for multiple sclerosis or CVA, depends on the patient profile and findings of the initial evaluation.

The workup of true cervical dysphagia is similar to that of transfer dysphagia. However, the absence of an obvious risk factor such as a stroke is an indication for cross-sectional imaging of the neck to rule out an extrinsic lesion compressing the cervical esophagus. If the evaluation of the transfer mechanism and proximal esophagus is negative, the patient should have an evaluation for distal esophageal pathology. The sensation of food sticking may be referred to the sternal notch or above in these thoracic esophageal conditions.

Several modalities exist to evaluate thoracic dysphagia. A barium esophagram is helpful in assessing the gross anatomic structure of the esophagus, including evaluation for intrinsic lesions and extrinsic compression. It may also be helpful in the diagnosis of achalasia. Frequently, a dilated esophagus without peristaltic contractions will be seen, with a contrast-filled esophagus and a narrow tapered

Figure 61-1 Two Types of Benign Esophageal Strictures.

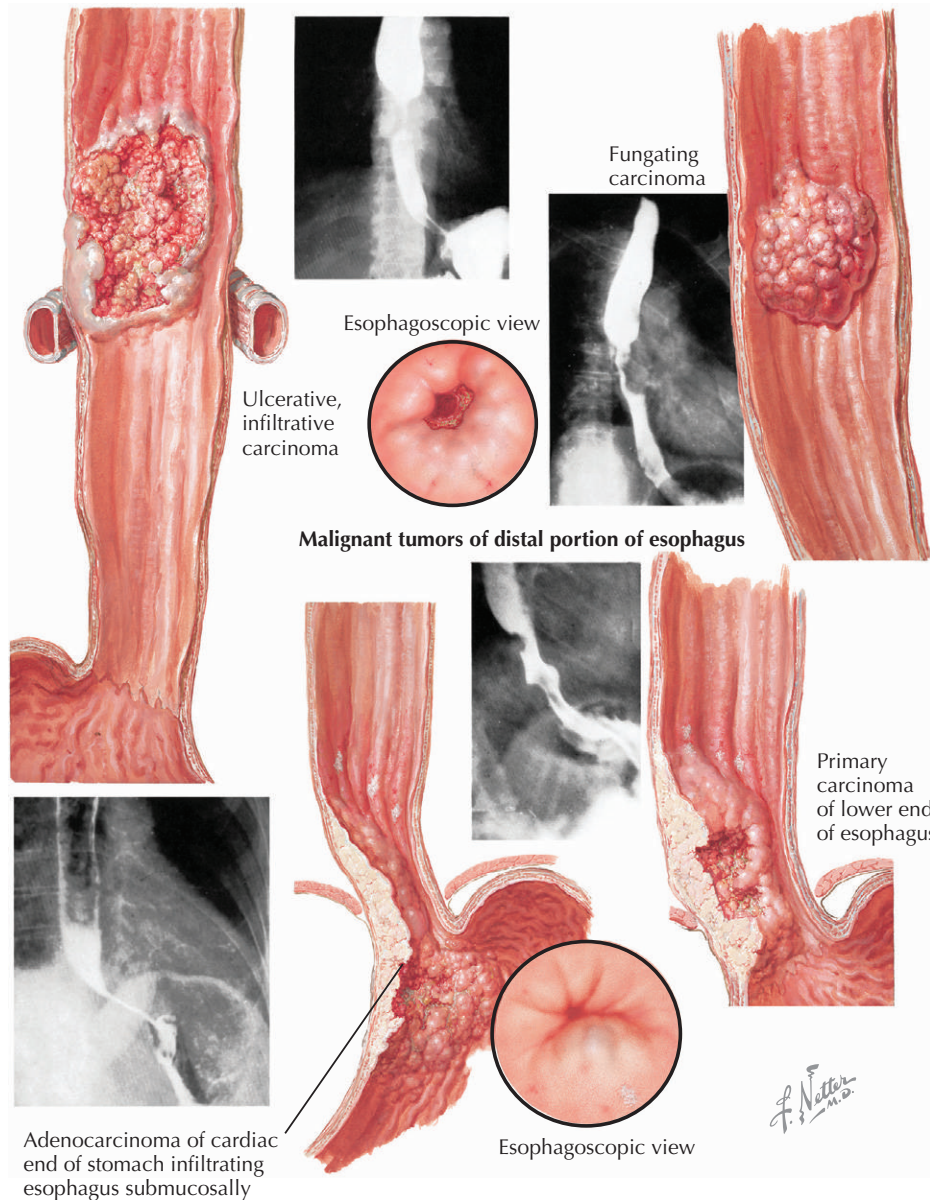

gastroesophageal junction, the so-called bird's beak appearance. When the location of dysphagia is uncertain, a tablet esophagram can help to further localize the pathologic region. Ultimately, many patients will require an upper endoscopy for thoracic dysphagia. Endoscopy allows the physician to assess the esophageal mucosa for esophagitis, to perform biopsies of masses, to dilate strictured regions, and to rule out subtle lesions that may have been missed on barium swallow. Additionally, in patients with suspected achalasia, upper endoscopy allows the exclusion of secondary achalasia, or pseudoachalasia, in which a tumor at the gastric cardia mimics the presentation of achalasia. In the absence of obvious structural abnormalities on upper endoscopy, esophageal biopsies are recommended to rule out eosinophilic esophagitis. If the structural studies do not reveal an obvious etiology for the problem, esophageal

manometry is then warranted to rule out esophageal motor disorders.

Management and Therapy

Optimum Treatment

Management of the patient with dysphagia ultimately depends on the type of dysphagia (Table 61-1). For patients with oropharyngeal dysphagia, therapy is directed at improving bolus transfer and nutritional intake, reducing pulmonary aspiration, and ameliorating the quality of life. If structural issues such as webs or strictures exist, they should be addressed initially, usually by endoscopic dilation. However, for most underlying causes of oropharyngeal dysphagia, the largest component of care for patients with oropharyngeal dysphagia is swallowing therapy by a

Figure 61-2 Malignant Tumors of Midportion and Distal Portion of Esophagus.

speech pathologist. Various maneuvers are taught that focus on increasing propulsion of the bolus from the mouth to the pharynx and subsequently through the upper esophageal sphincter, such as tucking the chin or tilting the head to the stronger side. Increasing bolus consistency with thickening products is valuable because thin liquids often cause the greatest problems. In highly selected patients, primarily those whose dysfunction is isolated to hypertension or impaired relaxation of the cricopharyngeus muscle, consideration may be given to surgical myotomy. Ultimately, if patients cannot support their nutritional needs through the oral route, or if there is significant pulmonary aspiration, enteral alimentation through gastrostomy or jejunostomy is required.

The management of esophageal dysphagia is tailored much more toward the underlying pathology. Achalasia can be managed with surgical myotomy or endoscopic pneumatic balloon dilation, depending on local expertise and patient preference. In patients with achalasia who are not candidates for surgical intervention, injection of botulinum toxin A into the lower esophageal sphincter is a useful but temporary treatment. The management of esophageal stenoses is directed at increasing the luminal diameter by endoscopic means. Benign strictures can be dilated with various types of dilating balloons or *bougies*, which are thin, flexible, tapered rods that gently widen the narrowed segment within the esophagus. The choice of dilating device used depends on the length and character

Figure 61-3 Inferior Esophageal (Schatzki's) Ring.

of stricture, the underlying etiology, and the preference of the endoscopist. Many mild stenoses, as well as Schatzki's rings, can be treated with just a single dilation. However, if the stricture is very tight upon presentation, or results from insults such as radiation, lye ingestion, or long-standing GERD, several sessions may be required over months to years to achieve optimal success. If the pathology is malignant in etiology, then curative resection should be attempted if possible. When the tumor is unresectable or the patient is inoperable, palliative care can be achieved with serial dilations, placement of endoscopic stents, or endoluminal ablative therapy.

For patients with esophageal motility disorders other than achalasia, management can be much more difficult. There is a dearth of well-designed randomized controlled trials for these disorders, especially since manometric criteria for diagnosing them are continually evolving. Aggressive control of GERD with proton pump inhibitors may improve esophageal motility or the dysphagia symptoms

to some degree, although it is unlikely to result in complete resolution. For patients whose symptoms are associated with diffuse esophageal spasm, smooth muscle relaxants, such as calcium channel blockers or long-acting nitrates, are frequently prescribed. Antidepressants, especially the tricyclics, can be tried as well to improve symptoms secondary to the central effects of these agents.

Avoiding Treatment Errors

The first major principle in evaluating dysphagia is to recognize that its presence is an alarm sign that warrants further evaluation, not an empiric trial of therapy for GERD or dyspepsia. Once a neoplastic etiology has been ruled out, further treatment strategies can be directed at the results of diagnostic testing. Second, because eosinophilic esophagitis has been increasingly recognized only within the past few years, a heightened level of suspicion should be maintained in patients who have dysphagia,

Table 61-1 Management of Dysphagia

Disorder	Management Options
Oropharyngeal dysphagia	Swallowing therapy Gastrostomy/jejunostomy Cricopharyngeal myotomy/botulinum toxin injection*
Cervical or esophageal stricture/ring/web	Endoscopic dilation Acid suppression (PPI)
Unresectable esophageal tumor	Serial endoscopic dilation Endoluminal ablation Endoscopic stenting
Achalasia	Surgical (Heller) myotomy Endoscopic pneumatic dilation Botulinum toxin injection Smooth-muscle relaxants (isosorbide dinitrate, nifedipine)
Other esophageal motility disorders	Acid suppression (PPI) Smooth muscle relaxants Tricyclic antidepressants
Eosinophilic esophagitis	Swallowed aerosolized fluticasone Systemic corticosteroids Cromolyn sodium Endoscopic dilation (judicious)

PPI, proton pump inhibitor.

*For selected patients with isolated upper esophageal sphincter dysfunction.

especially with recurrent food obstructions, but no obvious pathology on endoscopic, radiologic, or manometric investigation. If no structural lesions are encountered, random esophageal biopsies should be considered. Treatment of eosinophilic esophagitis is principally with swallowed aerosolized fluticasone, cromolyn sodium, or systemic steroids and endoscopic dilation must only be undertaken judiciously with appropriate informed consent.

Future Directions

The diagnosis and classification of esophageal motility disorders have been an active matter of research in motility labs, and new technology called multichannel intraluminal impedance (MII) has been developed recently. MII complements standard esophageal manometry by adding a formal assessment of bolus transit to quantify the function of the esophagus in dysphagia patients. It remains to be seen exactly how this new technology will affect patient care, and current research will hopefully clarify its utility. The basis of therapy for oropharyngeal and esophageal dysphagia will not likely change in the near future; however, injection of botulinum toxin A has been used to treat cricopharyngeal disorders and other nonachalasia esophageal motility disorders with some degree of success. Finally the ongoing development of gastrointestinal promotility agents will hopefully lead to improved therapy for patients with esophageal motor dysfunction in the coming years.

This comprehensive literature-based review examines the evaluation and management of patients with oropharyngeal dysphagia.

Ferguson DD: Evaluation and management of benign esophageal strictures. *Dis Esophagus* 18(6):359-364, 2005.

This review focuses on the options available for managing patients with benign strictures, from simple dilation techniques to more complex issues for refractory strictures.

Richter JE: Esophageal motility disorders. *Lancet* 358(9284):823-828, 2001.

The author discusses the manometric diagnosis of recognized esophageal motility disorders and the management options available for these conditions.

EVIDENCE

1. Lopushinsky SR, Urbach DR: Pneumatic dilatation and surgical myotomy for achalasia. *JAMA* 296(18):2227-2233, 2006.

This retrospective study found that patients with achalasia who had undergone either pneumatic dilation or surgical myotomy often required subsequent intervention (surgical or endoscopic) when followed for many years after their first treatment. The risk for requiring a subsequent intervention was higher in the pneumatic dilation group.

2. Remedios M, Campbell C, Jones DM, Kerlin P: Eosinophilic esophagitis in adults: Clinical, endoscopic, histologic findings, and response to treatment with fluticasone propionate. *Gastrointest Endosc* 63(1):3-12, 2006.

The authors reported that all patients in their series who were treated with swallowed aerosolized fluticasone improved clinically and histologically, but many had recurrent symptoms after completing the course of treatment.

3. Tutuian R, Castell DO: Combined multichannel intraluminal impedance and manometry clarifies esophageal function abnormalities: Study in 350 patients. *Am J Gastroenterol* 99(6):1011-1019, 2004.

This investigation highlighted the utility of multichannel intraluminal impedance to show normal and abnormal bolus transit in several esophageal motility disorders.

Diseases of the Liver— Abnormal Liver Function Tests, Nonalcoholic Fatty Liver Disease, and Drug- Induced Liver Injury

Introduction

Abnormal liver tests occur in 1% to 4% of the population. There are many causes for test abnormalities. Non-alcoholic liver disease (NAFLD) and drug-induced liver injury (DILI) are among the most common etiologies. More than 30% of the population meets criteria for obesity, and many of these individuals have underlying NAFLD. Clinicians are likely to encounter patients who have abnormal liver tests from NAFLD. The clinical picture is often complicated further by medications like statins used to treat the complications of obesity and associated with medication-induced liver function test abnormalities.

ABNORMAL LIVER CHEMISTRY TESTS

Etiology and Pathogenesis

Serum liver chemistry testing is often done during periodic health maintenance, in screening before blood donation, as part of insurance and employment physicals, and during hospitalizations. Proper interpretation of abnormalities in liver chemistries within the context of a patient's risk factors and medical history guide further evaluation and management. Because normal laboratory values are defined as the mean distribution and 2 standard deviations above or below the normal population, 2.5% of the population, by definition, will have one or more liver tests that are either below or above normal. Normal values for liver tests may vary by age, race, and gender.

Alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, and total bilirubin constitute the most common blood tests typically included in a liver panel. γ -Glutamyltransferase (GGT) and 5'-nucleo-

tidase are typically used to confirm the liver, rather than bone, as the source of alkaline phosphatase elevation. The above tests are erroneously labeled as liver "function" tests because ALT, AST, GGT, and alkaline phosphatase are enzymes and not markers of synthetic function. Albumin and prothrombin are proteins synthesized by the liver that can provide an estimate of liver synthetic function.

AST and ALT are abundant hepatic enzymes that catalyze the transfer of amino groups to form the hepatic metabolites pyruvate and oxalate. ALT is found in the hepatocyte cytosol, and AST is found in hepatocyte cytosol and mitochondria. Both are released into the blood when there is hepatocellular injury or death. AST is also found in heart, skeletal muscle, and blood. Bilirubin is a product of hemoglobin degradation. It is insoluble and requires conjugation, glucuronidation, before it can be secreted. Bilirubin uridine diphosphate-glucuronyl transferase conjugates bilirubin so that it can be secreted into the bile canaliculus. Alkaline phosphatase is an enzyme found in

many tissues, including liver, bone, intestine, and placenta. Elevations in alkaline phosphatase may be seen during pregnancy.

Clinical Presentation

Elevations in liver chemistries are usually detected during routine physical exams or during blood donation in asymptomatic patients. Patients with elevated liver tests from acute viral hepatitis or obstructive jaundice can manifest malaise, nausea, vomiting, or abdominal pain as presenting symptoms. Liver tests are not 100% sensitive for the presence of liver disease, and patients with chronic viral hepatitis B or C, or even cirrhosis, may have normal liver tests.

Differential Diagnosis

The differential diagnosis of elevated liver tests is broad (Box 62-1). A systematic approach to evaluation can help minimize testing and reduce costs initiated. In patients presenting with symptoms of jaundice, acute viral hepatitis, and gallstone disease, alcoholic hepatitis and drug-induced liver injury are in the differential. In asymptomatic patients who have elevations in liver tests, chronic viral hepatitis, fatty liver disease, and hemochromatosis warrant consideration.

Diagnostic Approach

Abnormal liver tests should be repeated with patients fasting and abstaining from alcohol and off of nonessential medications, including over-the-counter medicines and complementary or alternative medicines. Elevations in liver chemistries documented on two or more occasions require further evaluation.

The evaluation of patients with elevated liver tests should take into consideration the most common causes of chronic liver disease: alcohol use, medications, hemochromatosis,

chronic hepatitis C, and nonalcoholic fatty liver disease. Hepatitis B is relatively rare in the United States, having become less common after the implementation of universal immunization. Other liver disorders are relatively rare and should not be included in the initial evaluation unless a risk factor or predisposing condition is present. An abdominal ultrasound is useful for detecting gallstones, although it may miss common bile duct stones and fatty infiltration of the liver. Liver biopsy seldom identifies an etiology of liver disease that is not detected on blood testing but may be useful to stage the amount of liver fibrosis.

The pattern of liver test elevation may be useful for determining the underlying disease. Elevations in total bilirubin or alkaline phosphatase suggest cholestatic liver disease or obstruction, such as primary sclerosing cholangitis, primary biliary cirrhosis, pancreatic head mass or choledocholithiasis. Elevations in AST and ALT suggest hepatocellular disease. The pattern of elevation may be mixed with elevations of AST, ALT, alkaline phosphatase, and total bilirubin in drug-induced liver injury. Nonalcoholic fatty liver disease and drug-induced liver injury, two common causes of elevations in liver tests, are discussed in this chapter.

NONALCOHOLIC FATTY LIVER DISEASE

Etiology and Pathogenesis

NAFLD was first described by Ludwig in patients who presented with elevations in liver tests and hepatic steatosis on liver biopsy without a significant history of alcohol use. The current hypothesis is that two insults or “hits” cause liver injury in NAFLD. In the first hit, insulin resistance leads to the retention of lipids, particularly triglycerides, within hepatocytes. The underlying mechanism is decreased fatty acid disposal due to impaired mitochondrial β oxidation. Macrovesicular steatosis within hepatocytes arises from the first hit and produces a chicken-wire appearance on liver biopsy (Fig. 62-1). The second hit, oxidative stress, causes peroxidation of hepatocyte membrane lipids and cytokine production. The oxidative stress may be responsible for the progression from steatosis to steatohepatitis with or without fibrosis or cirrhosis (see Fig. 62-1). Adipokines, cytokines elaborated in fat cells, also play a role. Increased serum leptin and decreased adiponectin may promote hepatic steatosis and steatohepatitis.

The common etiologic factors for NAFLD are visceral obesity, type II diabetes mellitus, low high-density lipoprotein cholesterol, and hypertriglyceridemia. Mitochondrial dysfunction is linked to insulin resistance and hepatic steatosis. However, emerging evidence suggests a significant proportion of NAFLD patients lack these risk factors. Increasing age is associated with worse fibrosis, possibly because of increased NAFLD duration or increased hepatocyte mitochondria dysfunction in elderly people.

Box 62-1 Differential Diagnosis of Elevated Liver Tests

Figure 62-1 Nutritional Liver Diseases—Nonalcoholic Fatty Liver Disease.

Secondary hepatic steatosis or steatohepatitis is seen with inborn errors of metabolism and medications. Amiodarone, methotrexate, tamoxifen, glucocorticoids, nucleoside analogues, calcium channel blockers, nonsteroidal anti-inflammatory drugs, and the tetracycline antibiotics have been associated with hepatic steatosis. Secondary fatty liver disease has also been associated with weight loss surgeries creating extensive small bowel diversion, total parenteral nutrition, and jejunal diverticulosis with bacterial overgrowth.

Clinical Presentation

The clinical presentation of NAFLD is variable. The most common presentation is asymptomatic elevation of aminotransferases, usually up to fivefold elevated, with ALT

usually greater than AST. NAFLD is usually suspected in patients with abnormal liver chemistries after the exclusion of other liver diseases and the presence of fatty infiltration of the liver on imaging studies or unexplained hepatomegaly. The liver enzymes may fluctuate and may decrease with weight loss. NAFLD can be detected by ultrasonography, often done for unrelated reasons, such as investigation of right upper quadrant pain. Some patients can present with cryptogenic cirrhosis. Indeed, NAFLD may be the most common cause of cryptogenic cirrhosis.

The most common signs of NAFLD are visceral obesity and hepatomegaly. When presenting with cirrhosis, patients may have splenomegaly, spider angiomas, and palmar erythema. Mild to moderate elevation of ALT and AST is the most common and often the only laboratory

abnormality. The ALT/AST ratio is usually greater than 1, but decreases as cirrhosis develops. There is no correlation between the degree of AST or ALT elevation and histologic severity. Hypoalbuminemia, hyperbilirubinemia, and prolonged prothrombin time are seen in decompensated cirrhosis. Serum ferritin is frequently elevated, and in 6% to 11%, the transferrin saturation is elevated.

The diagnosis of NAFLD is suggested by the presence of NAFLD etiologic factors. As previously noted, imaging studies may reveal features that suggest fatty infiltration. Liver biopsy is the gold standard to confirm a diagnosis of NAFLD and to distinguish steatohepatitis from simple steatosis. Moreover, a liver biopsy will assess the extent of fibrosis in steatohepatitis and provide prognostic information. The steatohepatitis variant of NAFLD is characterized by histologic features, including steatosis, hepatocyte ballooning degeneration, lobular inflammation with polymorphonuclear leukocytes, lobular necrosis, Mallory bodies, and perisinusoidal fibrosis.

Differential Diagnosis and Diagnostic Approach

To diagnose NAFLD, secondary causes of hepatic fat must be excluded. Hepatitis C and alcoholic liver disease are particularly important because of the high prevalence of these two disorders. It is generally believed that a fatty liver does not develop with alcohol consumption levels of less than 20 g/day in females and less than 30 g/day in males.

Ultrasonography, computed tomography, and magnetic resonance imaging can identify hepatic steatosis and have been advocated as diagnostic tests for NAFLD. None is sufficiently sensitive to detect hepatic inflammation, fibrosis, or cirrhosis. With the inability to distinguish simple steatosis from steatohepatitis and to stage the severity of injury, liver biopsy remains the best diagnostic test for steatohepatitis. However, the lack of effective medical therapy for NAFLD and the risks associated with biopsy require careful consideration before making the decision to proceed.

Management and Therapy

Optimum Treatment

There is no currently established treatment for NAFLD. In the absence of proven therapies, the emphasis is to correct NAFLD etiologic factors. Sustained, gradual, and moderate (10% or less) weight loss through exercise and diet may improve liver enzymes and histology. The proximal gastric bypass operation may be superior to the vertical-banded gastroplasty for weight loss and may be beneficial in NAFLD, provided the weight loss is gradual and maintained. Insulin sensitizers that decrease hepatic steatosis and fibrosis are being investigated. In pilot studies using rosiglitazone and pioglitazone for 48 weeks, NAFLD patients had improvement in insulin sensitivity, liver his-

tology, and liver enzymes. In a small study, metformin for 4 months was associated with liver enzyme improvement. Subjects also lost a significant amount of weight. Therefore, it is uncertain whether the improvement was secondary to weight loss or to the metformin. Vitamin E at 400 to 1200 IU per day was associated with improvement in ALTs in children with NAFLD, but biopsy data were not collected as part of the trial. Betaine, a precursor of the hepatoprotective factor *S*-adenosyl methionine, has shown promise. However, NAFLD can recur and rapidly progress. The results of small trials using fibrates for hypertriglyceridemia are mixed, with the most rigorously designed showing no histologic benefit. There are currently no data on the use of 3-hydroxy-3-methylglutaryl-coenzyme A reductase inhibitors (i.e., the statins) for the treatment of NAFLD. Liver transplantation is offered to NAFLD patients with decompensated cirrhosis.

Avoiding Treatment Errors

A misconception in treating patients with NAFLD is that certain classes of medications should be avoided that have been associated with elevating aminotransferases. For example, statins are associated with elevations in aminotransferases. Clinicians are reluctant to prescribe statins in patients with NAFLD and hyperlipidemia. Patients with NAFLD who have indications for statins, especially hypertriglyceridemia, should be prescribed these and other agents for hyperlipidemia because there is no evidence suggesting an increased risk for severe liver injury in NAFLD patients treated with statins. The same line of reasoning holds true for patients with NAFLD and diabetes. NAFLD patients with diabetes who have indications for metformin or glitazones should be prescribed these medications.

Future Directions

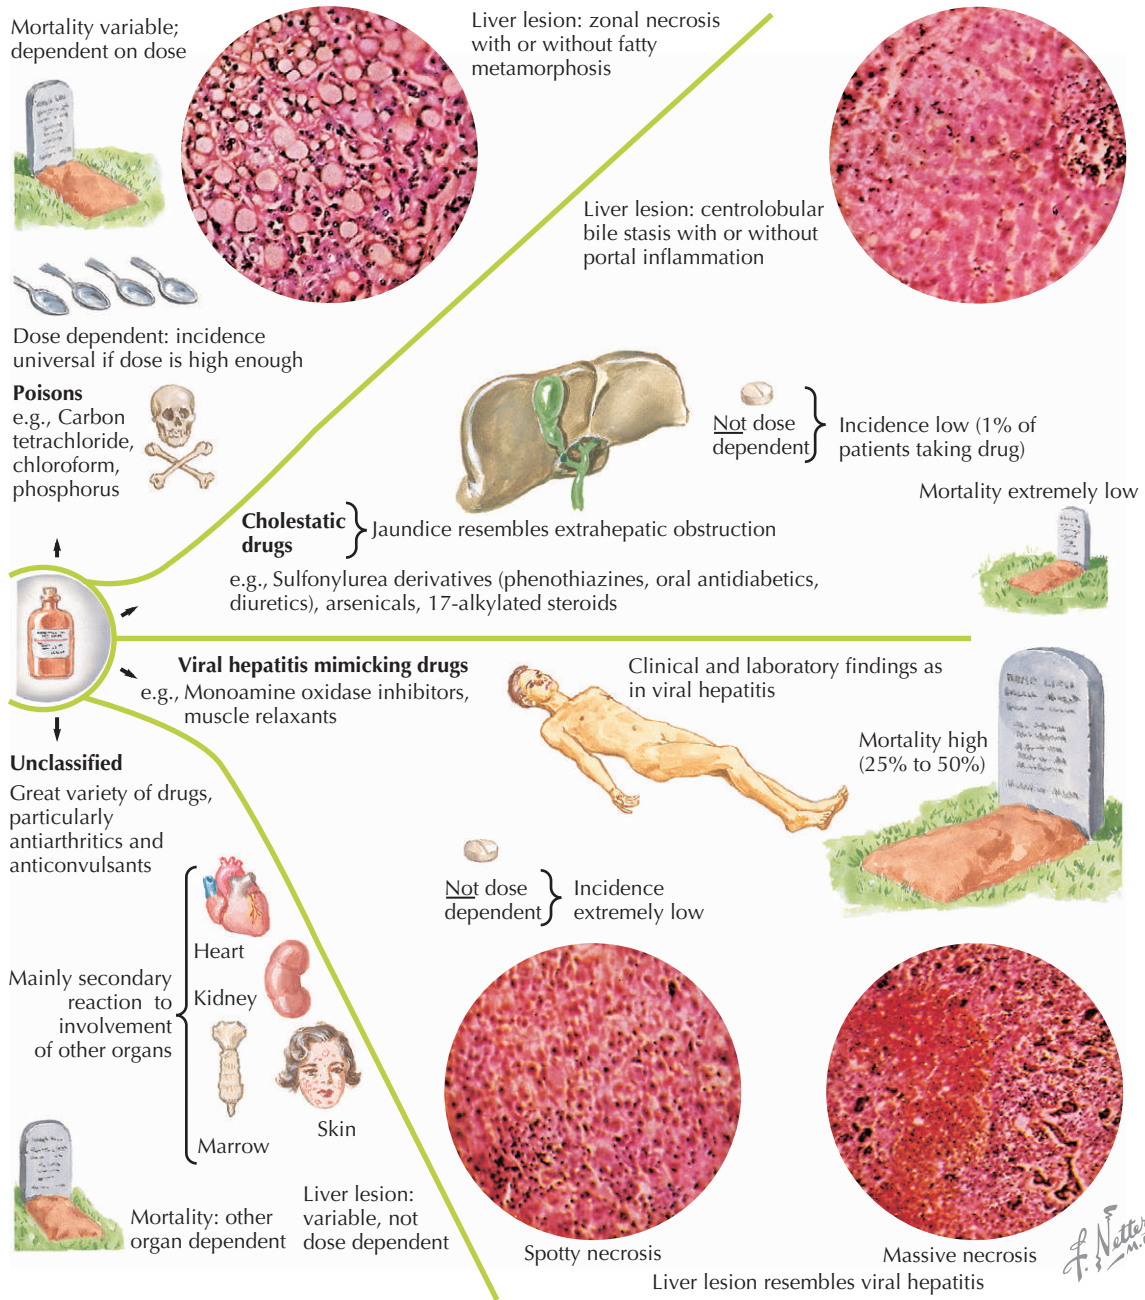

Because NAFLD is prevalent, larger, well-designed clinical trials with liver histology as an outcome are needed. The most promising drugs are the thiazolidinediones and statins. Studies of disease pathogenesis will help identify patients at greatest risk for progression and need of treatment. The nonalcoholic steatohepatitis clinical research network funded by the National Institutes of Health (NIH) is poised to answer many questions about the natural history and treatment of NAFLD.

DRUG-INDUCED LIVER INJURY

Etiology and Pathogenesis

Drug-induced liver injury (DILI) is typically classified as dose dependent or idiosyncratic. Most drugs are associated with idiosyncratic injury, defined as unpredictable elevations in liver tests that occur at any dose or duration of use (Fig. 62-2). Acetaminophen is an example of a dose-

Figure 62-2 Drug-Induced Hepatic Injuries.

dependent hepatotoxin; most individuals develop elevations in AST or ALT with a single dose of more than 10 g.

Hepatotoxicity from most drugs is believed to occur through a reactive metabolite. The metabolite may covalently bond to proteins that disrupt protein function, resulting in cell necrosis and death. Metabolites may act as haptens, and cell injury may occur through immune-mediated injury. On liver biopsy, drugs may produce characteristic patterns of injury, including spotty or massive necrosis, cholestasis, chronic hepatitis, or microvesicular or macrovesicular steatosis (see Fig. 62-2). Less common histologic patterns of DILI include fibrosis,

veno-occlusive disease, phospholipidosis, and peliosis hepatitis.

The factors that render an individual susceptible to developing DILI are largely unknown. Studies have described differences in genetic sequences of drug metabolism or human leukocyte antigen (HLA) haplotypes between individuals who did and did not develop DILI from a specific drug. Polymorphisms in glutathione S-transferase have been associated with DILI from tacrine and troglitazone. Polymorphisms in the HLA-DR haplotype are associated with cholestatic liver injury from amoxicillin-clavulanic acid. Genetic testing may eventually

prove to be useful for identifying individuals at increased risk for DILI from a specific drug.

Clinical Presentation

Fatigue, mild abdominal pain, and jaundice are among the most common symptoms reported by patients with DILI. Most patients may not experience any symptoms, and the first sign of a drug reaction is detected by a friend or clinician who notices scleral icterus. Medications associated with hypersensitivity reactions may be accompanied by a skin rash or peripheral eosinophilia. Generalized pruritus with or without a skin rash is characteristic of cholestatic reactions. Physical exam is typically unremarkable, but mild right upper quadrant tenderness to palpation is a frequent finding. Hepatosplenomegaly is not a common sign in DILI.

Differential Diagnosis

The differential diagnosis for DILI is broad, but most commonly acute viral hepatitis, gallstone disease, and autoimmune liver disease require exclusion (Box 62-2). DILI can be difficult to diagnose because there is no diagnostic test that can definitively implicate a drug as a cause for hepatotoxicity. The closest gold standard is a rechallenge in which the patient is re-exposed to a drug and redevelops hepatotoxicity. Rechallenge only occurs inadvertently; thus, there are few cases that meet this gold standard.

Diagnostic Approach

The temporal association between elevations in liver tests and the initiation of a drug and the exclusion of other causes of increased liver tests are important components in the diagnosis. Hepatitis A immunoglobulin M (IgM) should be obtained to exclude acute hepatitis A, and hepatitis B surface antigen and core IgM should be obtained to exclude acute hepatitis B. Abdominal imaging is necessary in patients who present with elevations in total bilirubin or alkaline phosphatase to exclude cholangitis or choledocholithiasis. DILI may be difficult to distinguish from autoimmune liver disease. Both can present with hepatocellular, mixed, or cholestatic patterns of liver injury. Autoantibodies are not pathognomic for autoimmune liver

Box 62-2 Differential Diagnosis of DILI

- Acute hepatitis A
- Acute hepatitis B
- Epstein-Barr virus hepatitis
- Cytomegalovirus hepatitis
- Autoimmune liver disease
- Cholangitis or choledocholithiasis
- Vascular insult (ischemic or thrombotic)
- Alcoholic hepatitis

disease, and patients with DILI may develop antinuclear antibodies. A liver biopsy can be helpful. The characteristic finding in DILI is the presence of eosinophils. Instruments have been developed to provide a quantitative score used to assign a probability that the implicated drug is the cause of the liver test abnormalities, but they are cumbersome and not used in clinical practice.

Drug reactions can be classified as hepatocellular, cholestatic, or mixed (Box 62-3). A hepatocellular reaction is defined as an ALT/alkaline phosphatase ratio greater than 5, a cholestatic reaction as an ALT/alkaline phosphatase ratio less than 2, and a mixed reaction as values between hepatocellular and cholestatic reactions. Cholestatic reactions typically take longer to resolve than hepatocellular reactions.

Management and Therapy

Optimum Treatment

Management of DILI should be directed at early recognition of hepatotoxicity and prompt discontinuation of the potential offending agent. With the exception of *N*-acetylcysteine for acetaminophen hepatotoxicity and deferoxamine for iron overdose, there are no antidotes for DILI. *N*-acetylcysteine should be administered if hepatotoxicity from acetaminophen is suspected, even if the acetaminophen level is undetectable. Although prescribing corticosteroids for DILI is frequently contemplated, there is no evidence supporting their use.

Box 62-3 Pattern of Liver Injury from Selected Drugs, Classes of Drugs, and Complementary Alternative Medicines

Hepatocellular

- Isoniazid
- Statins
- Acetaminophen
- Halothane
- Methyldopa
- Amanita mushrooms
- Chaparral

Cholestatic

- Amoxicillin-clavulanate
- Azathioprine

- Erythromycin
- Methyltestosterone
- Celandine

Mixed

- Phenytoin
- Trimethoprim-sulfamethoxazole
- Ketoconazole
- Allopurinol
- Valerian
- Germander
- Kava

Most patients with DILI recover without significant sequelae. However, if jaundice develops (total bilirubin >3 mg/dL), patients need to be followed more closely. Mortality rate is estimated at 10% in patients who develop jaundice following a hepatocellular injury (hepatocellular jaundice) from a drug reaction.

Prescribing Medications in Patients with Elevated Liver Tests

A common clinical scenario that arises is whether to prescribe a medication known to be associated with elevations in liver tests, such as statins, in patients with abnormal liver tests. Under most circumstances, the indication and benefit of the drug far outweigh the rare risk for DILI. Statins have not been associated with an increased risk for DILI in patients with elevated liver tests and can be prescribed for hypercholesterolemia in patients with NAFLD. Liver tests should be obtained before starting a medication associated with elevations in liver tests so that a new drug is not incorrectly implicated as a cause for liver test elevations in a patient who has underlying chronic liver disease. One approach is to continue patients on the drug as long as AST or ALT does not exceed 3 times the baseline value and the bilirubin does not exceed the upper limit of normal range.

Avoiding Treatment Errors

Recognizing DILI early, stopping the offending agent, and avoiding re-exposure are the mainstays of therapy. In a patient who typically does not complain of symptoms and presents with abdominal discomfort or nausea after starting a new medication, particularly a known hepatotoxin, such as isoniazid, it is reasonable to stop the medication and check liver tests. Steroids may be prescribed in certain situations, such as a hypersensitivity reaction, although there is no evidence to support the use of steroids in DILI.

Future Directions

Because DILI is among the most common reasons for regulatory action against a drug, there is much interest in developing accurate preclinical testing for identifying drugs that are potentially hepatotoxic. Hepatocyte cell culture systems and identification of genetic polymorphisms associated with DILI are among the most actively investigated areas. The Drug Induced Liver Injury Network is prospectively collecting DILI cases for potential genetic association studies.

Data from this study demonstrated that patients with fatty liver disease benefited from weight loss and exercise, supporting the clinicians' recommendation that changes in lifestyle can lead to improvement in liver disease.

Viral Hepatitis: Acute and Chronic Disease

Introduction

Acute viral hepatitis and chronic viral hepatitis are major sources of morbidity and mortality worldwide. There are an estimated 1.5 million new cases of hepatitis A each year. More than 2 billion people worldwide have been exposed to hepatitis B at some point during their lives, and 350 million of these remain chronically infected. Nearly 3% of the world's population is infected with hepatitis C, totaling about 170 million people.

Infection with one of the hepatotropic viruses (hepatitis A, B, C, D, E) (Table 63-1) can cause an acute, chronic, or acute and chronic illness. The clinical manifestations of these infections range from a viral prodrome to fulminant hepatic failure to chronic liver disease and cirrhosis. Other viruses, such as cytomegalovirus, Epstein-Barr virus, herpesvirus, and varicella-zoster virus, may also cause an acute hepatitis, but usually in the context of a systemic illness. In such cases, the liver is not the primary target of infection.

HEPATITIS A

Etiology and Pathogenesis

Hepatitis A is caused by the hepatitis A virus (HAV) and is transmitted in a fecal-oral manner. The most common method of transmission is through contaminated food or water. The infection is endemic in developing areas. There is an incubation period of anywhere from 1 to 6 weeks before the onset of symptoms (Fig. 63-1). HAV manifests as an acute illness, with exposure granting lifelong immunity. There is no chronic phase to HAV infection.

Clinical Presentation

The symptoms of HAV infection are nonspecific and can resemble a flu-like illness. Commonly, infected persons suffer from malaise, fatigue, nausea, and vomiting as well as low-grade fever and mild right upper quadrant pain. Diarrhea can also occur and facilitate transmission of HAV. As the illness progresses to the icteric phase of acute hepatitis, dark or tea-colored urine and jaundice are noted. The physical exam is often notable for icteric sclerae, jaundice and occasionally, a tender palpable liver. Like the

symptoms, however, physical exam signs are not specific for HAV.

Differential Diagnosis

Acute hepatitis caused by any of the hepatotropic viruses, acute systemic viral infection, drug hepatotoxicity, and cholangitis, among other etiologies, should all be considered in the differential diagnosis of acute hepatitis A.

Diagnostic Approach

Laboratory analysis of the patient with HAV demonstrates liver enzyme abnormalities with a pattern of acute hepatocellular injury. Initially, the serum transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]) can rise to greater than 10 times the upper limit of normal. Serum bilirubin becomes elevated as well, usually below 10 mg/dL, and is slower to rise and fall than the serum transaminases. In endemic areas, subclinical infection is common in children, and the likelihood of symptomatic acute icteric infection rises with the patient's age at acquisition. The definitive laboratory test for acute

Table 63-1 Hepatotropic Viruses				
	Mode of Transmission	Approximate Incubation	Endemic Areas	Potential for Chronicity
Hepatitis A	Fecal-oral Food-and water-borne outbreaks	1-6 wk	Developing countries	No
Hepatitis E	Fecal-oral Food- and water-borne outbreaks	1-6 wk	Mexico, SE Asia	No
Hepatitis B	Parenteral, sexual, perinatal	1-6 mo	Asia, Africa	Yes
Hepatitis D	Parenteral, sexual	1-6 mo	Mediterranean	Yes
Hepatitis C	Parenteral	1-6 mo	Egypt	Yes

Figure 63-1 Viral Hepatitis: Acute Form.

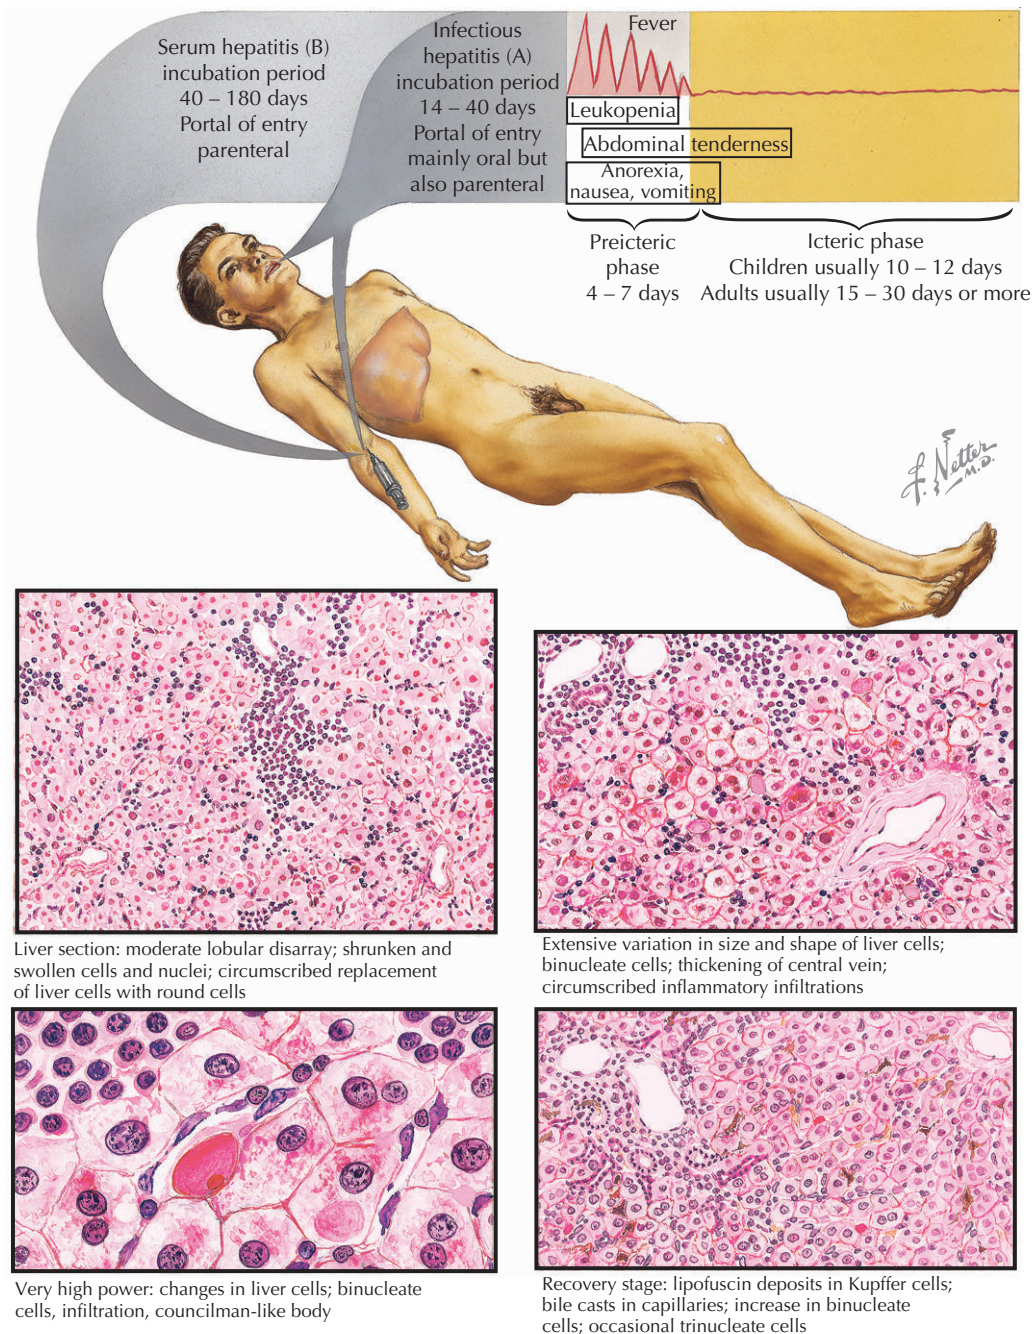

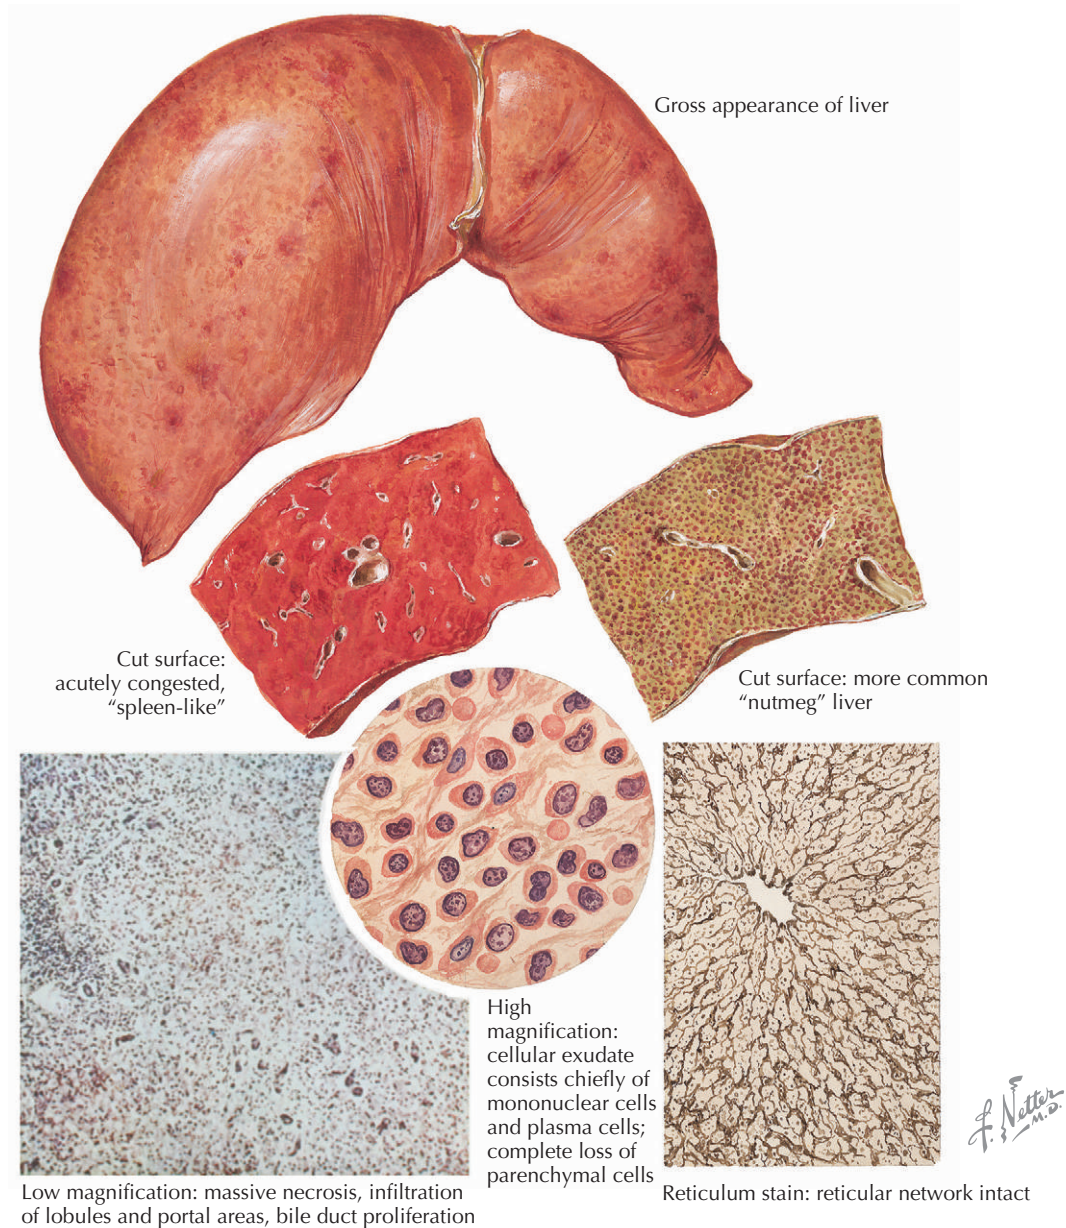

Figure 63-2 Viral Hepatitis: Fulminant Form (Acute Massive Necrosis).

hepatitis A is serum HAV IgM. Prior exposure or vaccination, and thus immunity, is confirmed by a reactive HAV total IgG.

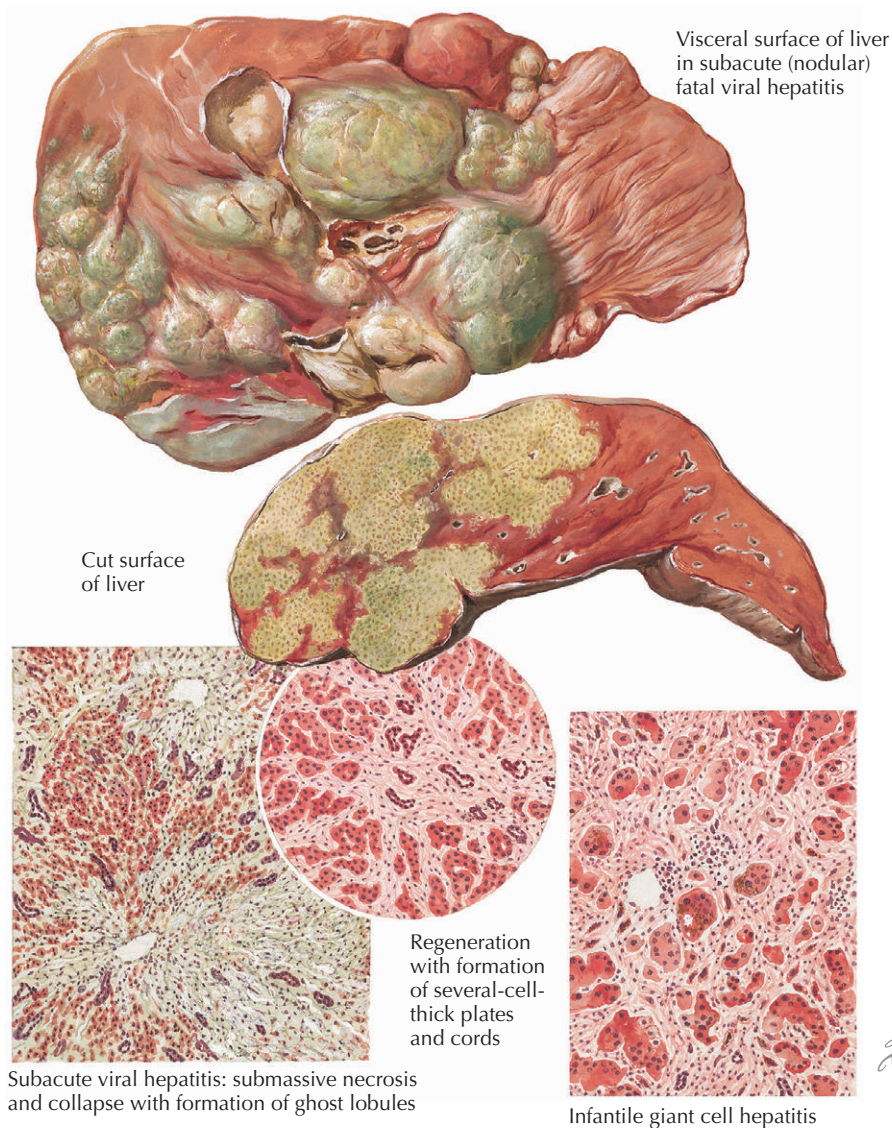

Management and Therapy

Optimum Treatment

There are no specific interventions for treatment except for supportive care and monitoring for the development of fulminant liver failure, a rare complication of HAV infection (Figs. 63-2 and 63-3). The urgency of evaluation of hepatitis and considerations for hospital admission or referral to a liver specialist are based on the functional

status of the patient, the tempo of changes in liver enzyme levels, and the presence of hepatic synthetic dysfunction. Patients with social support to monitor their status, who are sufficiently reliable to keep follow-up appointments, and who are able to maintain their oral intake may convalesce as outpatients. Those with evidence of progressive hepatic synthetic dysfunction (prolonged prothrombin time, altered mental status) should be hospitalized until clinical improvement is noted or referred for evaluation for liver transplantation if progressive liver failure develops.

Acute HAV infection must be reported to public health officials so that they can watch for clustering of cases and perhaps identify a common link to an outbreak. The index

Figure 63-3 Viral Hepatitis: Subacute Fatal Form.

case in HAV outbreaks is most infectious before the icteric phase of the illness. Fecal shedding of the HAV is at its peak while the patient suffers from nonspecific flu-like symptoms of malaise, nausea, and diarrhea. Close personal and household contacts are at risk for acquiring HAV from the index case. Close contacts of an index case should receive hepatitis A immune globulin within 2 weeks of exposure, which offers the best chance of preventing infection.

Most recent recommendations advise all children to receive the hepatitis A vaccine at age 1 year as part of routine childhood vaccinations. Catch-up vaccination of unvaccinated children between ages 2 and 18 years should also be considered. Susceptible adults, especially those at increased risk for HAV infection, such as travelers to developing countries where HAV is endemic, men who have sex with men, intravenous drug users, residents and

employees of institutionalized living facilities, and day care workers, should also be vaccinated for HAV. Patients with a chronic liver disease require HAV vaccination given their higher risk for hepatic decompensation if they acquire the virus.

HEPATITIS E

The hepatitis E virus (HEV) is another hepatotropic virus that is spread by the fecal-oral route. It is endemic to developing countries, especially in Central America and South and Southeast Asia. Like HAV, its incubation period is 1 to 6 weeks. HEV has no potential for inducing chronic liver disease. Pregnant women seem particularly at risk for development of fulminant liver failure; however, the overall rate of severe hepatitis is low. Serologic testing for anti-HEV is now available and should be considered if travel

Table 63-2 Serologic Profile of Hepatitis B

	Serum ALT	HBsAg	Anti-HBs	HBcAb	HBeAg	Anti-HBe	HBV DNA
Acute	++++	+	–	+ IgM	+/-	+/-	+/-
Resolved	Normal	–	+	+ (Total)	–	+	–
Chronic (wild type)	++	+	–	+	+	–	>20,000 IU/mL
Chronic (pre-core mutant)	++	+	–	+	–	+	>2000 IU/mL
Inactive carrier	Normal	+	–	+	–	+	<20,000 IU/mL
Vaccinated	Normal	–	+	–	–	–	–

to an endemic region occurred before the onset of acute hepatitis. Like hepatitis A, supportive care is the hallmark of treatment for hepatitis E. Most cases resolve spontaneously; however, the advent of encephalopathy or coagulopathy should prompt referral to a transplantation center.

HEPATITIS B

Etiology and Pathogenesis

The hepatitis B virus (HBV) has the potential to cause both acute and chronic hepatitis. Acute infection can range from a flu-like icteric illness to fulminant hepatic failure. Chronic HBV infection may remain asymptomatic or lead to cirrhosis, portal hypertension, hepatocellular carcinoma, and end-stage liver disease (Fig. 63-4). This DNA virus is transmitted sexually, parenterally, or perinatally. Nearly half of the world's population lives in areas where HBV is endemic, particularly parts of Asia and Africa (Fig. 63-5).

Clinical Presentation

Acute infection manifests with fever, anorexia, nausea, vomiting, and abdominal tenderness, followed by an icteric phase that, in adults, can last for more than a month. Nearly 95% of adults recover and develop natural immunity after acute infection. About 5% develop chronic HBV infection, whereas less than 1% develop fulminant hepatic failure. Newborns that acquire HBV from their mothers by vertical transmission have a 90% risk of developing chronic HBV.

Extrahepatic manifestations of HBV include urticaria, polyarteritis nodosa, and chronic kidney disease through membranous and membranoproliferative glomerulonephritis.

Diagnostic Approach

Acute hepatitis B produces liver enzyme abnormalities consistent with hepatocellular injury, with marked elevations of serum ALT and AST activities. In general, the ALT and AST will rise rapidly, often to levels greater than 10 to 15 times the upper limits of normal, followed by a

more gradual and sustained elevation of the serum bilirubin. Serologic confirmation of infection is essential, as is the correct identification of acute disease versus chronic carriers, vaccinated patients, and those with resolved infection and immunity. These various clinical scenarios are defined in Table 63-2. A patient may traverse several of these clinical stages during the natural course of their HBV infection (Fig. 63-4).

Management and Therapy

Acute Hepatitis B: Optimum Treatment

Like HAV infection, the mainstay of acute HBV infection is supportive care and surveillance for the signs and symptoms of hepatic dysfunction. The development of encephalopathy or coagulopathy is ominous, and patients should be immediately referred for transplantation evaluation. There appears to be no role for direct antiviral therapy in patients with acute hepatitis B, although the use of this therapy in severe acute hepatitis B remains controversial. People with acute HBV should have repeat serologic testing 6 months after the initial infection to confirm clearance of hepatitis B surface antigen (HBsAg) and immunity versus chronic infection.

Patients with acute HBV infection should be reported to local public health authorities. Susceptible persons who have had sexual contact with the index case within 2 weeks of presentation should receive hepatitis B immune globulin and the hepatitis B vaccine.

Chronic Hepatitis B: Optimum Treatment

Chronic HBV infection can progress to cirrhosis, portal hypertension, end-stage liver disease, and hepatocellular carcinoma. Some of these patients may be candidates for antiviral therapy if they have evidence of active HBV DNA replication in their serum. Several agents, including immunomodulators such as interferon and peginterferon and direct antivirals such as lamivudine, adefovir, entecavir, and telbivudine have demonstrated efficacy for the treatment of chronic hepatitis B. Decisions regarding treatment for chronic HBV and monitoring are complex, and patients may benefit from specialty evaluation. Patients with chronic

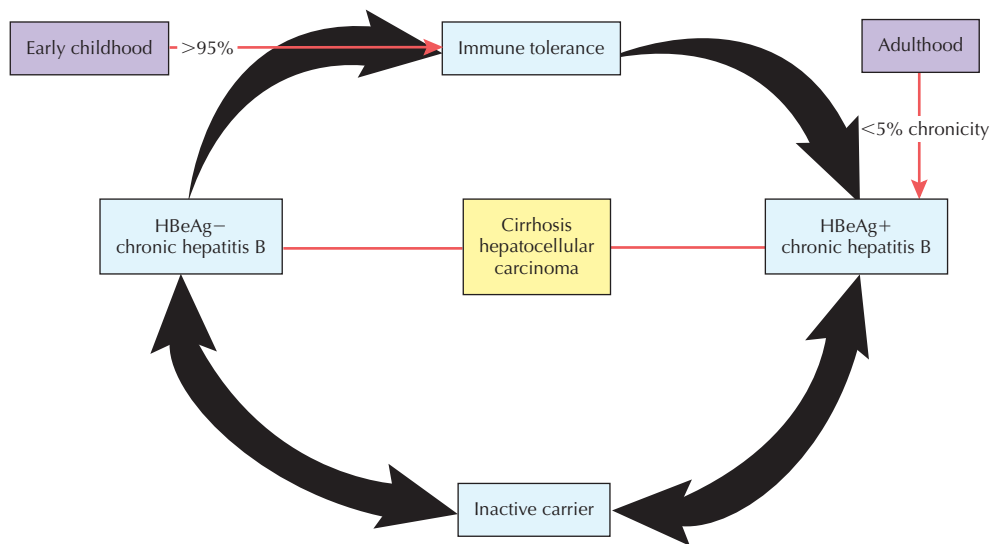

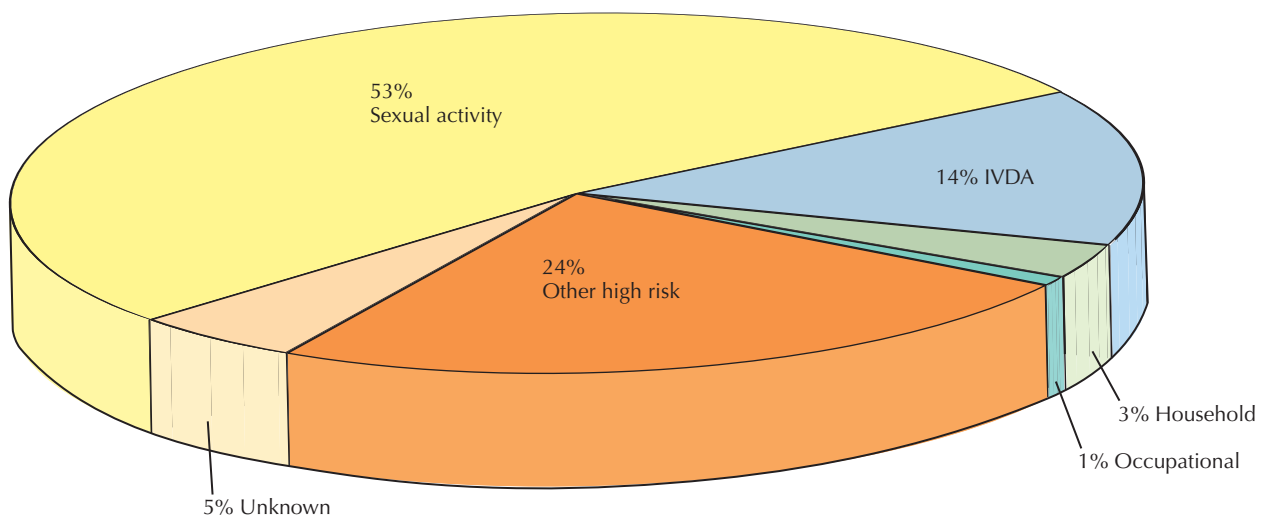

Figure 63-5 Acute Hepatitis B: Risk Factors 1991-1996.

IVDA, intravenous drug abuse. Adapted from *Epidemiology and Prevention of Viral Hepatitis*. Centers for Disease Control and Prevention. Available at: <http://www.cdc.gov>.

HBV should receive the hepatitis A vaccine. Because of the high incidence of hepatocellular carcinoma in patients with chronic hepatitis B, those at highest risk (cirrhotic patients, Asian men >40 years and women >50 years, African patients >20 years, and individuals with family history of hepatocellular carcinoma, among others) should be screened for liver cancer with hepatic ultrasound at 6- to 12-month intervals.

Prevention

Prevention is the key to decreasing the incidence of HBV infection. The hepatitis B vaccine is highly immunogenic

and induces protective antibodies in most people who receive the vaccine. Those who are immunosuppressed or already have advanced liver disease are the exceptions to this rule. Currently, vaccination against HBV is recommended for all newborns, health care workers, and patients with another liver disease. In the United States, thanks to newborn vaccinations and catch-up vaccination programs for older children, the incidence and prevalence of HBV infection should dramatically decrease within a generation. In other countries where HBV is endemic, newborn vaccinations have reduced the rates of vertical transmission, chronic HBV, and hepatocellular carcinoma.

HEPATITIS D

Hepatitis D virus (HDV) is a defective ribonucleic acid (RNA) virus that requires the hepatitis B surface antigen for replication. Thus, only people with acute HBV infection (coinfection) or chronic carriers of HBV (superinfection) are at risk for HDV infection. Also known as the *delta virus*, HDV is endemic to countries surrounding the Mediterranean Sea, particularly Italy and Turkey. This diagnosis should be considered in acute HBV patients who have a difficult clinical course or in chronic HBV patients who have a flare of their disease. Laboratory confirmation requires a positive serum HBsAg as well as the presence of hepatitis delta antibody. Therapy entails treatment of the underlying hepatitis B, if applicable, and continued supportive care.

HEPATITIS C

Etiology and Pathogenesis

Hepatitis C virus (HCV) infects nearly 2% of the population in the United States and 3% of the population worldwide. HCV differs from the other heterotropic viruses because it is much more likely to induce a chronic hepatitis. HCV can progress to hepatocellular carcinoma or cirrhosis and end-stage liver disease and, as a result, is a major public health problem. HCV is the leading cause of death from liver disease in the United States. An acute form of HCV does exist, but it is rarely encountered because nearly 75% of cases are asymptomatic.

Hepatitis C is a heterogeneous single-stranded RNA virus with six major genotypes. Genotype 1 is the most common type found in the United States, 70% of cases, with genotypes 2 and 3 accounting for the remainder. Genotype 4 is endemic to Egypt and the Middle East. Genotypes 5 and 6 are rarely encountered outside of southern Africa. Although the genotype does not impact severity of disease, genotype 1 is more often refractory to therapy.

The natural history of HCV infection is in dispute. Some patients will have stable, mild disease, whereas others will have disease progression over decades and develop cirrhosis. Factors associated with rapid disease progression include alcohol use, male gender, coinfection with HIV, and hepatic steatosis.

Clinical Presentation

Often, HCV is diagnosed after routine liver function tests, drawn for an alternative indication, are found to be abnormal. Most acute infections are asymptomatic; those with chronic infection have fatigue, malaise, and other nonspecific symptoms. Some patients' initial symptoms are those of chronic liver disease: jaundice, ascites, and confusion, often after they have unknowingly harbored the virus for decades.

Risk factors for infection include intravenous drug use (70%), blood transfusion before 1992 (6%), and occupational exposures (3%). Transmission by sexual exposure is possible, but the rate of transmission is low. Risks associated with tattoos, body piercing, and intranasal cocaine use are not well defined. Nearly 10% of HCV-infected people do not have an identifiable risk factor.

Extrahepatic manifestations of HCV infection include cryoglobulinemia, glomerulonephritis, porphyria cutanea tarda, and thyroid disease. There are associations among HCV, diabetes mellitus, lichen planus, and B-cell lymphoma.

Diagnostic Approach

Because chronic HCV is usually asymptomatic, screening with anti-HCV antibody for hepatitis C is recommended for all patients with an abnormal ALT, any history of intravenous drug use, blood transfusions or organ transplantation before 1992, hemophilia, or hemodialysis. Health care workers with documented exposure to HCV-infected blood and children born to HCV-infected mothers should also be screened.

In the setting of a risk factor or elevated ALT, the presence of anti-HCV is virtually diagnostic of HCV infection. Before consideration of therapy for HCV, the presence of HCV as a measure of active viremia and the genotype of HCV should be determined. Viral levels do not indicate the severity of infection but are useful in following response to therapy.

Management and Therapy

Optimum Treatment

If identified early, as in the case of an occupational exposure, acute HCV infection is amenable to treatment with interferon. Chronicity can be prevented in 98% of patients if treatment begins within 3 to 6 months after infection.

Patients with chronic HCV infection require the same health maintenance as any other patient with a chronic liver disease; hepatitis A and B immunizations and hepatocellular cancer screening in the presence of cirrhosis.

Liver biopsy is a generally safe and useful, although not a mandatory, tool in staging hepatitis C infection. Therapy is usually recommended for those with evidence of some degree of hepatic fibrosis, although all patients with chronic hepatitis C may be considered for antiviral therapy provided they have no contraindications.

The current regimen for HCV treatment is once-weekly subcutaneous injections of peginterferon administered with twice-daily ribavirin for 6 months to 1 year.

Successful HCV therapy is defined as an undetectable HCV RNA in serum 6 months after completion of therapy. This is called a *sustained virologic response* (SVR) and is synonymous with a "cure." Patients with genotype 1 HCV achieve SVR 40% to 50% of the time. Genotype 2 and 3

patients achieve SVR 75% to 80% of the time. Patients should be carefully screened before therapy. Interferon can exacerbate psychiatric illness and thus is contraindicated for patients with poorly controlled depression or bipolar disorder. Other side effects of therapy include neutropenia, hemolytic anemia, thrombocytopenia, and thyroid dysfunction. Treatment is also contraindicated for patients with significant cardiac disease or decompensated cirrhosis.

Patients should be counseled that there is no risk for transmission of hepatitis C through casual contact, sharing food, utensils, kissing, or hugging. Care should be taken to avoid sharing items that may be exposed to blood, like razors or toothbrushes. As above, the risk for sexual transmission is low, but measurable; sexual partners should undergo screening for HCV, but mandatory barrier protection is not routinely recommended in monogamous relationships. The risk for vertical transmission is also low. Currently, there are no recommendations for changing birthing practices or breast-feeding in HCV-positive women.

Avoiding Treatment Errors

The most common treatment error with the entire series of hepatotropic viruses is one of correct diagnosis and determination of chronicity. Care should be taken in interpreting the HAV serologies; if misread, an alternative diagnosis and thus expeditious treatment may be delayed. HAV IgM is indicative of acute disease, whereas a reactive HAV total antibody confirms immunity. The HBV serologies can be more confusing because there are subtle differences in the serologic profiles for acute disease, resolved infection, chronic active disease, chronic inactive carriers, and vaccinated individuals (see Table 63-2). Additionally, the period between 2 weeks and 4 months after infection, when the HBsAg has disappeared, but the hepatitis B surface antibody is not yet detectable, can make diagnosis more difficult. In individuals in whom the suspicion of acute infection is high, checking the hepatitis B core IgM titer can resolve this issue.

Treating HCV is fraught with possible complications, mostly due to the side effects of peginterferon and ribavirin. Anemia, leukopenia, thyroid dysfunction, and psychiatric problems can complicate therapy. Thus, referral to a subspecialist should be considered. The primary physician can play a large role in screening for hepatitis C patients with risk factors for infection, counseling newly diagnosed individuals, and assisting with the identification of candidates for antiviral therapy who will be jointly managed with the subspecialist.

FUTURE DIRECTIONS

Hepatitis B therapy is rapidly changing thanks to innovations made with nucleoside analogues used for HIV infection. Like HIV treatment, combination therapy with

interferons, lamivudine, entecavir, adefovir, and telbivudine will receive a new emphasis in coming years. The goal of combination therapy will be to prevent resistance and to improve eradication of HBV.

Understanding virus and host characteristics that influence progression of disease, and response to therapy, will be the key to advancing treatment for hepatitis C. Direct antivirals that inhibit key enzymes in HCV replication are under development.

Although therapy for chronic hepatitis B and hepatitis C will continue to evolve, prevention of viral hepatitis remains crucial. Although an HCV vaccine is not likely in the near future, extensive use of vaccinations for HAV and HBV has the potential to reduce, if not eliminate, these infections within a few generations as well as to significantly reduce the incidence of cirrhosis and hepatocellular carcinoma.

Cirrhosis

Introduction

Cirrhosis and its complications comprise one of the top 10 causes of mortality in this country. Cirrhosis of the liver is an irreversible alteration of hepatic architecture, characterized by diffuse fibrosis and areas of nodular regeneration. These nodules can be micronodular (<3 mm) or macronodular (>3 mm). Features of both micronodular and macronodular cirrhosis are frequently present in the same liver. Determining the etiology is often not possible based on the gross and microscopic appearance of the cirrhotic liver and requires careful utilization of the history, physical examination, biochemical and serologic tests, and histochemical stains.

Etiology and Pathogenesis

The relationship between alcohol abuse and cirrhosis is well established. Ethanol is a hepatotoxin that leads to the development of fatty liver, alcoholic hepatitis, and ultimately, cirrhosis (Fig. 64-1). The pathogenesis may differ depending on the underlying causes of the liver disease. In general, there is ongoing chronic inflammation either due to toxins (alcohol and drugs), infections (hepatitis virus, parasites), autoimmune phenomenon (chronic active hepatitis, primary biliary cirrhosis), or biliary obstruction (common bile duct stone, primary sclerosing cholangitis [PSC]), and recently well-recognized chronic inflammation caused by nonalcoholic fatty liver disease (NAFLD) with the subsequent development of diffuse fibrosis and cirrhosis (Box 64-1).

Clinical Presentation

Patients may be entirely asymptomatic or may present with nonspecific constitutional symptoms, or symptoms of liver failure, complications of portal hypertension, or both.

Nonspecific symptoms include weakness, lethargy, anorexia, weight loss, abdominal pain, loss of libido, altered sleep-wake pattern, and nausea or vomiting. Specific symptoms due to hepatic synthetic dysfunction and portal hypertension include jaundice, pruritus, coagulopathy leading to easy bruising, fluid retention with ankle edema, ascites, gastroesophageal variceal bleeding leading to hematemesis or melena, and symptoms of hepatic encephalopathy ranging from mild confusion to coma.

On physical examination, patients may have stigmata of chronic liver disease such as Dupuytren's contractures, palmar erythema, spider angiomas, parotid enlargement, and bruising. Palpation of the abdomen may reveal an enlarged or shrunken liver, splenomegaly, ascites, or dilated superficial anterior abdominal wall veins. Male patients may show signs of feminization (gynecomastia), testicular atrophy, and loss of body hair. Patients with hepatic encephalopathy may present with a "flapping tremor" or asterixis.

Differential Diagnosis

The new onset of ascites presenting with no history and stigmata of chronic liver disease may not be secondary to cirrhosis and portal hypertension. Other causes include portal vein occlusion, nephrotic syndrome, protein-losing enteropathy, severe malnutrition, myxedema, ovarian diseases (Meig's syndrome, struma ovarii), pancreatic ascites, chylous ascites, nephrogenic ascites, tuberculous peritonitis, or secondary malignancy.

The differential diagnosis for hematemesis and melena includes duodenal ulcer, gastric ulcer, esophagitis, gastritis, Mallory-Weiss tear, hematemesis, anastomotic ulcer, and Ménétrier's disease.

Diagnostic Approach

After a thorough history and physical examination, complete laboratory data, radiologic examination, and histologic studies may be necessary to establish the diagnosis and the most likely cause of cirrhosis.

Figure 64-1 Septal Cirrhosis.

The complete blood cell count may show anemia, leukopenia, or thrombocytopenia. Hypersplenism causes both leukopenia and thrombocytopenia. Chronic blood loss and vitamin deficiency can cause anemia. Prolongation of the prothrombin time occurs secondary to vitamin K deficiency or impaired clotting factor synthesis.

Serum biochemistry often demonstrates an elevated bilirubin level and a low albumin level. Some patients with established cirrhosis may have normal aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels. Elevated AST and ALT levels are found in patients with autoimmune hepatitis, viral hepatitis, alcoholic hepatitis, and drug-induced liver injury. Patients with cholestatic liver disease usually have elevated alkaline phosphatase, γ -glutamyltransferase, and conjugated bilirubin levels.

Several other serologic tests are necessary to establish cause: viral serology for hepatitis B (HBsAg), C (anti-HCV Ab), and quantitative DNA and RNA levels, respectively, to define the activity status; iron studies and *HFE* gene analysis for hereditary hemochromatosis; serum and 24-hour urine copper, ceruloplasmin level for Wilson's disease; α_1 -antitrypsin level and genotype for α_1 -antitrypsin deficiency. Serum autoantibodies (antinuclear antibody, anti-smooth muscle antibody, antimitochondrial antibody and anti-liver-kidney microsomal antibody) and quantitative serum immunoglobulins levels may help to diagnose autoimmune liver disease. Periodic evaluation of tumor markers is indicated to detect complicating primary hepatocellular carcinoma; these include alpha fetoprotein and the combination of carcinoembryonic antigen and CA 19-9. Moni-

Box 64-1 Causes of Cirrhosis

Infections: Hepatitis B, hepatitis C, possibly other viruses, schistosomiasis
Drugs and toxins: Alcohol, methyl dopa, methotrexate, isoniazid, amiodarone
Biliary obstruction: Primary and secondary sclerosing cholangitis, cystic fibrosis, biliary atresia, common bile duct stones
Metabolic disorders: Hereditary hemochromatosis, Wilson's disease, α_1 -antitrypsin deficiency, cystic fibrosis, glycogen storage disease
Autoimmune diseases: Chronic active hepatitis, primary biliary cirrhosis
Cardiovascular: Chronic right heart failure, Budd-Chiari syndrome, veno-occlusive disease
Miscellaneous: Nonalcoholic fatty liver disease, sarcoidosis, jejunoileal bypass, neonatal hepatitis
Cryptogenic: Unknown cause

toring for cholangiocarcinoma is recommended in patients with cirrhosis from PSC.

Radiologic studies (ultrasound with or without Doppler, computed tomography, or magnetic resonance imaging) provide additional diagnostic information. Although these studies are not always necessary, they are useful in screening for primary hepatocellular carcinoma and cholangiocarcinoma. They provide information in addition to serum tumor markers, which are commonly associated with cirrhosis of various causes.

Histologic examination of the liver biopsy specimen is often key for diagnosis. Micronodules, fatty infiltration, and Mallory's hyaline usually accompany alcoholic cirrhosis. Primary biliary cirrhosis, primary and secondary sclerosing cholangitis, and autoimmune hepatitis have typical histologic findings. Special stains such as Prussian blue for iron and periodic acid-Schiff diastase for α_1 -antitrypsin globules can confirm the diagnosis. Liver biopsy is necessary to stage the disease, to help determine the prognosis, and to guide optimum therapy. There are various noninvasive measurements of liver fibrosis in the serum and liver by measuring markers of connective tissue and liver stiffness. The sensitivity and specificity of serum markers (hyaluronic acid, type III procollagen peptide, etc.) for detection of extensive fibrosis are not acceptable. The measurement of liver stiffness with transient elastography and its correlation to fibrosis have been validated in viral hepatitis and cholestatic liver diseases. The results provide a promising simple and reliable noninvasive means to assess liver fibrosis; however, in clinical practice, its use to replace the liver biopsy is yet to be determined.

Management and Therapy

In general, management of cirrhosis includes the following:

- Withdrawal of the causative agent (e.g., alcohol, drugs)
- Treatment of the specific underlying cause (e.g., antiviral therapy for viral hepatitis, prednisone or azathioprine for autoimmune hepatitis, phlebotomy for hemochromatosis, D-penicillamine or trientine for Wilson's disease)
- Treatment of underlying risks for NAFLD (obesity, diabetes, hyperlipidemia, drugs)
- Treatment of decompensated cirrhosis: ascites, infection, gastrointestinal hemorrhage, hepatic encephalopathy, and hepatorenal syndrome
- Orthotopic liver transplantation for decompensated cirrhosis if the patient is a suitable candidate

Ascites

Patients with cirrhosis in whom ascites develops need a diagnostic (10 to 20 mL) abdominal paracentesis. Indications include new-onset ascites, clinical deterioration with fever, abdominal pain, and change in mental status. The factors producing ascites in cirrhosis are a low serum albumin level, hepatic outflow block with overproduction of lymph, and portal venous hypertension. Ascites can be mild, moderate, or severe on the basis of the amount of fluid in the peritoneal cavity (Figs. 64-2 and 64-3).

Optimum Treatment

The initial treatment includes restriction of dietary sodium intake and the use of oral diuretics. Approximately 20% of patients respond to sodium restriction alone. Sodium is usually limited to 2 g (90 mEq) per day. Diuretics include spironolactone and furosemide. More than 90% of patients respond to this combination therapy. The maximum spironolactone dose is 400 mg/day, and for furosemide, 160 mg/day. Amiloride, 10 to 20 mg/day, is an alternative to spironolactone if there are side effects such as tender gynecomastia.

Approximately 10% of patients with cirrhosis will develop ascites refractory to routine medical treatment with sodium restriction and diuretic therapy. Large-volume paracentesis (LVP) can be used before alternative therapies such as transjugular intrahepatic portosystemic shunt (TIPS) or peritoneovenous shunt. TIPS is a relatively safe nonsurgical procedure that is effective in reducing portal hypertension. TIPS placement is indicated in cirrhotic patients with refractory ascites who require LVP more than 2 or 3 times per month. Compared with serial LVP, placement of an uncovered TIPS stent is more effective at preventing ascites from recurring; however, an increased incidence of hepatic encephalopathy and shunt dysfunction rates after TIPS placement are complications that increase its cost. The development of a newer polytetrafluoroethylene-covered stent may provide better results in shunt dysfunction rates and patient survival. The TIPS procedure has gained wide popularity and provides a bridge to liver transplantation in patients with advanced cirrhosis.

Figure 64-2 Ascites.

Peritoneovenous shunt (LeVeen/Denver) can be used if the placement of a TIPS is contraindicated.

Avoiding Treatment Errors

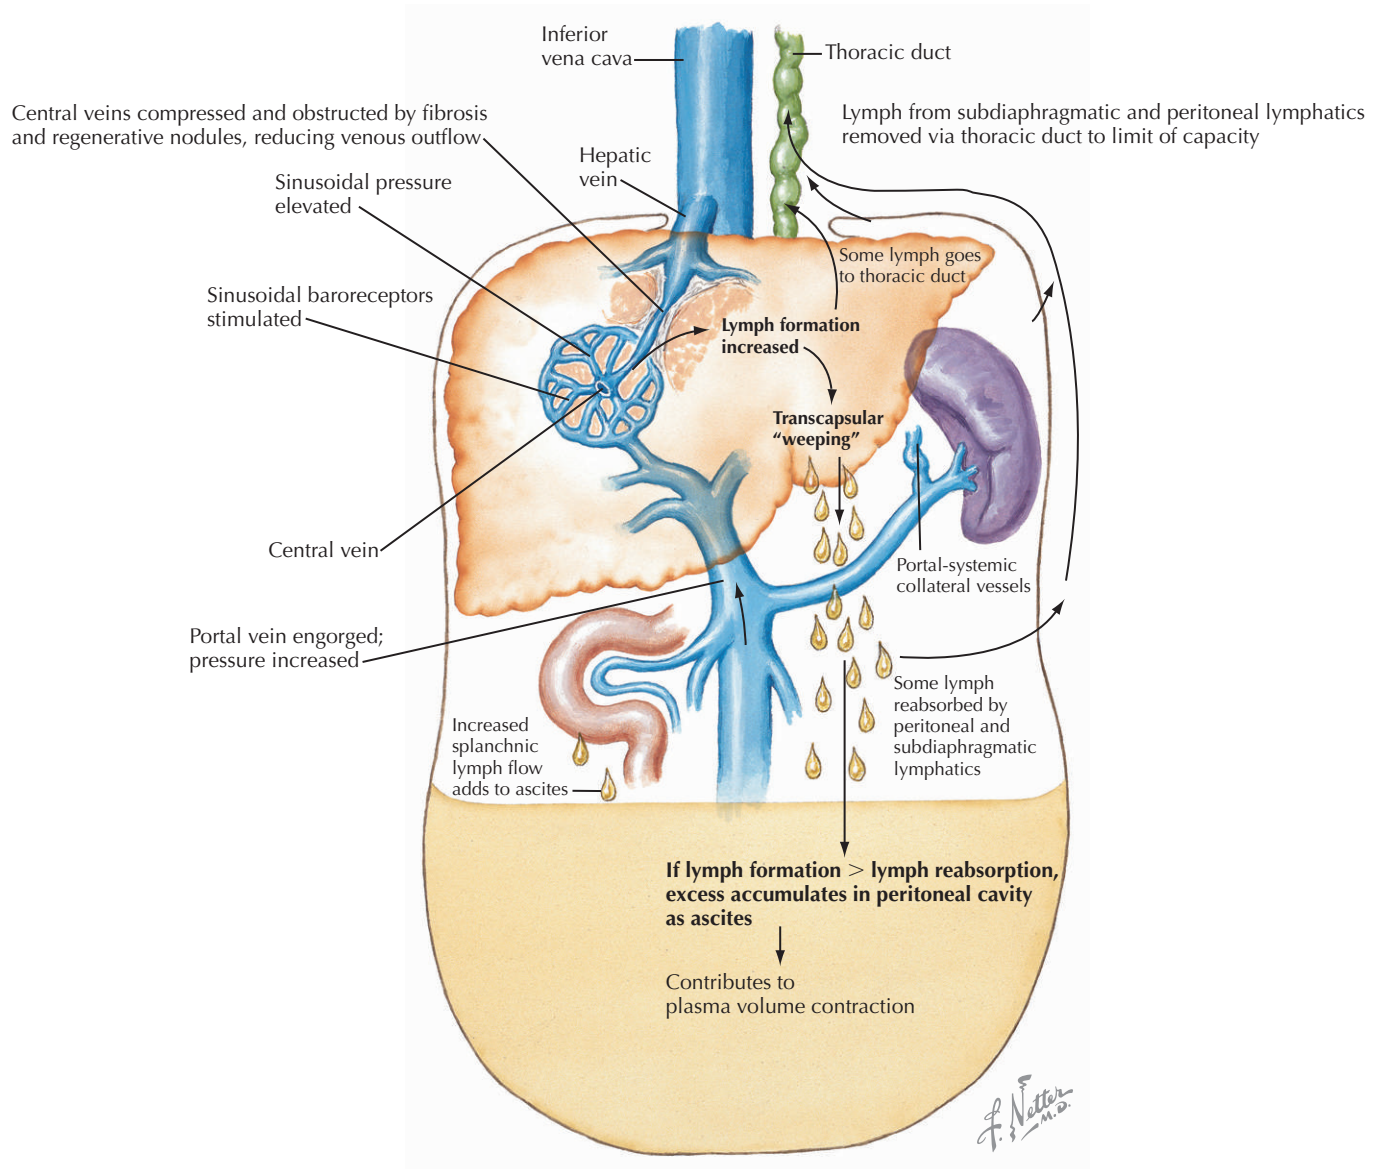

Making an appropriate diagnosis before initiating treatment is critical. Diuretic therapy should be used cautiously and in a stepwise fashion to avoid potential severe electrolyte and fluid imbalance and renal dysfunction. For patients with refractory ascites, the risks and benefits of placement of a peritoneovenous shunt or TIPS should be evaluated thoroughly for a successful outcome.

Gastrointestinal Hemorrhage

Gastroesophageal variceal bleeding is the most ominous complication of cirrhosis (see Fig. 64-4).

Optimum Treatment

Initial management of suspected variceal bleeding requires immediate hospitalization, volume resuscitation, and airway protection for massive bleeding. If the diagnosis is reasonably certain, pharmacologic therapy with somatostatin or its analogue octreotide can be initiated. If

Figure 64-3 Pathophysiology of Ascites Formation.

endoscopy confirms esophageal varices, endoscopic therapy with either variceal ligation or sclerotherapy is indicated. Endoscopic therapy controls acute variceal bleeding in 80% to 95% of patients, a success rate superior to pharmacologic agents or balloon tamponade. There is a 50% to 80% risk for recurrent variceal bleeding. Options to prevent recurrent variceal bleeding include endoscopic ligation or sclerotherapy, nonselective β -blockers (propranolol, nadolol), surgical shunts, TIPS, and liver transplantation.

TIPS is one of the most promising therapies for the control of acute variceal bleeding. The goal of TIPS is to achieve a hepatic venous gradient of less than 12 mm Hg and a reduction or loss of contrast opacification of varices.

TIPS is reserved for those patients who are refractory to endoscopic therapy along with pharmacotherapy or who have acute, severe bleeding from gastric varices. The technical success rate and control of acute variceal bleeding is more than 90% (Fig. 64-4).

Avoiding Treatment Errors

Gastroesophageal hemorrhage carries a high morbidity and mortality; timely aggressive resuscitation and therapeutic interventions are important in the management of these critically ill patients. Airway protection by ventilator support should be done to avoid aspiration pneumonia in patients with agitation and massive bleeding.

Figure 64-4 Endoscopic Appearance of Esophageal Varices with Evidence of Recent Hemorrhage.

Hepatic Encephalopathy

Hepatic encephalopathy represents a constellation of reversible neurologic signs and symptoms accompanying advanced, decompensated liver disease or extensive portosystemic shunting. The pathogenesis of hepatic encephalopathy remains unclear. It is partially attributable to toxic compounds that are derived from the metabolism of nitrogenous substrates in the gut that bypass the liver through an anatomic and functional shunt. The four stages of hepatic encephalopathy are based on mental status and neurologic findings:

- Stage 1: Mild confusion and incoordination are present.
- Stage 2: Asterixis is consistently present and the patient has obvious personality changes.
- Stage 3: The patient is somnolent and is disoriented on arousal.
- Stage 4: The patient is comatose.

Common precipitating factors include deterioration in hepatic function, gastrointestinal hemorrhage, excess protein intake, alcohol, sedatives or hypnotics, surgery, hepatoma, infection, dehydration, electrolyte imbalance (hypokalemia), constipation, and placement of a surgical shunt or TIPS.

Optimum Treatment

Management includes identification and correction of any precipitating factor, restriction of dietary protein to 40 g/day, and administration of lactulose. Antibiotics to decontaminate the gut, such as neomycin, metronidazole, amoxicillin, and rifaximin, can be added if there is no response to dietary manipulation and lactulose or if there is intolerance to lactulose. Rifaximin, a nonaminoglycoside antibiotic derived from rifamycin, has gained popularity because it is not absorbed from the gut, thereby eliminating potential toxicities of other antibiotics (renal failure, ototoxicity, and peripheral neuropathy) and has broad-spectrum anti-

bacterial coverage. Patients with severe refractory hepatic encephalopathy need urgent liver transplantation.

Avoiding Treatment Errors

Identification of precipitating factors correctly is the key in the management of hepatic encephalopathy. Ensuring the optimal use and effectiveness of lactulose requires the adequate education and understanding of patients and their family members. The result is improved compliance and avoidance of potential side effects. Antibiotics that are absorbable should be used cautiously to avoid their potential toxicities.

Hepatorenal Syndrome

Hepatorenal syndrome is a distinct type of progressive acute renal failure that develops in a patient with cirrhosis in whom all other causes of renal dysfunction have been excluded. It is a functional type of renal failure. If the liver disease improves, normal renal function returns. The pathogenesis of the hepatorenal syndrome is unknown. The probability of hepatorenal syndrome in cirrhosis is about 20% in 1 year and 40% in 5 years. Hyponatremia and azotemia are characteristic. The urinary sodium concentration is less than 10 mEq/L. The urinary sediment is unremarkable. Other important chemical findings include a urine-to-plasma creatinine ratio of more than 30 and a urine-to-plasma osmolality ratio of more than 1.

Optimum Treatment

In the management of hepatorenal syndrome, specific causes for renal failure should be excluded (i.e., acute tubular necrosis, prerenal azotemia from intravascular volume depletion, drug-induced nephrotoxicity, or pre-existing chronic renal disease). Renal replacement therapy should be considered for patients who are potential candidates for liver transplantation. Experimental forms of

therapy include prostaglandin E₁, dopamine, terlipressin, peritoneovenous shunt, and TIPS.

Avoiding Treatment Errors

The hepatorenal syndrome carries a high mortality, and liver transplantation can reverse the syndrome. Therefore, timely and comprehensive evaluation of patients to determine their candidacy for liver transplantation is important in their management.

Liver Transplantation

Optimum Treatment

Liver transplantation is no longer experimental and is considered the standard of care for patients with advanced cirrhosis. With improved surgical technique and better immunosuppressive drugs, it has become a successful therapy for end-stage liver disease with long-term survival rates approaching 90% and excellent quality of life. Unfortunately, the gap between the numbers of deceased donors and recipients continues to widen.

Living donor liver transplantation (LDLT) is used by many transplantation centers worldwide. First used in a child in 1989, LDLT has become a viable alternative for pediatric recipients. Over the past decade, LDLT has been used successfully in adult recipients with patient and graft survivals similar to those with deceased donor liver transplantation. The rate-limiting factor is the availability of suitable donors for this procedure. With appropriate donor and recipient selection, further refinement in surgical technique, and increasing experience, LDLT may give superior results. About 5% to 10% of liver transplantations in the United States have involved the use of living donors.

Avoiding Treatment Errors

Liver transplantation is the only definitive therapy in decompensated cirrhosis. About 18,000 patients in the United States are on the United Network of Organ Sharing waiting list, and the number increases 25% per year. Only about 5000 to 6000 deceased donor liver transplantations are performed each year in the United States. Because there is an excess of potential recipients, careful identification and evaluation of transplant recipients is critical.

Future Directions

Major improvements in diagnostic techniques now allow the diagnosis of chronic liver diseases earlier in their

course. Improvement in pharmacologic agents that include antiviral drugs (hepatitis B and C) will help to prevent progression to cirrhosis.

Liver transplantation is a highly effective option in the management of advanced cirrhosis. Hepatocyte, stem cell, and xenotransplantation may provide additional therapeutic options in the management of end-stage liver disease.

Celiac Disease

Introduction

Celiac disease occurs throughout the world and has prevalence estimates ranging from 1 in 500 to 1 in 67, except in Japan, where the prevalence is very low. A large study demonstrated a prevalence in the United States of 1 in 133 for those with no risk factors, 1 in 56 among individuals with gastrointestinal symptoms associated with the disease, 1 in 39 in second-degree relatives of celiac disease patients, and 1 in 22 in first-degree relatives. Therefore, about 3 million people in the United States have the disease. However, it is estimated that fewer than 5% of affected individuals have been diagnosed.

Celiac disease is one of a number of diseases of the small intestine that can cause malabsorption syndrome. Others include Whipple's disease, diffuse mucosal malignancies, bacterial overgrowth syndrome, and short bowel (Fig. 65-1).

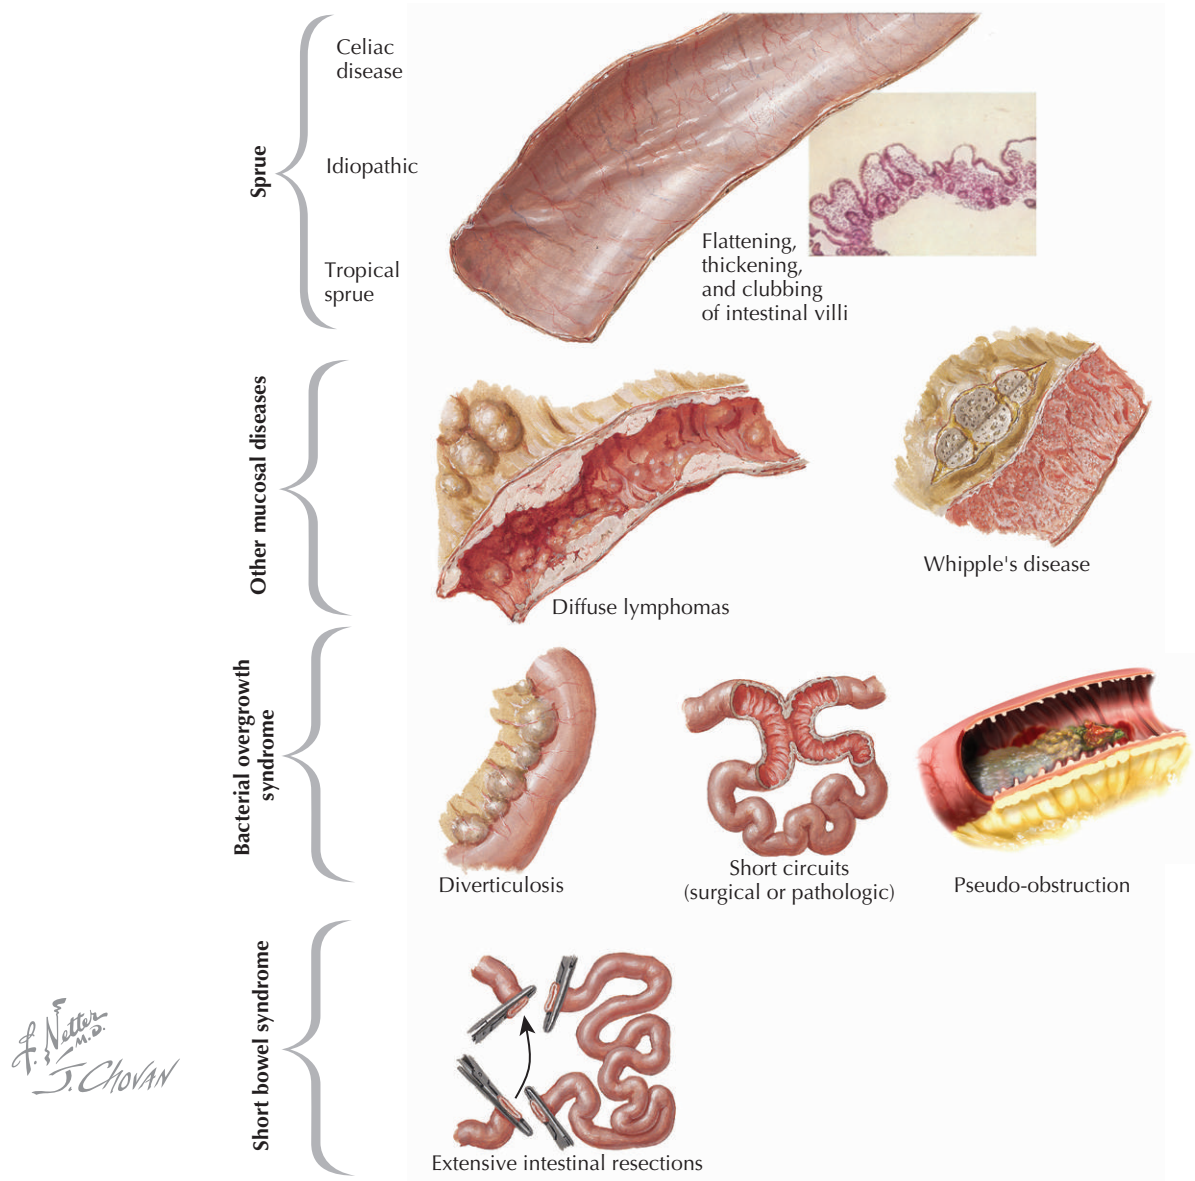

Etiology and Pathogenesis

Celiac disease results from an immune response to peptides present in gluten, a protein found in wheat, and similar proteins found in rye and barley. The toxic peptides are resistant to intraluminal and brush border proteolytic activity, enter the submucosa either through or between epithelial cells, and are transformed to more antigenic forms by the enzyme tissue transglutaminase. The immune response stimulates a T-lymphocyte attack on small bowel mucosa, resulting in an epithelial stress response and death of enterocytes—an autoimmune process. Only genetically susceptible individuals develop the disease, and multiple genes are involved. The presence of one of the human major histocompatibility molecules, HLA-DQ2 or HLA-DQ8, is almost essential and occurs in about 98% of cases. In addition to dietary gluten exposure and genetic susceptibility, some triggering event may be necessary to initiate the disease. Damage to the small intestinal mucosa is manifested histologically by a progression of changes, which include migration of lymphocytes to intraepithelial locations, crypt hyperplasia, shortening and thickening of the villi, and shortening of the columnar epithelial cells. Tissue transglutaminase promotes the immune response by converting glutamine side chains of the toxic peptides to glutamate and also cross-linking these residues to lysine in other proteins, including in the enzyme itself. Serum antibodies against tissue transglutaminase (TTGA) are useful

diagnostically and are the same as endomysial antibodies (EMA), although characteristics of the two tests for the antibody are such that they may occasionally give different results.

Clinical Presentation

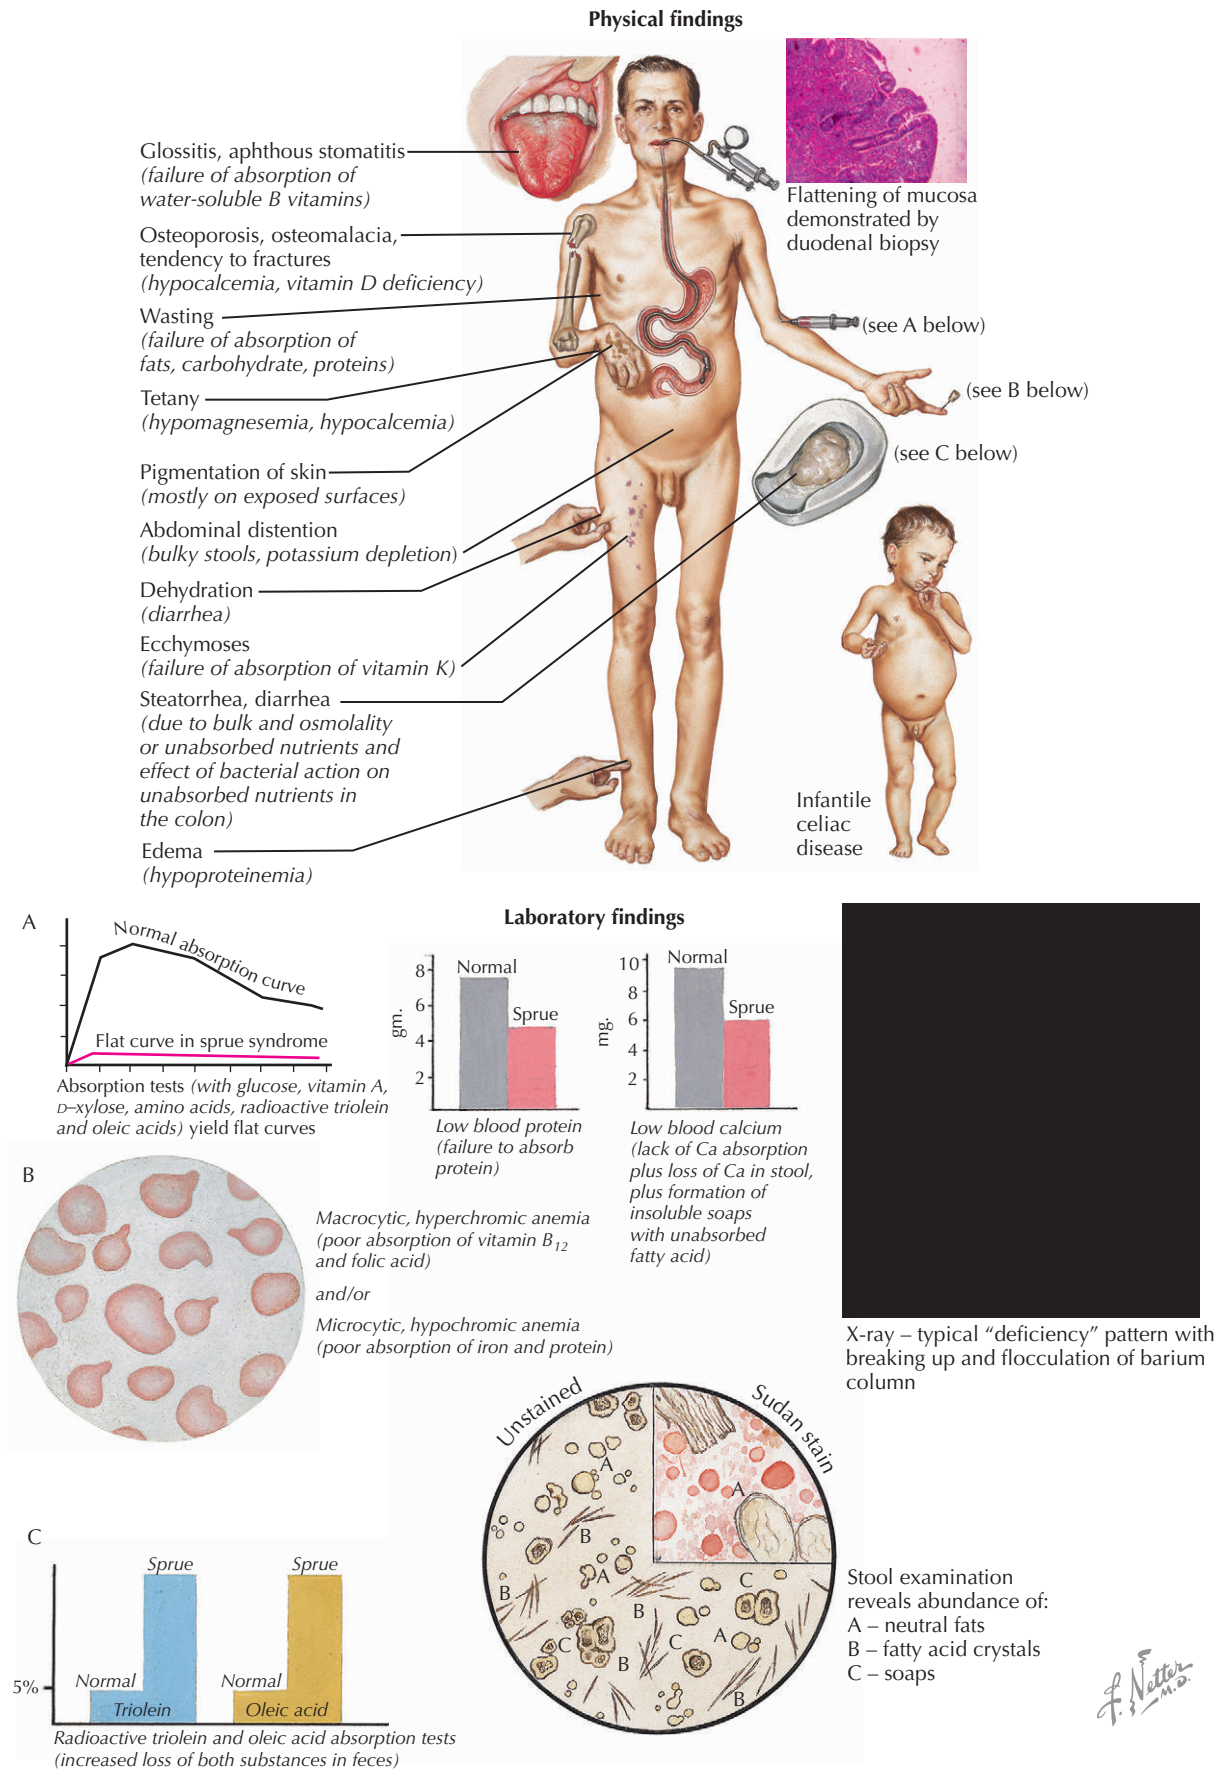

Symptoms and signs leading to diagnosis may be intestinal (e.g., diarrhea) or nonintestinal (e.g., anemia or bone loss). Relatives of celiac disease patients and individuals with conditions associated with celiac disease are increasingly being diagnosed with screening blood tests or endoscopic duodenal biopsies despite having no symptoms attributable to the disease. The mode of presentation has changed over time with the advent of serologic tests, endoscopic duodenal biopsies, and greater awareness of the disease. Features leading to the diagnosis at a major medical center between 2000 and 2004 were diarrhea in 37% of cases, anemia in 13%, screening in 12%, bone disease in 8%, incidental in 5%, and other features in 26%. The incidental diagnosis was usually the result of unexpected discovery of an abnormal duodenal mucosa during upper endoscopy for reflux or dyspepsia symptoms. The other features leading to diagnosis included abdominal pain, constipation, weight loss, neurologic symptoms (peripheral neuropathy, seizures, ataxia), dermatitis herpetiformis, macroamylasemia, hypoproteinemia, elevated sedimentation rate, need for

Figure 65-1 Malabsorption Syndrome: Small Intestinal Causes.

increased amounts of oral medication, and liver test abnormalities. Additional presenting signs and symptoms reported by others include irritable bowel syndrome, nausea, vomiting, dyspepsia, bloating, abdominal distention, glossitis, muscle cramps, bleeding, miscarriage, infertility, growth retardation, paresthesias, weakness, lassitude, hyposplenism, and small bowel intussusception. The diagnosis is most frequently made in 40- to 60-year-olds, although prevalence of the disease appears to be equal in children and adults. Females are three times more frequently affected than males. The disease is diagnosed in obese and even morbidly obese individuals. The mean delay from onset of symptoms to diagnosis is 4 to 5 years.

The classic presentation of celiac disease, dominated by signs and symptoms of malabsorption, is now very rare in developed countries but can occur. Advanced malabsorption syndrome is characterized by diarrhea; weight loss or poor weight gain; and bulky, greasy, and unusually foul-smelling stools (Fig. 65-2). Signs of vitamin or mineral deficiencies may include glossitis from B vitamins and iron deficiency, osteomalacia from vitamin D and calcium deficiency, tetany from calcium and magnesium deficiency, and ecchymoses from vitamin K deficiency. Edema may result from hypoalbuminemia caused by decreased protein absorption, decreased hepatic synthesis of albumin, and protein-losing enteropathy. Medications and nutrients are poorly absorbed. Anemia may be macrocytic, due to folic

Figure 65-2 Advanced Malabsorption Syndrome.

acid and occasionally vitamin B₁₂ malabsorption, microcytic, due to iron and protein malabsorption, or mixed.

Several malignancies are associated with celiac disease, including non-Hodgkin's lymphoma, small intestinal adenocarcinoma, and squamous carcinoma of the esophagus and head and neck. They may be discovered before, at, or after the diagnosis of celiac disease, but the incidence of malignancies, with the possible exception of lymphoma, decreases over several years after beginning a gluten-free diet.

Differential Diagnosis

The great variety of ways that celiac disease can present results in a broad differential diagnosis. For those presenting with diarrhea, the differential includes irritable bowel syndrome, lactase deficiency, inflammatory bowel disease, giardiasis, small bowel bacterial overgrowth, pancreatic insufficiency, human immunodeficiency virus enteropathy, radiation enteropathy, and food allergy. Celiac patients are often lactose intolerant because of lactase deficiency resulting from decreased lactase activity in the damaged mucosa. This secondary lactase deficiency must not be mistaken for primary acquired lactase deficiency. In the differential for anemia, one must consider colon or gastric neoplasm or pernicious anemia; possible causes for decreased bone mineral density include age-related osteoporosis, hypogonadism, thyroid disease, and primary or metastatic bone neoplasm.

Diagnostic Approach

A high level of clinical suspicion is important, recognizing the many ways the disease can present. The availability of a noninvasive and highly sensitive and specific diagnostic test, namely detection of antibodies to tissue transglutaminase, has been a major advance. The diagnosis should be confirmed, in almost all instances, by upper endoscopy and small bowel mucosal biopsy. Final confirmation requires an unequivocal response of clinical signs or symptoms or mucosal histology to gluten withdrawal.

Serum antibodies, immunoglobulin G (IgG) and immunoglobulin A (IgA), against tissue transglutaminase can be detected as either EMA or TTGA. The IgA antibodies are more sensitive and specific than IgG antibodies. However, about 2% of celiac disease patients are IgA deficient; therefore, a serum IgA level may be needed to properly interpret the serologic test. The cost-effectiveness of ordering a serum IgA level when celiac disease serology is ordered is not known. It is probably more cost effective to order an IgA level only if the EMA-IgA or TTGA-IgA is weakly positive or the EMA-IgG or TTGA-IgG is elevated. In the EMA test, antibody is detected by its attachment to connective tissue in monkey esophagus or human umbilical cord using immunofluorescence, although an enzyme-

linked immunoassay has been reported. Sensitivity of 90% to 97% and specificity of 98% to 99% for EMA-IgA have been reported. The TTGA-IgA test is an enzyme-linked immunoassay. When it is done using recombinant or purified human tissue transglutaminase, as opposed to earlier tests using guinea pig antigen, sensitivity is 94% to 95% and specificity is 95% to 97%. Sensitivity of both tests is lower in celiac disease with milder mucosal changes, and can be negative when mucosal changes are minimal. Antibody levels decrease and may disappear after 6 to 12 months of gluten withdrawal. Either test is more specific than antigliadin and antireticulin tests, which should no longer be used to diagnose celiac disease. Although some believe the antigliadin and antireticulin tests help identify celiac disease patients with minimal histologic changes who benefit symptomatically from a gluten-restricted diet, the apparent benefit may be a placebo response. Other investigators report that the antigliadin test is more sensitive than EMA or TTGA for diagnosing gluten-associated neurologic disease.

As a general rule, mucosal biopsy should be done in all patients before initiating diet therapy. Exceptions can include patients with biopsy-proven dermatitis herpetiformis and those with high-titer TTGA or EMA who have classic symptoms or a relative with celiac disease. The mucosal changes have been thought to begin in the duodenum and progress slowly distally, very seldom reaching the terminal ileum. However, studies have revealed some patients with patchy changes and some with positive biopsy results only in the distal duodenum or jejunum, although this observation was not supported by other studies. To minimize the chance of missing a mucosal abnormality, at least two biopsy specimens should be obtained from the second, third, and fourth parts of the duodenum each, if possible. An experienced surgical pathologist should report the histologic abnormalities and classify them as Marsh type I (increased intraepithelial lymphocytes, IELs), II (increased IELs and crypt hyperplasia), IIIa (partial villous atrophy), IIIb (subtotal villous atrophy), or IIIc (total villous atrophy). Studies show that celiac disease is eventually confirmed in 95% of patients with Marsh III lesions, in most with Marsh II, but only in 10% with Marsh I.

Almost all celiac disease patients have one or both of the HLA antigens, DQ2 and DQ8. Therefore, their absence essentially excludes the diagnosis with a negative predictive value of 99.9%. However, the antigens are present in 30% to 40% of the general population, so the presence of one or both of these antigens has a positive predictive value of only 1.7%. Situations in which testing may be useful include individuals with weakly positive serology and equivocal biopsies, individuals who have placed themselves on dietary restriction months earlier and insist on knowing if they have the disease but do not want to go off the diet for a prolonged time, and children of individuals with diagnosed celiac disease who hope to avoid periodic serologic testing in future years.

Small bowel radiographs, stool fat assay, and the D-xylose absorption test are neither sensitive nor specific enough to be useful for diagnosing celiac disease. The utility of capsule endoscopy is promising but has not been adequately studied.

A therapeutic trial of a gluten-free diet is not appropriate for several reasons. The diet is difficult and lifelong for celiac disease and should not be started without a confirmed diagnosis. Individuals who do not have the disease may experience some improvement of symptoms on the diet, leading to a false-positive diagnosis. The diet may not be followed well and, even if it is, up to 30% of celiac disease patients will require longer than a month to respond, and up to 5% will take longer than 6 months. Therefore, patients may not follow the diet well or long enough, leading to a false-negative diagnosis. Finally, once on the diet, patients often seek medical help to make a definitive diagnosis in order to decide if they should stay on a strict diet or their relatives should be considered at increased risk. Because both the serologic test and biopsy may normalize with time on the diet, diagnostic tests should not be done until the patient has been on a gluten-containing diet for at least 6 weeks, and preferably 3 months.

Individuals with any of the many features listed under "Clinical Presentation" for which there is no other reasonable explanation should be considered for testing. Testing the large number of individuals who meet Rome criteria for irritable bowel syndrome or those who have a documented decrease in bone mineral density remains controversial. The reported incidence of celiac disease among individuals with reduced bone mineral density compared with controls who have normal bone density ranges from the same to a 10-fold increased incidence.

An increased prevalence of celiac disease has been documented in a number of conditions. The conditions and reported prevalence, compared with a prevalence of 0.5% to 1% in the general population, include dermatitis herpetiformis (100%), type I diabetes mellitus (2.5% to 10%), Sjögren's syndrome (10%), Addison's disease (8%), autoimmune thyroid disease (1% to 5%), inflammatory bowel disease (2% to 18%), Down syndrome (1% to 10%), autoimmune hepatitis (6%), primary biliary cirrhosis (5% to 10%), autoimmune myocarditis (4%), IgA deficiency (2%), and microscopic colitis. Routinely screening all patients with these conditions for celiac disease is not recommended because current data do not indicate a clear outcome benefit for early detection and treatment of asymptomatic individuals. Instead, physicians taking care of patients with any of these conditions should be aware of the association and maintain a low threshold for testing those with symptoms that could be a result of celiac disease. Because abnormal small bowel mucosa, often patchy and mild, is present in 100% of biopsy-proven dermatitis herpetiformis patients, and the skin lesion improves on a gluten-restricted diet independent of the severity of the mucosal lesion, small bowel biopsy is not mandatory in this condition.

In practice, the diagnosis of celiac disease often presents a dilemma. A substantial number of patients present with serology, histology, symptoms, or response to gluten withdrawal that are not consistent with each other. Because there is not complete agreement among experts about the designation or management of such individuals, a brief opinion, if not quite a consensus, is in order.

The diagnosis of *celiac disease* requires a compatible histologic abnormality of the small intestinal mucosa that improves on a gluten-restricted diet. However, if the patient also has symptoms compatible with celiac disease that respond to the diet, the symptomatic response can be accepted as adequate indirect evidence of histologic improvement so that a repeat mucosal biopsy is not required to establish the diagnosis.

Patients with positive serology and positive histology but no significant symptoms are designated as having *silent* or *asymptomatic celiac disease*. There is disagreement about whether these patients should be placed on a gluten-restricted diet. This should be decided after thorough discussion with the patient of the risks and benefits of therapy.

Patients with positive serology but mucosal histology that is normal or shows only increased IELs (Marsh I) are designated as having *latent* or *potential celiac disease*, assuming a false-positive serologic test can be reasonably excluded. The same designation is used for patients with previously diagnosed celiac disease who maintain normal histology when gluten is later reintroduced. On long-term follow-up, some patients with latent celiac disease go on to develop full-blown celiac disease, and some maintain or revert to normal serology and histology. Diet therapy is optional.

Patients with negative serology and mucosal histology showing only increased IELs (Marsh I) may have latent or even symptomatic celiac disease, but most do not. Many other conditions cause this histology, including bacterial overgrowth syndrome, food allergies, enteric parasites, inflammatory bowel disease, drugs including nonsteroidal anti-inflammatory agents and proton pump inhibitors, and gastric *Helicobacter* species infection. Details of the number, distribution, and type of IELs in various conditions are still being investigated. Diet therapy is not recommended.

Patients with flat intestinal mucosa and positive serology, who do not improve symptomatically or histologically after a year on an adequate gluten-restricted diet, or patients who responded initially and then stopped responding, are designated as having *refractory celiac disease* (RCD). They usually respond to a combination of immunosuppressant and gluten restriction. Other patients with flat mucosa and usually negative serology, who are not gluten sensitive, are designated as having *idiopathic sprue*. The etiology of this condition is unknown, although some of these patients improve on restriction of dietary

proteins other than gluten, and some respond to immunosuppression.

In contrast to patients who have the mucosal abnormalities of celiac disease, there are patients, with or without positive serology, who have normal mucosal histology but have symptoms that respond to gluten withdrawal, for example, ataxia, peripheral neuropathy, aphthous stomatitis, or diarrhea. The pathophysiology and nomenclature for these conditions are unsettled. Some of these patients may actually have a mucosal abnormality that is missed because it is patchy or because it is submicroscopic, seen only by electron microscopy. Others are best designated as having *gluten sensitivity* or *gluten sensitivity syndrome*. Gluten sensitivity has been defined as a systemic disease caused by heightened immunologic responsiveness to ingested gluten in genetically susceptible individuals that may primarily attack one or more organs such as the intestine (celiac disease), skin (dermatitis herpetiformis), central nervous system (gluten ataxia, seizures), peripheral nerves (peripheral neuropathy), muscles, or other tissues. Deposition of TTGA-IgA or other types of IgA has been found in the histologically normal intestinal mucosa and in other tissues, including brain, in some of these cases. The prevalence of gluten sensitivity in the absence of celiac disease is unknown.

Management and Therapy

Optimum Treatment

The mainstay of treatment is elimination of gluten from the diet, which is far from easy. Gluten or a similar toxic protein is present in wheat, rye, and barley. The average daily U.S. diet contains 9000 to 15,000 mg of gluten, and a slice of bread contains 1500 to 2000 mg. The minimum toxic dose of gluten for celiac disease patients is unclear and is probably not the same for all patients. A daily amount of 100 mg of gluten, the amount in about 1/20 slice of bread, was shown to produce histologic changes in a group of patients with the disease, so ideally, the diet should be restricted to less than that, probably 10 to 50 mg daily. One well-studied patient was sensitive to 1 mg of gluten per day. However, in practice, many patients on a gluten-restricted diet are ingesting 1000 mg or more of gluten daily. It is possible, but by no means certain, that many celiac patients can tolerate 200 to 1000 mg daily with minimal symptoms or risk. Pure oats are safe, but commercial oat products are usually contaminated with other grains, so oat products should also be avoided at least until the patient is free of the presenting celiac symptoms and then only if the oat product is thought to be pure. Most patients report experiencing symptoms within 24 hours after accidentally ingesting gluten, but absence of such immediate symptoms is not an indication that the diet is gluten free.

Initially, the dietary restrictions may seem overwhelming. Counseling by a dietitian experienced in treating celiac disease is essential. Many helpful resources are available on the Internet (see “Additional Resources”). Talking with someone who has had celiac disease for several years and is doing well can be a great help to the newly diagnosed patient.

A multivitamin and multimineral supplement providing about the recommended daily amounts should be given twice daily for the first 6 months of dietary therapy and once daily thereafter. Any anemia should be characterized. Iron or folic acid deficiency should be treated with appropriate oral supplements. Determine a serum 25-hydroxy vitamin D level for any newly diagnosed patient. If it is below normal, give 50,000 IU of vitamin D₂, or preferably vitamin D₃, orally 1 to 7 times weekly, depending on the level, and redetermine the serum level in 1 to 3 months. Adjust the dose to keep the serum 25-hydroxy vitamin D level in the high-normal range. Determine bone mineral density, and if it is low, repeat after 1 year of diet and vitamin therapy. If it has not improved, consider bisphosphonate or calcitonin therapy.

Clinic visits, in conjunction with seeing a dietitian, should be at 1- to 2-month intervals initially to ensure that the patient understands and is following the diet, and every 6 to 12 months thereafter. Each visit should include a review of the patient's diet, symptoms, and mood. Serum folic acid, carotene, 25-hydroxy vitamin D, and ferritin levels should be checked periodically if they were initially low. Monitoring the serum TTGA level yearly is recommended. It usually decreases and becomes negative after 6 to 12 months of appropriate diet therapy. An increase in titer is presumptive evidence of inadequate dietary compliance. Routine follow-up duodenal biopsies are not recommended. The occurrence of abdominal pain, weight loss, bleeding, or reoccurrence of diarrhea should be investigated with a careful history, and, if indicated, small bowel and colon biopsy, abdominal and pelvic computed tomography scan, or capsule endoscopy.

Symptomatic response to treatment often takes more than a month and may take up to 1 year. In a group of 161 patients with diarrhea as the major symptom, the cumulative response (cessation of diarrhea) after starting the diet was 3% in 1 day, 32% in 1 week, 69% in 1 month, and 87% in 6 months.

Reasons for lack of symptomatic response to dietary therapy (approximate percentages) are accidental or deliberate gluten ingestion (47%); incorrect diagnosis (10%); complication of celiac disease such as lymphoma, small bowel cancer, or ulcerative jejunitis (10%); coexisting disease such as small bowel bacterial overgrowth, lymphocytic colitis, collagenous colitis, pancreatic insufficiency, giardiasis, lactase deficiency, or irritable bowel syndrome (17%); and RCD (16%).

The definition of RCD is evolving. By strict definition, it is an enteropathy that is histologically consistent with

celiac disease that either responds initially to a gluten-restricted diet but stops responding or has not responded histologically or symptomatically after 12 months of diet therapy but responds with addition of immunosuppressive therapy. Two forms of RCD are distinguished. Patients with RCD I have a normal IEL population, respond well to diet and immunosuppression, and have a good prognosis. Patients with RCD II have an abnormal (immature) IEL population, do not respond well to diet and immunosuppression, and have a generally poor outcome, many dying of disseminated enteropathy-associated T-cell lymphoma within 1 year of starting treatment. Immunosuppressant therapy for RCD has included oral corticosteroids or azathioprine and intravenous anti-tumor necrosis factor- α antibodies (infliximab). Some patients with RCD have a thickened subepithelial band of collagen, termed *collagenous celiac disease*.

Avoiding Treatment Errors

Few physicians are knowledgeable about the details of a gluten-free diet. However, the physician can and should provide the knowledge, encouragement, and resources to help the patient become committed to the diet and expert in following it. The patient must be willing to read labels even on products known previously to be free of gluten, contact pharmaceutical companies to ensure that prescription and nonprescription medications being taken are gluten free, read printed or online material written by knowledgeable individuals, plan ahead and talk with the chef when eating out, and join a support group, if available. Wheat strains and products that are forbidden and that a patient may not recognize as wheat include durum, kamut, spelt, einkorn, emmer, farro, semolina, couscous, farina, orzo, bulgar, graham flour, and triticale. Products that may contain gluten unanticipated by the patient include medications, malt, modified food starch, rice syrup, soy sauce, hydrolyzed plant protein, hydrolyzed vegetable protein, extracts, spices, ice cream, canned fruit, canned soups, many candies, imitation seafood, flavored coffees, root beer, beer and many other alcoholic drinks, envelope adhesive, lipstick, and lip balm. Wheat starch contains trace amounts of gluten and is excluded from the diet, at least in the United States.

Products that are gluten free if not contaminated include rice, corn, millet, sorghum, potato, chestnut, almond, soy, amaranth, arrowroot, buckwheat, quinoa, sweet potato, and teff. Flours from these products are usually deficient in B vitamins and iron, so patients on a gluten-free diet should be supplemented.

Occasionally a patient, because of misinformation or a compulsive nature, becomes overly cautious. So long as normal dishwashing and sanitation are practiced, it is not necessary for the patient to maintain a separate set of kitchenware, for a spouse to wash the face and brush the teeth before kissing the patient, or for the patient to avoid

use of shampoos and body lotions containing gluten. Gluten peptides are too large to be absorbed through intact skin. On the other hand, significant gluten may be ingested from butter, peanut butter, or other spread contaminated with bread by a previous user or from toasting gluten-free bread in a toaster oven that is not thoroughly cleaned after being used to toast gluten-containing bread. With time and appropriate resources, the patient can become educated and careful without being excessively compulsive.

Future Directions

At a clinical level, it will be important to document the risk for asymptomatic celiac disease, the benefit and burden of treating the asymptomatic patient, and the related issue of who, if anyone, should be screened for the disease. Better documentation of the minimum toxic dose of gluten is needed. Less intrusive therapy will certainly be welcomed, including a very achievable goal of more, and more clearly labeled, gluten-free foods and drugs, and a more challenging goal of reducing or eliminating dietary restrictions. This might be accomplished by developing wheat and other grains genetically engineered to eliminate the toxic peptides, bacterial endopeptidases that digest the toxic peptides when taken orally with gluten-containing foods, and drugs that prevent the toxic peptides from entering the mucosa or activating the immune system.

Hypercoagulable States

Introduction

Hypercoagulable states are conditions that predispose to thrombosis. They can be inherited or acquired. Thrombophilia is the tendency to develop thromboses. Formerly, idiopathic thrombosis characterized a thrombosis in which an underlying hypercoagulable state could not be identified. The term is best avoided because many cases of so-called idiopathic thrombosis can now be attributed to one or more of the known thrombophilias and, thus, are not truly unexplained any more. Thromboses can be separated into those associated with transient risk factors and those not associated with transient risk factors.

Etiology and Pathogenesis

Overview

In hypercoagulable states, an imbalance between the procoagulant and fibrinolytic mechanisms may lead to thrombosis. Several known disturbances of plasmatic coagulation result predominantly in venous thromboembolism (Box 66-1). Relatively little is known about disturbances in blood vessel wall and platelet function that lead to hypercoagulability. About half of patients with venous thromboembolism without transient risk factors have an inherited or acquired thrombophilia (Table 66-1). Patients with arterial thromboembolism do not usually have an identifiable hypercoagulable abnormality (Box 66-2). Thrombosis is a multifactorial process, with environmental and lifestyle factors, as well as inherited and acquired thrombophilias.

The Individual Thrombophilias

Factor V Leiden

Factor V Leiden is a point mutation in the coagulation factor V gene, discovered in 1994 and named for the city of Leiden, the Netherlands. It is the most common known inherited risk factor for venous thromboembolism. The mutation results in a factor V protein (Arg506Gln) that cannot be normally inactivated by its physiologic inactivator, activated protein C (APC), thus causing APC resistance. It is the most common inherited risk factor for venous thromboembolism (Fig. 66-1). The heterozygous

state is a mild risk factor for venous thrombosis (risk increased 3-fold); the homozygous state is associated with a higher risk (increased 18-fold). Factor V Leiden is not a risk factor for arterial events, except in young women who smoke tobacco. Found primarily in whites, the mutation does not occur in native Africans or Asians. About 5% of the general U.S. population and, due to mixture of races, 1.2% of the African American population is heterozygous for factor V Leiden.

Prothrombin 20210 Mutation

The prothrombin 20210 mutation, a point mutation in the noncoding sequence of the prothrombin gene (G20210A), is associated with elevated prothrombin (factor II) levels. Discovered in 1996, it is the second most common inherited risk factor for venous thromboembolism (see Table 66-1). It is a mild risk factor for venous thromboembolism (risk in heterozygotes increased 2-fold to 4.8-fold compared with individuals without this mutation), but is not a risk factor for arterial thrombosis. The mutation is found in the same population as the factor V Leiden mutation; 2.3% of the overall U.S. population and 0.5% of the African American population is heterozygous for the mutation.

Protein C Deficiency

Protein C deficiency, a moderate risk factor for venous thromboembolism (risk is 7 to 15 times increased compared with a control population), is caused by a multitude of mutations. However, clinical penetrance is variable, and selected families are at greater risk. Arterial thrombosis is

less common in individuals with protein C deficiency than venous events.

Protein S Deficiency

Protein S deficiency is a mild risk factor for venous thromboembolism and increases the risk for venous thromboembolism about twofold. However, the clinical picture is variable among families. Arterial thrombosis is less common in individuals with protein S deficiency than venous events. It is caused by a large number of different mutations.

Box 66-1 Hypercoagulable States Predisposing to Venous Thromboembolism

Acquired

Surgery, trauma, prolonged immobilization
Older age
Obesity, smoking
Hormones (oral contraceptives, pregnancy, hormone replacement therapy)
Malignancy, chemotherapy
Previous venous thromboembolism
Inflammatory disorders (Crohn's disease, ulcerative colitis)
Myeloproliferative disorders
Hyperhomocysteinemia (inherited or acquired)
Antiphospholipid antibodies (see Fig. 66-2)
 Anticardiolipin antibodies
 Lupus anticoagulant
 Anti- β_2 -glycoprotein I antibodies
Paroxysmal nocturnal hemoglobinuria

Inherited

Factor V Leiden (G1691A mutation)
Prothrombin G20210A mutation
Protein C deficiency
Protein S deficiency
Antithrombin deficiency
Rare causes (e.g., dysfibrinogenemia, elevated PAI1 levels)
Elevated levels of factor VIII, factor IX, factor XI, or fibrinogen (inherited or acquired)
Factor XIII Val34 Leu polymorphism (protective against venous thromboembolism)

Antithrombin

Antithrombin deficiency is associated with venous thromboembolism, less commonly with arterial events, and has variable clinical penetrance. Selected families are at high risk, and half of individuals in these families have thromboses before the age of 30 years. Overall, antithrombin deficiency appears to be a moderate to strong risk factor for venous thromboembolic disease, but accurate risk estimates are not available because the disorder is uncommon. A variety of different mutations lead to the deficiency.

Homocystinuria and Homocystinemia

Homocystinuria is a rare homocysteine metabolism disturbance in children, leading to extremely high serum homocysteine levels. Fifty percent of these patients have arterial or venous thromboses before the age of 30 years. Homocystinemia is a disorder of mildly to moderately increased

Box 66-2 Hypercoagulable States Predisposing to Arterial Thromboembolism

Acquired

Arteriosclerosis
Vasculitis
Heparin-induced thrombocytopenia
Thrombotic thrombocytopenic purpura (acquired or inherited)
Hemolytic-uremic syndrome (usually acquired)
Hyperhomocysteinemia (acquired or inherited)
Antiphospholipid antibodies (see Fig. 66-2)
 Lupus anticoagulant
 Anticardiolipin antibodies
 Anti- β_2 -glycoprotein I antibodies

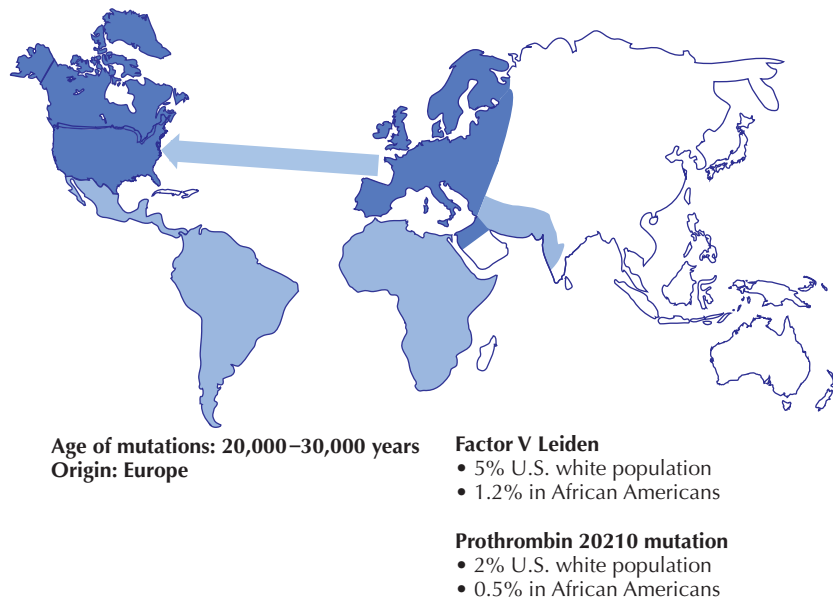

Inherited

Deficiency of protein C, protein S, antithrombin
Rare causes (dysfibrinogenemia)
Elevated levels of fibrinogen, factor VIII, and von Willebrand factor (inherited or acquired)
Factor XIII Val34 Leu polymorphism (protective effect against arterial thromboembolism)

Table 66-1 Prevalence of Hypercoagulable States in Venous Thromboembolism

Hypercoagulable State	Prevalence in Unselected Patients with Venous Thromboembolism (%)	Prevalence in Patients with Venous Thromboembolism without Transient* Risk Factors (%)
Protein C deficiency	3	1-9
Protein S deficiency	1-2	1-13
Antithrombin III deficiency	1	0.5-7
Factor V Leiden	12-21	52
Prothrombin 20210 mutation	6	16-19
Hyperhomocysteinemia	10-14	18.8
Antiphospholipid antibodies	8.5-14	No reliable studies available

* Transient risk factors: surgery, trauma, and immobilization.

Figure 66-1 Factor V Leiden and Prothrombin 20210 Mutations.

serum homocysteine levels, associated with an increased risk for venous thromboembolism, arteriosclerosis, and arterial thromboembolism. Elevated levels may also be found in patients with a homozygous mutation in the methylene-tetrahydrofolate reductase gene (thermolabile C677T MTHFR) and individuals double heterozygous for the C677T MTHFR and A1298C MTHFR polymorphisms; however, these mutations are not risk factors for thromboembolic disease by themselves if homocysteine levels are normal. Elevated homocysteine levels can be decreased in many individuals with folic acid, or a combination of folic acid, vitamin B₆, and vitamin B₁₂. However, lowering of the homocysteine level does not lead to a decreased risk for arterial or venous thrombosis.

Antiphospholipid Antibody Syndrome

Antiphospholipid antibody (APLA) syndrome is defined as the occurrence of thrombosis (arterial or venous) or recurrent pregnancy loss in patients with repeatedly positive APLA tests (see Fig. 66-2). It occurs as the primary APLA syndrome not associated with any other diseases, or as the secondary APLA syndrome, associated with autoimmune diseases, malignancy, or drugs (see Chapter 152).

Diagnostic Approach

Opinions vary about what constitutes an appropriate workup and who requires testing. If testing is done, then appropriate timing of testing and correct interpretation of test results are essential, as is education of the patient and family about thrombophilia in the case of an inherited disorder.

In venous thromboembolism not associated with surgery, trauma, or prolonged immobilization, the following tests may be helpful: factor V Leiden, prothrombin 20210 mutation, protein C activity, protein S activity, antithrombin activity, homocysteine level, and antiphospholipid antibodies (lupus anticoagulant, anticardiolipin immunoglobulin G [IgG] and immunoglobulin M [IgM] antibodies, anti- β_2 -glycoprotein I antibodies). Malignancy as an underlying contributor to the thromboembolism warrants consideration and evaluation using a thorough medical history, physical examination, and appropriate screening tests.

In unexplained arterial thromboembolic events, thrombophilia tests may include protein C activity, protein S activity, antithrombin activity, homocysteine, and antiphospholipid antibodies (lupus anticoagulant, anticardiolipin IgG and IgM antibodies, anti- β_2 -glycoprotein I antibodies). A lipid profile (low-density lipoprotein, cholesterol, triglycerides, lipoprotein-a) may also be appropriate to assess for risk factors of premature arteriosclerosis. Furthermore, a thorough evaluation of all causes of arterial thromboembolism (e.g., arteriosclerosis, intracardiac thrombus, atrial fibrillation, patent foramen ovale) is important.

The diagnosis of factor V Leiden is made by either genetic (polymerase chain reaction) or coagulation (APC resistance) testing. APC resistance and factor V Leiden are not synonyms; 5% to 10% of patients with APC resistance do not have factor V Leiden, but another abnormality, such as a lupus anticoagulant, that interferes with the APC-resistance assay. An abnormal APC resistance test should be followed by the genetic test for factor V Leiden.

A normal APC resistance test excludes the presence of factor V Leiden and does not need to be followed by a genetic test.

The diagnosis of prothrombin 20210 mutation is made by genetic testing (polymerase chain reaction). Factor II activity levels are not helpful.

The evaluation of protein C deficiency requires measurement of protein C activity levels, also referred to as *functional protein C*. Obtaining only a protein C antigen level will miss the occasional functional protein C deficiency that is caused by a dysfunctional protein. Protein C activity levels are low in patients taking vitamin K antagonists (e.g., warfarin, phenprocoumon). Levels normalize up to 2 weeks after discontinuation of warfarin. They are also low in liver disease.

Protein S circulates in the plasma in two forms: bound to the transport protein C4b-binding protein, and unbound, as free protein S. Only the free protein is enzymatically active. Tests include protein S activity (*functional protein S*), free protein S antigen, and total protein S antigen. Obtaining only free or total protein S antigen levels is insufficient to exclude protein S deficiency, because a patient may have normal protein S antigen levels, but a functional deficiency caused by a dysfunctional protein S molecule. Low protein S activity levels occur in patients taking oral contraceptives or hormone replacement therapy, during pregnancy, during oral anticoagulant treatment, in the setting of liver synthetic dysfunction, and at the time of an acute thrombotic event. Congenital protein S deficiency cannot be diagnosed under these circumstances. Levels normalize up to 3 weeks after discontinuation of oral anticoagulants.

Antithrombin activity can be low in the acute setting of a thromboembolism, during heparin therapy, in patients with liver synthetic dysfunction, and in nephrotic syndrome. Low levels in these circumstances do not necessarily indicate congenital antithrombin deficiency.

Plasma homocysteine levels increase after a protein-rich diet, but the change is typically less than 10% from baseline, an elevation that, for practical purposes outside of clinical studies, is not relevant. Because the MTHFR polymorphisms do not appear to be associated with arterial or venous thromboembolism, nor with pregnancy complications, there is no clinical indication to test for them if homocysteine levels are normal.

APLAs are a heterogeneous group of antibodies (Fig. 66-2) that can be detected in the laboratory by either functional coagulation assays (*lupus anticoagulant*) or enzyme-linked immunosorbent assay (e.g., anticardiolipin and anti- β_2 -glycoprotein I antibodies). These tests are discussed in detail elsewhere (see Chapter 152).

Testing for rare causes of thrombophilia, such as dysfibrinogenemia, plasminogen deficiency, paroxysmal nocturnal hemoglobinemia, and myeloproliferative disorders is preferably done after consultation with a thrombophilia specialist.

Figure 66-2 Antiphospholipid Antibodies.

Management and Therapy

Optimum Treatment

The presence or absence of certain thrombophilic risk factors may have bearing on the length of anticoagulant treatment after venous thromboembolism and on the accuracy of anticoagulation monitoring (in the case of the presence of antiphospholipid antibodies), and may have implications for other family members. Management and therapy of various arterial and venous thromboembolic problems are discussed in the other chapters of this book (see Chapters 29, 31, 67, and 125). Referral for evaluation in a specialized thrombophilia center deserves careful consideration for patients with spontaneous or unusual thrombotic events and for asymptomatic individuals with known thrombophilia. The opportunity to perform thrombophilia testing brings the responsibility to counsel patients and their families about the implications of positive or negative test results and to educate them about their thrombophilia. Some patient education tools are available on the Internet.

Avoiding Treatment Errors

Knowledge of the factors that cause false-positive and false-negative test results (Table 66-2; Box 66-3) is important to avoid labeling a patient with a thrombophilia that the patient does not have, or missing the presence of a thrombophilia.

Future Directions

Significant developments in thrombophilia include the identification of new genetic polymorphisms and haplotypes that predispose carriers to venous or arterial thromboembolism, and the performance of clinical studies that

Table 66-2 Influence of Acute Thrombosis, Heparin, and Warfarin on Thrombophilia Test Results

Test	Acute Thrombosis	Unfractionated Heparin	Low Molecular Weight Heparin	Vitamin K Antagonists
Factor V Leiden genetic test	Reliable	Reliable	Reliable	Reliable
Activated protein C resistance assay	Reliable ¹	<i>Caveat</i> ²	<i>Caveat</i> ²	Reliable ¹
Prothrombin 20210 genetic test	Reliable	Reliable	Reliable	Reliable

Deep Venous Thrombosis and Pulmonary Embolism

Introduction

Deep venous thrombosis (DVT) and pulmonary embolism (PE) are the two most important clinical events that occur in individuals with venous thrombosis. Approximately 0.1% of the population will experience a DVT, and PE is the third leading cause of cardiovascular mortality. Early diagnosis and treatment of DVT and PE substantially reduce mortality and morbidity, but autopsy series consistently find that DVT and PE are still underdiagnosed. The numerous publications of algorithms aimed at improving diagnostic accuracy and optimizing treatment illustrate the frequency with which both DVT and PE elude diagnosis. In this chapter, we review the various presentations of these syndromes and provide an overview of the most promising modalities for early diagnosis and treatment.

Etiology and Pathogenesis

Deep venous thromboses may occur anywhere in the venous system, but most begin in the lower extremities between the lower leg and the pelvis. Virchow's classic triad of vessel wall injury, stasis, and hypercoagulability is as relevant today as when proposed for understanding the pathogenesis and risk factors for thrombosis. Both stasis and vessel wall injury can lead to platelet aggregation, which triggers the clotting cascade, including cellular and protein components. This can result in an imbalance in the naturally occurring procoagulant and anticoagulant proteins, and formation of an intravascular thrombus. Chapter 66 describes this complex system in more detail.

Although pulmonary emboli usually result from embolization of thrombi in the venous system of the lower extremities or pelvis, one must also consider the inferior vena cava (IVC), renal or upper extremity veins, and even the right side of the heart as potential sources of pulmonary emboli (Fig. 67-1). Thrombi can also form in smaller veins below the popliteal vein, but these thrombi rarely embolize, and thus present a low risk.

Many of the classic risk factors for DVT or PE affect one aspect of Virchow's triad (Fig. 67-2). Immobility from surgery, trauma, or paralysis can lead to stasis because

venous flow in the lower extremities is partially dependent on muscular contraction. By entirely different mechanisms, surgery, trauma, or infection can cause vessel wall injury. Additionally, most malignancies are accompanied by some degree of hypercoagulability, a complication particularly well documented in mucinous adenocarcinomas and referred to as *Trousseau's syndrome*.

Another common cause of DVT involves pregnancy; the combination of a hypercoagulable state, local venous stasis (from the uterus compressing the IVC), and immobility (e.g., with travel) is a common setting for DVT in individuals who have none of the above risk factors. Indeed, other identified hypercoagulable states are increasing in number and are discussed in Chapter 66. Understanding the settings in which DVT and PE occur may offer the clinician a clue toward diagnosis. However, it is important to consider the clinical findings (Tables 67-1 and 67-2), particularly for patients with no known precipitants.

Clinical Presentation

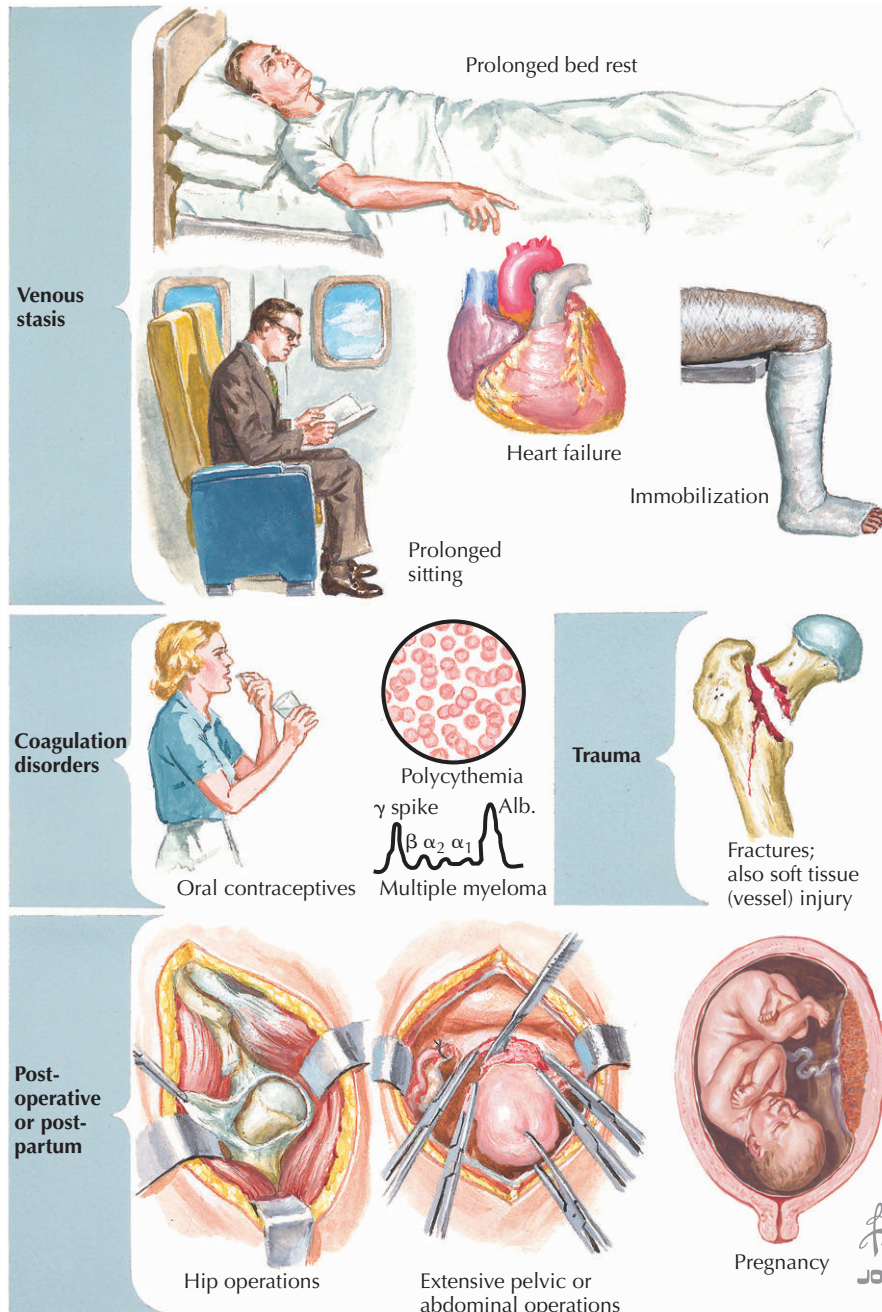

Patients with DVT or PE present with a spectrum of symptoms ranging from mild tenderness or swelling in the calf to acute dyspnea and syncope. A careful history may reveal one or more of the predisposing risk factors listed

Figure 67-1 Deep Venous Thrombosis.

in Tables 67-1 and 67-2. The classic constellation of symptoms for an isolated DVT includes unilateral leg symptoms of swelling, tenderness, and dilated collateral veins. As previously noted, most patients do not present with this complete set of findings, making early diagnosis more challenging. It is important to remember, however, that about 40% of patients with isolated DVT will have asymptomatic PEs on ventilation-perfusion (\dot{V}/\dot{Q}) scans. For this reason, patients with either DVT or PE should be considered to have both until proved otherwise.

The more ominous presentation of PE may (but does not invariably) include the symptoms of DVT and also reflects the effect of acute cessation of perfusion to parts of the lung. The sudden onset of dyspnea and tachycardia may be the initial clue (Fig. 67-3). Other common symptoms and signs include chest pain (pleuritic or nonpleuritic), hemoptysis, pleural rub, hypoxemia, or fever (less than 38.9°C). A patient who also has syncope, hypotension, or signs of new-onset right-sided heart failure falls into the category of severe PE. At highest risk are those patients

Figure 67-2 Predisposing Factors for Pulmonary Embolism.

with PE who present with hemodynamic compromise. One should always include PE in the differential diagnosis for patients presenting in cardiogenic shock until another cause is proved.

Differential Diagnosis

Many processes can masquerade as a DVT or PE and, thus, should be kept in mind while proceeding through diagnostic algorithms. One of the most important factors

in determining the probability of DVT or PE is the likelihood of a competing diagnosis. For DVT, the most common competing diagnoses are muscle strain or leg injury, venous insufficiency, lymphatic obstruction, popliteal cyst, drug-induced edema, and cellulitis. The differential diagnosis of dyspnea and tachycardia is also quite long and includes pneumonia, congestive heart failure, myocardial infarction, chronic obstructive pulmonary disease, pulmonary hemorrhage, and aspiration pneumonitis. One of the first steps in the diagnosis of DVT or PE is to assess the likelihood that one of the competing diag-

Table 67-1 Clinical Model for Predicting Pretest Probability for Deep Venous Thrombosis

Clinical Feature	Score
Active cancer (treatment ongoing or within previous 6 months or palliative)	1
Paralysis, paresis, or recent plaster immobilization of the lower extremities	1
Recently bedridden for >3 days or major surgery within 4 weeks	1

noses accounts for the symptoms and physical examination findings.

Diagnostic Approach

The most accurate and cost-effective approach to the diagnosis of DVT and PE remains an active area of research and a challenge for clinicians. Currently, most authors recommend algorithms that combine the pretest probability with careful selection of diagnostic tests. Because DVT and PE are commonly missed, these diagnoses must be kept in mind until proved otherwise. This does not mandate comprehensive testing for a given patient, but the pretest probability for DVT and PE increases in circumstances when other leading diagnoses are excluded in the course of the initial assessment.

Deep Venous Thrombosis

The diagnostic evaluation for suspected DVT should begin with an assessment of the pretest probability. Countless models have been proposed. The most widely used model was developed by Wells and associates (see Table 67-1). Unfortunately, because of varied presentations, the clinical diagnosis of DVT is very inaccurate, leading to difficulty establishing an accurate pretest probability. This issue is presented in greater detail in Chapter 3. Pretest probability is extremely important, however, in interpreting the results of noninvasive tests for DVT (as in other clinical syndromes), as described later.

Table 67-2 Algorithm to Determine Pretest Probability of Pulmonary Embolism

Clinical Feature	Score
Clinical symptoms of DVT	3
Heart rate >100 beats/min	1.5
Immobilization or surgery in the previous 4 weeks	1.5
Previous objectively diagnosed DVT or PE	1.5
Hemoptysis	1
Malignancy	1
PE as likely as or more likely than an alternative diagnosis	3

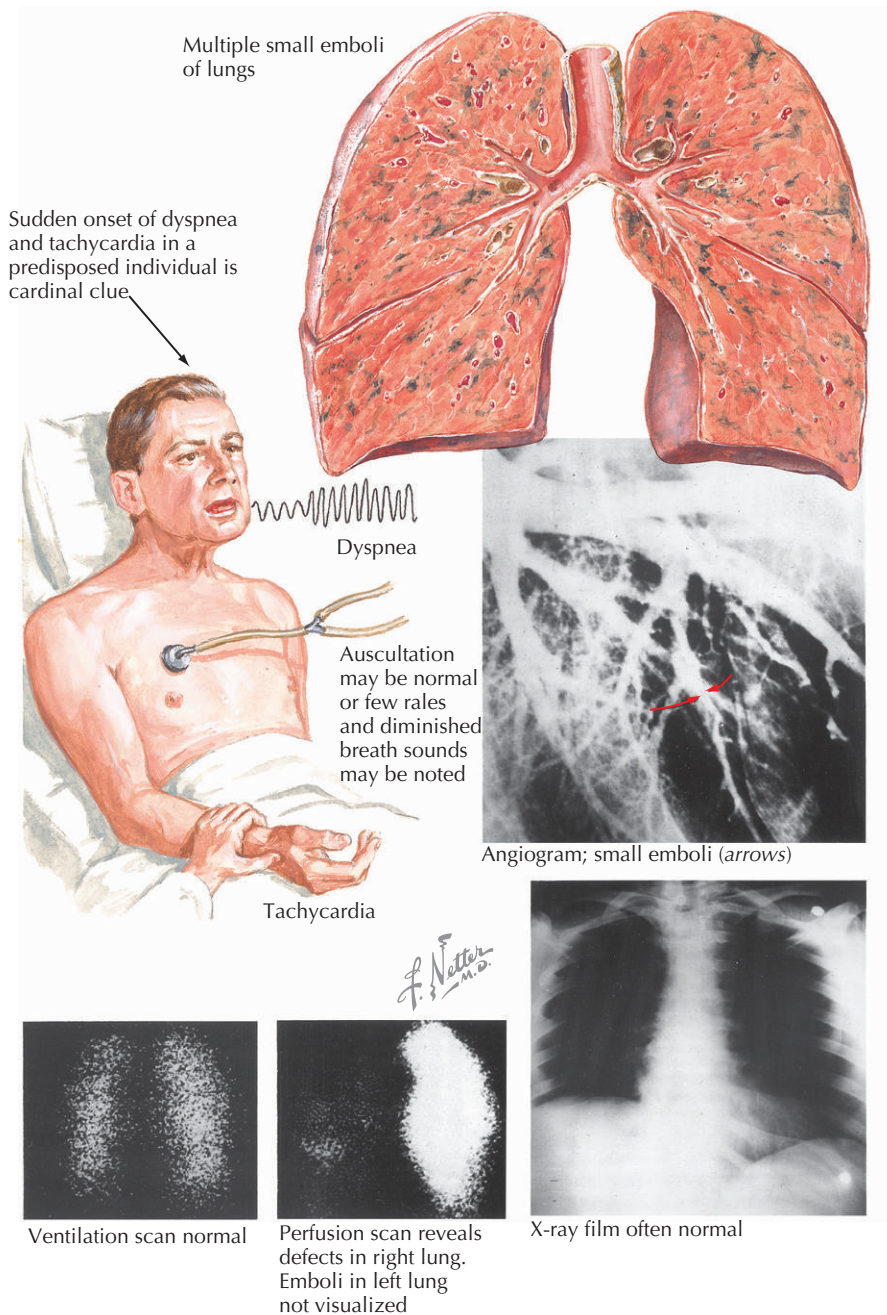

DVT, deep vein thrombosis; PE, pulmonary embolism. Probability: high >6 pts, moderate 2 to 6 pts, low <2 pts. Adapted from Wells PS, Anderson DR, Rodger M, et al: Excluding pulmonary embolism at the bedside without diagnostic imaging: Management of patients with suspected pulmonary embolism presenting to the emergency department by using a simple clinical model and D-dimer. *Ann Intern Med* 135(2):98-107, 2001.

The options for objective testing include D-dimer, compression venous ultrasonography, impedance plethysmography, and contrast venography. Contrast venography remains the gold standard for the diagnosis of DVT, and compression venous ultrasonography has largely replaced impedance plethysmography as the noninvasive diagnostic test of choice. The accuracy of compression venous ultrasonography has greatly reduced the need for contrast venography.

The D-dimer assays measure a degradation product of cross-linked fibrin and are commonly used in assessment of DVT. Theoretically, any patient with active coagulation should have an elevated D-dimer, suggesting the usefulness of a negative result to rule out DVT. Clinically, the D-dimer can sufficiently lower the probability of DVT in the low-risk group to avoid proceeding with ultrasound. In the moderate- and high-risk groups, the false-negative rate of the D-dimer is too high to render it useful. For patients in the moderate- or high-risk group, clinicians should proceed directly to ultrasound. Additionally, a positive result on a D-dimer test is woefully nonspecific and cannot be used to diagnose DVT. Certain patient groups are known to have especially high rates of false-positive results, including hospitalized patients and those who have had recent surgery or malignancy.

Compression venous ultrasonography leads the list of noninvasive tests for the diagnosis of DVT. A positive test result occurs when the femoral or popliteal veins are non-compressible under ultrasound visualization. The ability to perform this test in a timely manner is the most difficult barrier because most studies must be done during normal working hours. The sensitivity and specificity of this test have been reported to be as high as 95% and 96%, respectively, for symptomatic, proximal DVT, although this clearly depends on the skill and experience of the technolo-

Figure 67-3 Embolism of Lesser Degree without Infarction.

gist and interpreting physician. For the diagnosis of isolated thrombosis in the calf vein, sensitivity and specificities are 60% to 70%, but as previously described, patients with only distal thromboses are at very low risk. When the ultrasound result confirms the clinical suspicion, one can stop further testing and proceed with therapy. Another test is required only if there is discord between the clinical suspicion and the ultrasound result.

Contrast venography is occasionally needed as the arbiter of discordant results between the clinical predictor model and the initial ultrasound. If a patient is thought to

be at low risk, but has a positive ultrasound, venography is used to confirm the result. A negative venogram will abrogate long-term anticoagulation. Alternatively, if clinical suspicion is high but the ultrasound result is negative, most clinicians will consider venography to be certain that the ultrasound did not yield a false-negative result. The use of serial ultrasound examinations instead of venography has been proposed, but expert opinion varies on the efficacy of this approach, and head-to-head comparisons are limited. Certainly, this approach is preferable in individuals at risk for contrast dye nephropathy or with known dye allergy.

Serial duplex examinations should be considered 7 days after the initial workup.

Pulmonary Embolism

The diagnosis of PE begins in the same manner—with an assessment of the clinical probability of disease (see Fig. 67-3). Table 67-2 is a useful set of clinical criteria to determine pretest probability of PE. The last item is determined by the physician based on all available clinical data, includ-

ing history, physical examination, electrocardiography (ECG), and chest radiography. In the initial study of this tool, patients in the high-risk group had an incidence of 41%; the moderate-risk group, 16%; and the low-risk group, 1.3%.

The ECG does not reliably diagnose PE, but it may offer clues to its presence. The classic ECG finding of $S_1Q_3T_3$ is infrequently present, and nonspecific ST- or T-wave changes appear more commonly (Fig. 67-4). Evidence of new right ventricular strain or right-axis deviation

can be an early marker for massive PE. The ECG can also help determine whether other differential diagnoses, particularly myocardial infarction, are present.

The chest radiograph is mainly helpful in identifying other diagnoses and lessening the likelihood that the presentation is caused by PE. The classic findings of pulmonary infarct that have been described (Hampton's hump or a dilated proximal pulmonary artery) are rarely seen.

The D-dimer test occupies the same place in the workup of PE as it does for DVT. In a patient in the lowest risk group, a negative D-dimer makes the presence of a PE unlikely. In any other group of patients, the D-dimer is not useful.

The imaging procedures for the determination of PE are computed tomography (CT) scan, \dot{V}/\dot{Q} scan, and pulmonary angiography.

The contrast-enhanced CT scan has gained rapid acceptance in the diagnosis of PE and has decreased the use of \dot{V}/\dot{Q} scanning for most groups of patients. The CT has a high specificity and sensitivity for emboli in the proximal pulmonary arteries and the large branches, and is constantly improving in the diagnosis of subsegmental defects. A recent meta-analysis suggests that the CT scan is sufficiently sensitive and specific to use in diagnosis of PE. For patients with a high clinical suspicion of PE, a negative CT result should be followed with additional testing such as lower extremity ultrasound or pulmonary angiogram. The CT can be used in settings where underlying lung pathology makes \dot{V}/\dot{Q} scanning difficult to interpret and can be helpful for evaluating other suspected diagnoses. One important limitation of CT scanning is that it requires the administration of venous contrast material, which may be contraindicated in some groups of patients. The CT scan has largely replaced the \dot{V}/\dot{Q} scan in clinical practice.

The \dot{V}/\dot{Q} scan remains a reliable noninvasive test for diagnosis of PE. The possible test results include normal, low probability, intermediate probability, and high probability. A normal \dot{V}/\dot{Q} scan will eliminate the possibility of PE, and a high probability scan will diagnose PE. Low or intermediate probability scans lack the accuracy to either dismiss the diagnosis of PE entirely or to begin therapy, and, depending on the clinical setting, may mandate further testing. Many other illnesses can complicate interpretation of the test, including neoplasm, infection, and heart failure. A normal baseline radiograph increases the chances that the \dot{V}/\dot{Q} scan will yield useful results. In our institution, many of our complicated patients, for whom knowing a diagnosis is essential, will be placed in the low or intermediate category and require further testing.

As for DVT, angiography remains the gold standard for the diagnosis of PE. This invasive procedure requires passage of a catheter into the pulmonary arteries and injection of contrast under fluoroscopy. The mortality risk of pulmonary angiography is less than 0.5% in skilled hands, and thus is far less than the complications of misdiagnosis

of PE. Delaying anticoagulation in patients with thrombus can be disastrous, and chronic unnecessary anticoagulation should be avoided. Thus, any patient with a high clinical suspicion of PE but an ambiguous diagnosis should undergo pulmonary angiography.

In the stable patient, an often reasonable alternative is to perform lower-extremity venous ultrasonography. Although not all PEs result from DVT, the presence of DVT offers confirmatory evidence that, in the presence of appropriate symptoms, the patient has had a PE.

Management and Therapy

Optimum Treatment

The recommendations for therapy for DVT and PE are currently the same, except for very large PEs, or PEs in the presence of hemodynamic compromise. The efficacy of anticoagulation is clear, but controversies remain over the acute management of DVT and PE and the necessary length of long-term anticoagulation. Both of these are addressed in the American College of Chest Physicians (ACCP) guidelines in more detail.

Acute management of DVT and PE requires administration of heparin. Multiple studies have evaluated the effectiveness of continuous-infusion unfractionated heparin (UH) and low-molecular-weight heparin (LMWH), both of which are indirect thrombin inhibitors (requiring the presence of antithrombin III). Most authorities consider both therapies effective for DVT and hemodynamically stable PE. Many hospitals have developed standard protocols for the administration of UH, and we strongly support this approach. At our hospital, UH is started with a bolus dose of 80 IU/kg and a continuous infusion of 18 IU/kg/hr. The activated partial thromboplastin time (aPTT) should be checked 6 hours after initiation and the dose of heparin adjusted to reach an aPTT of 1.5 to 2.3 times normal. Studies have demonstrated that subcutaneous UH can be administered twice daily as an alternative to intravenous UH. Most guidelines (including the ACCP guidelines) recommend giving a 5000-unit intravenous bolus followed by 17,500 units subcutaneously twice daily.

Many physicians prefer LMWH because of its ease of administration (subcutaneously once or twice daily) and because therapeutic monitoring is not usually required. Several studies indicate that LMWH is at least as effective as UH for the treatment of DVT and PE. Because LMWH is subject to renal clearance, it is not recommended for patients with renal failure. In stable patients, LMWH can be given on an outpatient basis. Note that different preparations of LMWH vary in their relative antithrombin and anti-Xa activities, and they may not be readily interchangeable. Altogether, however, the only reason that LMWH is not the clear treatment of choice for patients with DVT and PE is its cost, which is much higher than that of UH.

Table 67-3 Duration of Anticoagulation for Deep Venous Thrombosis and Pulmonary Embolism

3 months	First event with reversible or time-limited risk factor
≥6 months	First episode of DVT/PE with documented deficiency of protein C or protein S, or the factor V Leiden or prothrombin 20210 gene mutation, homocystinemia, or high factor VIII levels
12 months or lifetime	First event with: <ul style="list-style-type: none"> ▪ Cancer (therapy with LMWH for first 3-6 months is safer and more effective) ▪ Antiphospholipid antibody ▪ Two or more thrombophilic conditions (e.g., combined factor V Leiden and prothrombin 20210 gene mutations) ▪ Idiopathic
	Recurrent event

DVT, deep vein thrombosis; LMWH, low-molecular-weight heparin; PE, pulmonary embolism. From Buller HR, Agnelli G, Hull RD, et al: *Antithrombotic therapy for venous thromboembolic disease*. *Chest* 126(3 Suppl):401S, 2004.

Fondaparinux is a newer antithrombotic agent that may be of use for the acute treatment of DVT or PE. Initial data suggest it is a reasonable alternative to UH or LMWH. At our center, fondaparinux is considered if a patient develops heparin-induced thrombocytopenia. Fondaparinux is contraindicated for patients with creatinine clearance of less than 30 mL/min.

Long-term anticoagulation is recommended for any patient with either DVT or PE, and at this time, warfarin is the mainstay of this therapy. Warfarin exerts its effect by inhibiting the formation of vitamin K–dependent proteins, and thus does not achieve therapeutic anticoagulation until it has been administered for several days. It is currently recommended to start warfarin concurrently with heparin therapy and continue administration of heparin until the International Normalized Ratio reaches the therapeutic range of 2.0 to 3.0.

The duration of anticoagulation depends on the underlying cause of the thrombosis and is still a subject of much debate and research. The current ACCP guidelines are reasonable (Table 67-3), but these recommendations may change as we learn more about the causes of idiopathic venous thromboembolism.

Most patients can be treated according to the previous guidelines. However, patients with very large PEs or with PE and hemodynamic compromise may require a more aggressive approach. Thrombolytic therapy has been studied in patients with massive PE but has not uniformly proved to decrease mortality, probably because of the comorbidities present in patients with massive PE. However, most experts agree that hemodynamically unstable patients should be considered for thrombolytic therapy. If thrombolytic therapy is considered, the potential for bleeding (particularly from an underlying malignancy) must be carefully weighed. Surgical embolectomy should be considered for patients with massive PE and hemodynamic compromise with contraindications to thrombolytic therapy or who fail thrombolysis.

Another subset of patients who require special consideration includes those with contraindications to anticoagulation or with repetitive DVT or PE. In individuals with

contraindications to anticoagulation, an IVC filter may be inserted to lessen the chance of further pulmonary emboli. Temporary filters that can be removed after the situation is resolved are now available. Occasionally, long-term IVC filters are used as a last option in patients with a contraindication to anticoagulation, although in this circumstance, complications can arise from local thrombosis at the site of the filter.

Avoiding Treatment Errors

To avoid treatment errors, the treating clinician should carefully review the patient's creatinine clearance (in case of consideration of LMWH) and any previous allergies to heparin, including heparin-induced thrombocytopenia. In patients with renal insufficiency, UH is a better choice than LMWH. For patients with a history of heparin-induced thrombocytopenia, clinicians should consider fondaparinux and consultation with a coagulation specialist.

Prophylaxis

Prevention of DVT and PE has been well studied and proved effective in several instances. Patients at high risk for DVT and PE include (in order of descending risk) those undergoing surgical procedures (especially orthopedic and neurosurgical); after ischemic stroke; and medical patients with cancer, heart failure, severe lung disease, or myocardial infarction. Those at highest risk clearly benefit from more aggressive measures to prevent thrombus formation. Therapy with LMWH or fondaparinux is recommended for patients undergoing hip or knee replacements. For patients at lower risk (medical patients), the best therapy remains unclear. Current guidelines recommend subcutaneous UH or LMWH as reasonable choices for prophylaxis of DVT and PE among medical patients. Ultimately, DVT and PE prophylaxis should be instituted for any patients at risk. A detailed analysis of the vast research in this area can be found in the ACCP guidelines on prevention of venous thromboembolism.

Future Directions

The diagnostic algorithms of DVT and PE will benefit from further refinement of the imaging modalities, but the most exciting developments will be in anticoagulants with fewer side effects and a broader therapeutic window.

This prospective cohort study demonstrates the safety and usefulness of using pretest probability to manage the workup of patients with suspected PE.

Disseminated Intravascular Coagulation

Introduction

Disseminated intravascular coagulation (DIC) is a complex coagulation disorder that is characterized by widespread activation of the clotting and fibrinolytic systems, with resultant thrombotic and hemorrhagic complications. DIC is not a disease, but rather a clinicopathologic syndrome resulting from various inciting conditions (Box 68-1).

Etiology and Pathogenesis

DIC is the result of inappropriate and excessive activation of the hemostatic process. The pathologic activators of this process are only partially understood. One or more mechanisms are likely, including the de novo synthesis or release of tissue factor into the systemic circulation following endothelial injury (in extensive trauma, abruptio placentae, or retained dead fetus); production of tissue factor-like substances by circulating malignant tumor cells or amniotic fluid; and vessel wall disruption leading to platelet activation, followed by activation of the hemostatic system (in sepsis, extensive burns, hypothermia, hypoxemia and acidosis, and extensive carcinomatosis).

Unchecked activation of the coagulation system leads to excessive thrombin generation, with subsequent fibrin formation. Fibrin is widely deposited throughout the vasculature, particularly in small-caliber vessels, resulting in end-organ dysfunction. Natural regulatory proteins, such as antithrombin III (AT) and protein C, are consumed in the process. Additionally, secondary activation of the fibrinolytic system typically occurs, resulting in the generation of fibrin and fibrinogen split products. However, in many forms of DIC, such as in sepsis, the excessive synthesis and release of plasminogen activator inhibitor by endothelial cells is counterproductive and results in insufficient fibrinolysis to remove the ubiquitous deposited fibrin.

In DIC, procoagulant, anticoagulant, and fibrinolytic factors are consumed (Fig. 68-1). Circulating thrombin

also leads to platelet activation, which further enhances the prothrombotic state. Consumption of platelets leads to thrombocytopenia. When procoagulant activity dominates (such as in cancer and sepsis), thrombi formed in the microvasculature produce multiorgan failure. However, if fibrinolytic activation or the consumption of procoagulant factors and platelets dominate, bleeding may ensue. The latter outcome may be seen, for example, in acute promyelocytic leukemia owing to synthesis of plasminogen activators by the leukemic cells and in DIC associated with surgery or obstetric disasters. Microangiopathic hemolytic anemia (MAHA) occurs when thrombi narrow the lumen of the microvasculature, and erythrocytes, in their attempt to pass through, become fragmented. In this circumstance, hemolysis occurs, with the circulation of fragmented red blood cells (helmet cells or schistocytes).

Clinical Presentation

The clinical presentation of DIC is highly variable and is determined to a large extent by the underlying etiology (Box 68-1). In many cases, clinical complications may be subtle or even absent. Although vaso-occlusive manifestations are significantly more prevalent overall, certain subtypes of DIC may be associated with bleeding, usually in the form of widespread microvascular oozing from mucocutaneous surfaces. Manifestations of this microvascular oozing can include easy bruising, microscopic or macroscopic hematuria, or bleeding from venipuncture or intra-

Figure 68-1 Disseminated Intravascular Coagulation (DIC).

venous catheter sites, surgical wounds, or endotracheal tubes. At the most extreme end of the spectrum is fulminant DIC, for example as seen in severe sepsis, presenting as massive and diffuse bleeding, unmanageable by blood product transfusions (Fig. 68-2). As outlined previously, bleeding is more frequently encountered in hyperacute forms of DIC, in which there is rapid and uncompensated consumption of clotting factors and platelets as a result of hyperfibrinolysis. Low-grade DIC is found most frequently in patients with sepsis or malignant tumors and, rarely, in

the obstetric patient with a retained dead fetus. Because liver synthetic function is able to replace the consumed coagulation proteins and a steady state is reached, patients may be asymptomatic, and the diagnosis of DIC is made only by laboratory testing.

DIC in the obstetric patient can be particularly challenging to diagnose and manage because of the high risk to both the mother and fetus and, in part, because DIC can present in any of several different ways. Amniotic fluid embolism occurs in 1 : 20,000 to 1 : 30,000 deliveries,

Box 68-1 Clinical Conditions Associated with Disseminated Intravascular Coagulation

- Sepsis and severe infection
- Trauma (e.g., polytrauma, neurotrauma, fat embolism)
- Organ destruction (e.g., severe pancreatitis)

 - Large aneurysms
 - Kasabach-Merritt syndrome
- Severe hepatic failure
- Severe toxic or immunologic reactions
 - Snake bites
 - Recreational drugs
 - Transfusion reactions
 - Transplant rejection
- Therapy with prothrombin complex concentrates

carries a 26% to 86% maternal mortality rate, and is responsible for about 10% of maternal deaths. Amniotic fluid embolism can occur during labor, during cesarean birth, or within 30 minutes postpartum. Fulminant, diffuse hemorrhage develops because of the consumption of coagulation factors. Acute hypotension, hypoxemia, and cardiopulmonary arrest may occur as a result of widespread microthrombi. Previous pregnancy, carriage of a male fetus, and a history of allergies and atopy are risk factors, but prolonged labor and the use of oxytocin are not. A less severe DIC, ranging from mild vaginal bleeding to maternal hemorrhagic shock, may occur in abruptio placentae. The extent of DIC in septic abortion, intra-amniotic infection, and postpartum endometritis is variable.

Diagnostic Approach

The diagnosis of DIC should only be contemplated when an associated underlying cause has been identified. There is no single laboratory test for the diagnosis of DIC, but a typical DIC laboratory panel includes a prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen activity assay, platelet count, and a D-dimer or fibrin degradation product (FDP) level. A diagnostic scoring algorithm utilizing these widely available coagulation tests was proposed by the International Society of Thrombosis and Haemostasis in 2001. The design of this scoring system has a pathophysiologic basis, incorporating the concepts of nonovert and overt DIC as distinct entities, each with its own scoring system (Table 68-1). Overt DIC can be defined as a state in which the vascular endothelium

and blood and its components have lost the ability to compensate and restore homeostasis in response to injury. The result is a progressively decompensating state with thrombotic multiorgan dysfunction, bleeding, or both. Nonovert DIC may be defined as a clinical vascular injury state that results in stress to the hemostatic system, the response to which, for the moment, is sufficient to forestall further rampant inflammatory and hemostatic activation. The nonovert DIC score emphasizes repeat assessments because the overall trend is an important facet for both diagnosis and prognosis. To some extent, these subsets reflect different points in the continuum, although it is clear that nonovert DIC may be associated with adverse outcomes in critically ill patients independently of progression to overt DIC.

Both scoring systems have been validated in prospective studies, generally in the intensive care unit setting. In overt DIC, a score of 5 or more is considered to be diagnostic, as it is in nonovert DIC (see Table 68-1). It should be noted that the term *fibrin-related products* can include direct assays for the presence of fibrin (e.g., soluble fibrin monomers) and indirect assays of fibrin generation (such as D-dimer, FDPs). Of these, D-dimers are now the most frequently used assay in North America. The scoring system for the diagnosis of nonovert DIC (see Box 68-1) includes, in addition to the previously mentioned global studies, more specific (but less widely available) tests, such as plasma antithrombin and protein C levels.

It should be especially noted that a low plasma fibrinogen level is not a sensitive marker of DIC, nor is it considered necessary for the diagnosis. In fact, high plasma fibrinogen levels are much more frequently encountered. In addition, even though a review of the peripheral blood smear should be performed, MAHA in DIC is neither invariably present, nor required to make the diagnosis.

Differential Diagnosis

Often the clinical and laboratory presentation is such that DIC cannot be diagnosed with absolute certainty. Many of the patients in whom the diagnosis of DIC is entertained are in the intensive care unit and have multiple medical problems. The coagulopathy and thrombocytopenia in these patients are often multifactorial. The differential diagnosis includes coagulopathy resulting in liver synthetic dysfunction in chronic or acute liver failure; thrombocytopenia caused by hypersplenism; vitamin K deficiency in the postsurgical or intensive care unit patient; dilutional coagulopathy and thrombocytopenia after multiple red blood cell transfusions; heparin- or other drug-induced thrombocytopenia; thrombotic thrombocytopenic purpura (TTP); hemolytic-uremic syndrome (HUS); other MAHA; immune-mediated thrombocytopenia triggered by infection; or infective endocarditis. Measurement of factor VIII activity can be used to differentiate between severe DIC and severe liver synthetic dysfunction. Although factor

Figure 68-2 Disseminated Intravascular Coagulation (DIC) in Fulminant Bacterial Sepsis

VIII is low in severe DIC, it is normal or elevated in most instances of severe liver synthetic dysfunction. The activity of the vitamin K–dependent factors (II, VII, IX, X) can be compared with that of non–vitamin K–dependent factors (fibrinogen, AT, V, VIII, XI, XII) to differentiate between vitamin K deficiency and DIC. In the pregnant or postpartum patient, the differential diagnosis includes preeclampsia, eclampsia, HELLP syndrome (hemolysis, elevated liver enzymes, low platelet count), and TTP/HUS.

Management and Therapy

Optimum Treatment

Management of DIC should focus on the treatment of the underlying disorder, blood product support in the bleeding patient, and consideration of the use of heparin, AT concentrate, or activated protein C concentrate (drotrecogin alfa [Xigris]). In the handful of small prospective randomized clinical trials that have been performed, no clear benefit of heparin has been demonstrated in DIC. However, heparin anticoagulation is appropriate for those patients with a documented thromboembolic event, acral ischemia, or purpura fulminans. There remains a range of

Table 68-1 Scoring System for Disseminated Intravascular Coagulation of the International Society of Thrombosis and Haemostasis

1. **Risk assessment:** Does the patient have an underlying disorder known to be associated with overt DIC?
If no: Do not use this algorithm.
If yes, order global coagulation tests: platelet count, prothrombin time, fibrinogen, and soluble fibrin monomers or fibrin degradation products (such as D-dimer)

2. **Score global coagulation test results and calculate total score:**

Test Result	Score
Platelet Count	
>100 = 0	<input type="checkbox"/>
<100 = 1	
<50 = 2	
Prolonged Prothrombin Time	
<3 sec = 0	<input type="checkbox"/>
>3 sec and <6 sec = 1	
>6 sec = 2	
Fibrinogen Level	
>100 mg/dL = 0	<input type="checkbox"/>
<100 mg/dL = 1	
Elevated Fibrin-Related Markers	
No increase = 0	<input type="checkbox"/>
Moderate increase = 2	
Strong increase = 3	
Total:	<input type="checkbox"/>

3. Evaluate total score:

If total score ≥ 5 : compatible with overt DIC; repeat scoring daily

If total score < 5 : suggestive (not affirmative) for nonovert DIC; repeat in the next 1 to 2 days

DIC, disseminated intravascular coagulation.

opinion on the most appropriate dosing protocol for heparin.

The patient with DIC who is bleeding clearly needs blood product support. In the nonbleeding patient with DIC who is at increased risk for bleeding (e.g., postsurgical, postpartum, intubated), blood products may also be indicated. In other nonbleeding patients with DIC, blood product transfusions are probably not routinely indicated. It has been proposed that blood product transfusions, such as plasma and platelets, may worsen DIC, but this theory has neither been proved nor disproved. However, avoidance of transfusion products in DIC patients not at risk for bleeding appears prudent. In the absence of any randomized trials (or even consensus guidelines) on the use of blood products in DIC, reasonable transfusion goals in the DIC patient who is bleeding or is being prepared for an invasive procedure are a platelet count higher than

$50 \times 10^9/L$, fibrinogen more than 100 mg/dL, and maintenance of PT and aPTT as close to the normal range as possible.

The various blood product and drug therapies used in DIC are as follows.

Fresh Frozen Plasma

Fresh frozen plasma (FFP) contains all coagulation factors, but none in concentrated form. Thus, a bleeding patient with severe DIC might require such large volumes of FFP to achieve the previously mentioned targets that the potential for fluid overload would be a real limitation. To avoid a dilutional coagulopathy in the patient who receives multiple packed red blood cell (PRBC) transfusions, a patient should receive one bag of FFP for every 4 units of PRBCs.

Cryoprecipitate

Cryoprecipitate contains mainly fibrinogen, factor VIII, von Willebrand factor, and fibronectin. In some countries, not including the United States, purified fibrinogen products are available. In the United States, cryoprecipitate is the product of choice for hypofibrinogenemia. One dose of cryoprecipitate (derived from 10 donors) increases the fibrinogen plasma level by about 100 mg/dL in a non-DIC patient, but generally less in a patient with ongoing consumption due to DIC.

Platelet and Red Blood Cell Transfusions

One bag of apheresis platelets from a single donor, or 5 to 6 pooled units from whole blood collection, typically leads to an anticipated increase in platelet count of 30,000 to 60,000/ μL in the non-DIC patient, and less in the DIC patient. PRBCs should be transfused as needed, although it is not known what the optimal hemoglobin level is in patients with DIC.

Drotrecogin Alfa

Drotrecogin alfa (recombinant human activated protein C concentrate) was shown to decrease mortality in adult patients with severe sepsis and has been approved by the U.S. Food and Drug Administration (FDA) since 2001. Drotrecogin alfa is an intravenous anticoagulant that proteolytically inactivates coagulation factors Va and VIIIa. In addition, it may possess anti-inflammatory, profibrinolytic, and antiapoptotic activities in vivo. A recent post hoc analysis of the Pivotal Recombinant Human Protein C Worldwide Evaluation in Severe Sepsis (PROWESS) study demonstrated that (1) overt DIC, as defined by the International Society on Thrombosis and Haemostasis scoring system and representing about 30% of the total cohort, is a strong predictor of mortality in severe sepsis; and (2) patients with overt DIC are the most likely to benefit from the use of activated protein C concentrate. The benefit of the drug in noninfectious DIC has not been examined to date.

Antithrombin (III) Concentrate

Antithrombin III (AT) concentrate indications are not clear-cut. In a large phase III prospective randomized study on the use of AT concentrate in severe sepsis, no significant reduction in 90-day mortality could be shown compared with placebo. However, post hoc analyses have suggested that benefit might have been observed had the use of concomitant heparin been excluded, and if randomization had been limited to patients with DIC at baseline. Although this suggests that AT concentrates may yet be shown to have some benefit in DIC, the level of evidence at this time is insufficient to recommend its routine use.

Avoiding Treatment Errors

When considering the use of blood products and anticoagulant drugs in DIC, the indications should be carefully assessed, as should the potential bleeding complications of heparin, antithrombin, and drotrecogin alfa.

Future Directions

It is clear that the role of established and new anticoagulants in the treatment of DIC should be further examined. In particular, the demonstrated proinflammatory and procoagulant activities of thrombin make it an attractive therapeutic target, if excessive bleeding can be avoided. The role of drotrecogin alfa in severe sepsis has recently been questioned by several prospective clinical trials. It may be that the agent is of most benefit in a subset of patients with more life-threatening disease associated with DIC. Despite this, it would be of interest to examine the efficacy and safety of drotrecogin alfa in nonsepsis-related DIC, and recombinant thrombomodulin or other new anticoagulants in phase II and III studies. FDA approval of fibrinogen concentrate for bleeding patients with DIC is desirable, as is a clinical study of recombinant factor VIIa.

This prospective clinical trial demonstrates that high-dose antithrombin therapy had no effect on 28-day all-cause mortality in adult patients with severe sepsis and septic shock when administered within 6 hours after the onset, but that there was some evidence to suggest a treatment benefit of antithrombin in the subgroup of patients not receiving concomitant heparin.

Anticoagulation Management

Introduction

Several anticoagulants are in clinical use, and additional agents are in development (Table 69-1). Although anticoagulants can be very effective in preventing thrombotic events, they can also lead to devastating bleeding complications (Fig. 69-1). Thus, detailed knowledge of their optimal dosing and monitoring, their clearance mechanisms and drug interactions, and the management of supratherapeutic levels and bleeding complications is essential to minimize risk and optimize efficacy.

Unfractionated Heparin, Low-Molecular-Weight Heparin, and Fondaparinux

Heparins are a mixture of different lengths of polysaccharides. *Unfractionated heparins* have a mean length of 40 monosaccharide units. They inactivate thrombin, and, to a much lesser degree, factor Xa (Fig. 69-2). Low-molecular-weight heparins (LMWHs) are derived from unfractionated heparin through chemical and physical fractionation processes. In contrast to unfractionated heparins, LMWHs have a mean length of 15 monosaccharide units and preferentially inhibit factor Xa and, to a lesser degree, thrombin. *Fondaparinux* (Arixtra) is a synthetic pentasaccharide of the antithrombin-binding region of heparin and can be considered an extremely low-molecular-weight heparin. It has specific anti-Xa inhibitory activity, without any activity against thrombin.

Dosing and Monitoring

Heparin

Unfractionated heparin at therapeutic doses typically needs to be monitored with the activated partial thromboplastin time (aPTT; see Fig. 69-2). The therapeutic aPTT range depends on the heparin sensitivity of the aPTT reagent and the instrument used by a laboratory. There is no standardization of the aPTT for heparin therapy, as there is for the prothrombin time (PT) through the International

Normalized Ratio (INR) for vitamin K antagonist therapy. Optimally, a coagulation laboratory should provide the clinicians with the therapeutic heparin aPTT range for the reagent-instrument combination used in that laboratory, and clinicians should use a nomogram for heparin dosing. If a laboratory-specific therapeutic aPTT range has not been established, then an aPTT ratio of 2.0:2.5 of the mean aPTT of the normal range can be used as an approximation. It should be noted, however, that this range is subtherapeutic with some aPTT reagents, and heparin underdosing may occur.

Heparin is mostly cleared by the reticuloendothelial system and, to a smaller degree, by the kidney; patients with renal failure may require less heparin for therapeutic aPTTs to be achieved. The plasma half-life of heparin depends on the dose given: the half-life of unfractionated heparin is about 60 minutes after a 100 U/kg intravenous (IV) bolus. A patient taking therapeutic doses of continuous-infusion IV unfractionated heparin will likely have a return to baseline aPTT within 3 to 4 hours after discontinuation of heparin. A loading dose of 80 U/kg heparin IV followed by a continuous infusion of 18 U/kg/hr is usually an appropriate starting dose for patients at average risk for bleeding. For patients at increased risk for bleeding, such as those receiving concomitant thrombolytics or with thrombocytopenia, this dosing may have to be modified. The aPTT should be determined 6 hours after initiation of heparin and each dose change, and once daily after a therapeutic aPTT has been achieved.

Table 69-1 Anticoagulants in Clinical Use and Selected Agents in Development

Generic	Brand Name*	Dosing†
Heparin		
Unfractionated heparin	Various names	Various nomograms; aPTT adjusted
Dalteparin	Fragmin	<i>Prophylaxis:</i> various doses <i>Full-dose:</i> 100 U/kg every 12 hr SC or 200 U/kg every day SC
Enoxaparin	Lovenox	<i>Prophylaxis:</i> various doses
	Clexane	<i>Full-dose:</i> 1.0 mg/kg every 12 hr or 1.5 mg/kg every day SC
Tinzaparin	Innohep	<i>Prophylaxis:</i> various doses <i>Full-dose:</i> 175 U/kg every day SC

aPTT, activated partial thromboplastin time; INR, International Normalized Ratio; SC, subcutaneous.

Low-Molecular-Weight Heparins

The various LMWHs (see Table 69-1) differ in their chemical composition; therefore, dose recommendations for prophylaxis and treatment indications differ for the various drugs. The lack of significant plasma protein

binding of LMWHs gives them a more predictable anticoagulant effect than unfractionated heparin. As a result, fixed or weight-adjusted dosing is possible. For this reason, laboratory monitoring of their anticoagulant effect is unnecessary except in unusual circumstances. Peak plasma levels are reached 3 to 4 hours after injection. The half-

Figure 69-1 Intracranial Hemorrhage in a Patient Taking a Vitamin K Antagonist.

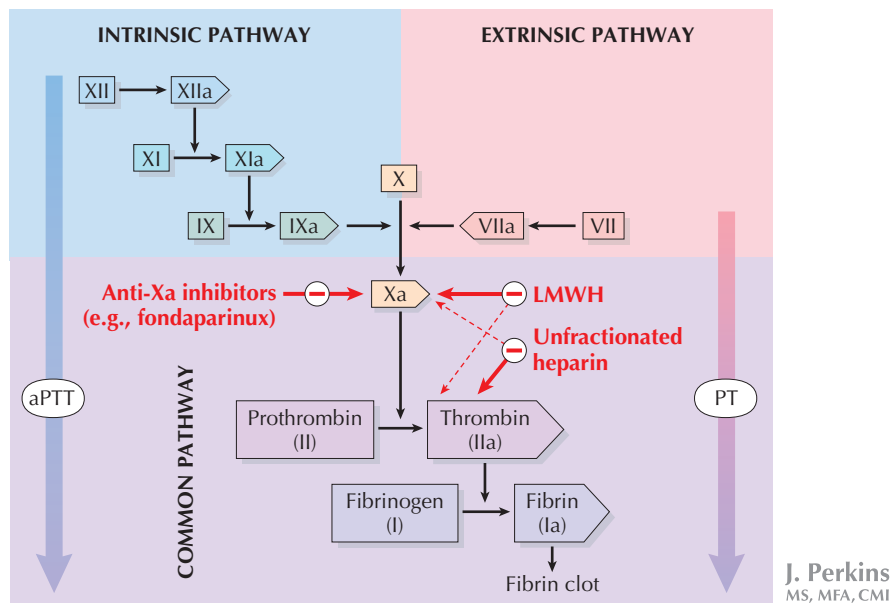

Figure 69-2 Coagulation Cascade.

lives of the various agents differ, ranging between 3 to 7 hours. Once- or twice-daily dosing regimens are available for the different LMWHs. In special patient populations, for whom monitoring of LMWH becomes necessary, an anti-Xa level (also called quantitative heparin level) should be obtained. The aPTT is typically only slightly prolonged in patients treated with LMWH and is not a useful parameter to measure the anticoagulation status of that patient. Because the LMWHs are cleared by the kidney, dose reduction and anti-Xa monitoring are needed in patients with creatinine clearances of less than 30 mL/min. LMWHs should be avoided and unfractionated heparin used instead in patients with severe renal impairment or dialysis dependence. In obese patients, LMWH dosing should be based on actual body weight, but in the patient with a body mass index of 40 kg/m² or more, anti-Xa level determination should be considered to avoid overanticoagulation. Therapeutic anti-Xa levels are in the order of 1.0 to 2.0 U/mL for once-daily dosing, and 0.6 to 1.2 U/mL for twice-daily dosing, obtained 3 to 4 hours after subcutaneous (SC) injection. Anti-Xa levels should always be obtained if a patient taking LMWH has a recurrent thrombotic event or a significant bleed, to determine whether the patient was subtherapeutically or supratherapeutically anticoagulated.

Fondaparinux

Fondaparinux (Arixtra) is given subcutaneously and reaches its peak plasma level at 2 hours. It has a half-life of 17 to 21 hours and is dosed once daily. Because it does not significantly bind to plasma proteins, it can be given as a fixed dose, either in prophylactic or therapeutic doses (see Table 69-1). Fondaparinux, like the LMWHs, is excreted by the kidney and should not be used in patients with renal failure. Fondaparinux does not appear to cause the clinical syndrome of heparin-induced thrombocytopenia (HIT) and can be considered as an alternative anticoagulant in patients with established HIT.

Bleeding

If bleeding occurs in a patient taking unfractionated heparin, intravenous protamine, which neutralizes heparin, can be given. Because protamine can lead to bleeding complications if overdosed, the minimal amount of protamine to neutralize heparin should be given. LMWH is only partially reversed by protamine. However, in case of significant bleeding while taking LMWH, protamine should be considered. For major bleeding, recombinant factor VIIa (NovoSeven) should be considered. It is unlikely that protamine has any effect on fondaparinux. Thus, in major bleeding associated with fondaparinux, recombinant factor VIIa is the treatment of choice. Fresh frozen plasma (FFP) likely has little, if any, effect on bleeding associated with heparin, LMWH, and fondaparinux, however systematic studies assessing its effect and efficacy have not been performed.

Heparin-Induced Thrombocytopenia

HIT is an incompletely understood immunologic phenomenon in which antibodies to the heparin–platelet factor 4 complex form. It is defined as the occurrence of thrombocytopenia in a patient treated with heparin and the presence of a positive test for heparin-associated antibodies. Although in some patients these antibodies are clinically irrelevant, in others they lead to thrombocytopenia and, in about one third of such patients, to thrombotic events. These can be arterial or venous and most commonly occur in large to mid-sized vessels, causing deep venous thrombosis, pulmonary embolism, or arterial occlusion resulting in myocardial infarction, stroke, or gangrene of extremities or digits (Fig. 69-3). Strict classification criteria for HIT require a platelet count decrease to less than 100,000/ μ L or a decrease in platelet count of more than 50% from baseline. A less strict definition for HIT is a platelet count decrease to less than 150,000/ μ L or a decrease of more than 30% from baseline. The clinical picture of HIT (thrombosis plus demonstration of heparin-associated antibodies) occasionally occurs even in patients who do not have a decrease in their platelet count. A high suspicion for HIT is needed in any patient who develops a decreasing platelet count while taking heparin or a patient with a new thrombotic event that has occurred during heparin therapy.

Tests that can be used for diagnostic purposes include (1) heparin–platelet factor 4 antibody enzyme-linked immunosorbent assay (HIT-PF4 ELISA), (2) heparin-induced platelet aggregation (HIPA) study, and (3) heparin-induced serotonin release assay. The HIT-PF4 ELISA is the most sensitive assay to detect HIT antibodies, but the least specific for clinically relevant antibodies. Many patients exposed to high doses of heparin, such as patients with cardiopulmonary bypass surgery, develop heparin–platelet factor 4 antibodies, which often do not lead to thrombocytopenia or thrombosis. The HIT-PF4 ELISA is the diagnostic test most widely used for HIT. The HIPA test and heparin-induced serotonin release assay are functional assays. They are more specific for the pathogenic antibodies that actually cause the clinical picture of HIT. However, they are more time consuming to perform and are not widely available.

HIT most commonly occurs in patients treated with unfractionated heparin, but it can also develop in patients treated with LMWHs. It more commonly occurs with IV heparin exposure, but can also occur with SC dosing or heparin-coated catheters. If there is a clinical suspicion for HIT, heparin should be discontinued and alternative anticoagulants started. The choices are (1) hirudins (lepirudin or bivalirudin IV; desirudin SC), (2) argatroban IV, (3) Orgaran IV or SC, and (4) fondaparinux SC (see Table 69-1). Because there is cross-reactivity of the HIT-PF4 antibodies between unfractionated heparin and LMWHs, the latter are not a treatment alternative when HIT caused

Figure 69-3 Digital Ischemia in a Patient with Heparin-Induced Thrombocytopenia.

by unfractionated heparin has occurred. HIT-PF4 antibodies do not appear to cross-react with fondaparinux to cause HIT, and fondaparinux has, therefore, in recent years become an attractive treatment option. To date, however, large treatment trials using fondaparinux in HIT have not been performed. Initiation of warfarin should be delayed until the platelet count has increased to 100,000/ μL , preferably to 150,000/ μL . Vitamin K antagonists should not be started without a patient receiving one of the alternate anticoagulants, and administration of both anticoagulants should be overlapped for at least 5 days and until the warfarin therapy has resulted in an INR greater than 2.0. Detailed recommendations for platelet count monitoring in patients taking heparin, as well as for the diagnosis and treatment of HIT, are available in the guidelines of the American College of Chest Physicians (ACCP).

Oral Anticoagulants

Coagulation factors are synthesized in the liver. The factors II, VII, IX, and X (see Fig. 69-2) require the presence of vitamin K to become fully functional. The available oral

anticoagulants (see Table 69-1) are all vitamin K antagonists. Because the half-lives of some of these factors are quite long (50 hours for factor II), the full antithrombotic effect of vitamin K antagonists is not reached for several days after starting these drugs.

An important issue in the use of oral anticoagulants is the short half-life of protein C, an endogenous anticoagulant with a half-life of about 8 hours. Protein C levels can decrease early after initiation of vitamin K antagonist drug therapy, thus rendering the patient hypercoagulable during the first few days of treatment, before factor II has decreased sufficiently to protect the patient from thrombosis. Thus, vitamin K antagonists create a prothrombotic state in the first 5 days, before they have a full anticoagulant effect. This puts the patient at risk for vitamin K antagonist-induced skin necrosis (Fig. 69-4) or progression of thrombosis, unless a parenteral anticoagulant is given overlapping with the vitamin K antagonist for at least 5 days and until the INR is above 2.0. Such overlap is not needed in the patient initiated on vitamin K antagonists who does not have an acute thrombotic event, such as a patient with newly discovered atrial fibrillation without transient ischemic attack or stroke.

Figure 69-4 Vitamin K Antagonist–Induced Skin Necrosis.

Dosing and Monitoring

The anticoagulant effect of vitamin K antagonists is determined by measuring the PT (see Fig. 69-2), expressed as the standardized INR. The typical loading dose of warfarin in a hospitalized patient is 5 mg daily on day 1 and 2, with subsequent dosing based on the INR measurement after the first two doses. A frail or elderly patient, one who has been treated with prolonged antibiotics, has liver disease, or has undergone intestinal resection, will need a lower dose in the first few days. Some clinicians prefer using higher loading doses of 7.5 mg or 10 mg, particularly in an outpatient with normal nutritional status. For maintenance dosing, the highest dose requirements for keeping a patient in the therapeutic range are in men younger than 50 years (median dose, 6.4 mg/day), the lowest in women older than 70 years (median dose, 3.1 mg/day). Occasional patients need doses as high as 20 or 30 mg per day.

The effectiveness of coordinated anticoagulation clinics in improving anticoagulation control, reducing bleeding and thromboembolic event rates, and decreasing health care cost by reducing hospitalizations and emergency department visits has been shown. The use of so-called point-of-care instruments or near-patient-testing devices in clinics, using a blood drop from a fingerstick for whole blood PT testing, allows immediate reporting of the result to the patient and dose adjustment. Patients can also use these devices at home for self-monitoring and, if trained well and encouraged by the health care system in which they live, for self-management. If patients are carefully selected and trained, the use of point-of-care testing can improve anticoagulation control, decrease in thrombo-

embolic and bleeding complications, and achieve higher patient satisfaction.

Supratherapeutic INRs, Bleeding

The management of elevated INRs and bleeding that occurs in patients taking vitamin K antagonists depends on the degree of INR elevation and the presence or absence of risk factors for bleeding and whether active bleeding is present or not. Management options have been published as recommendations from the ACCP (Table 69-2) and include omitting the next anticoagulant dose and giving vitamin K. Too much vitamin K should be avoided if there is no major bleeding, because it may lower the INR dramatically and, as a result, make re-anticoagulation of the patient more difficult. FFP can lower the INR to some degree but not markedly. FFP does not reverse overanticoagulation completely because the short half-life of coagulation factor VII of 4 to 6 hours would require huge doses of FFP to be given for full reversal. If complete and immediate INR reversal is needed, such as when treating a major bleeding or life-threatening event in a patient on vitamin K antagonists, a prothrombin complex concentrate (e.g., Bebulin, Profilnine) or recombinant factor VIIa (NovoSeven) should be given.

Fluctuating INRs

Some patients treated with vitamin K antagonists may, at times, have unexpected and seemingly unexplained high or low INRs, or may have significant INR fluctuations over

Table 69-2 Recommendations for Management of Elevated INRs in Patients Taking Vitamin K Antagonists

INR	Bleeding	Risk Factor for Bleeding	Intervention
<5.0	No	No/yes	Omit next VKA dose and reduce dose
5.0-9.0	No	No	Omit next VKA doses and reduce dose
5.0-9.0	No	Yes	Vitamin K, <5 mg by mouth
>9.0	No	No/yes	Vitamin K, 5-10 mg by mouth
Serious bleed at any INR	Yes	No/yes	Vitamin K, 10 mg IV + FFP or PCCs
Life-threatening bleed	Yes	No/yes	Vitamin K, 10 mg IV + PCCs. Consider recombinant VIIa

FFP, fresh frozen plasma; PCCs, prothrombin complex concentrates, VKA, vitamin K antagonist. *Modified from Ansell J, Hirsh J, Poller L, et al: The pharmacology and management of the vitamin K antagonists: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest 126(3 Suppl):204S-233S, 2004.*

time. In these situations, the following reasons for aberrant or fluctuating INRs should be considered: (1) Was the out-of-line INR a lab error? Lab errors are more common when there was significant trouble at the time of blood draw with tissue trauma or when the blood tube was not filled appropriately. (2) Has any new prescription medication that could affect protein binding or the half-life of warfarin been started or has any one been discontinued? (3) Is the patient taking any new over-the-counter medications, vitamins, herbs, homeopathic medications, or weight control pills, which may have a similar effect? (4) Is the patient taking his or her various medications at the same times as usual? (5) Have there been dietary changes that would change the patient's vitamin K intake? (6) Has the patient recently had an infection or diarrhea? (7) Is the patient noncompliant with taking the oral anticoagulant or confused about the prescribed dose to take? (8) Was the package of the oral anticoagulant outdated? (9) Does the patient have a lupus anticoagulant? (10) Has there been an unusual amount of stress, sleep deprivation, or physical activity in the days preceding the INR test? If no reason for widely fluctuating INRs can be determined, daily supplementation with low-dose vitamin K, for instance, at a dose of 150 µg/day, can lead to better INR control in some patients.

Side Effects

Bleeding is the main side effect of oral anticoagulant therapy. The risk for bleeding is highest in elderly individuals; in persons who have not had stable anticoagulant control and have a tendency to supratherapeutic INRs; in patients with comorbidities that increase the bleeding risk, such as malignancy, uncontrolled hypertension, or a pre-existing bleeding disorder; and in the first few months of anticoagulant initiation. A striking, yet rare side effect of oral and parenteral anticoagulants is that of purple toe syndrome (Fig. 69-5), a violaceous painful discoloration of the feet and sometimes the hands. The etiology is thought to be formation of cholesterol emboli, released from atherosclerotic lesions as a result of plaque rupture or as a

Figure 69-5 Purple Toe Syndrome Associated with Vitamin K Antagonist Therapy.

result of weakening of the fibrin mesh overlying atheromatous lesions. Evidence of cholesterol embolization in other skin areas can also be present, leading to livedo reticularis and renal impairment.

Periprocedural Bridging Therapy

Whether there is a need to stop oral anticoagulant therapy before a surgical or radiologic procedure depends on the bleeding risk associated with the procedure. How soon before the procedure the drug should be stopped depends on the INR that the patient has when the drug is stopped and the half-life of the drug being used. Warfarin, when

Table 69-3 Recommendations When Interrupting Warfarin Therapy for Invasive Procedures*

Risk for Clot	Preoperative	Postoperative
Low	Stop warfarin about 4 days before surgery	Prophylactic dose LMWH/UFH (if intervention causes thrombotic risk)
Intermediate	No LMWH/UFH	Restart warfarin
	Stop warfarin about 4 days before surgery	Prophylactic dose LMWH/UFH
High	Prophylactic dose LMWH/UFH	Restart warfarin
	Stop warfarin about 4 days before surgery	LMWH/UFH (no dose recommendation given)
	Full-dose LMWH/UFH 2 days before surgery	Restart warfarin

* These recommendations are all so-called grade C recommendations, i.e., very weak recommendations, where treatment alternatives may be equally reasonable.

LMWH, low-molecular-weight heparin; UFH, unfractionated heparin. *Modified from Ansell J, Hirsh J, Poller L, et al: The pharmacology and management of the vitamin K antagonists: The Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest 126(3 Suppl):204S-233S, 2004.*

targeted to keep the INR between 2 and 3, can typically be stopped 5 days before a procedure for which an INR of about 1 is required. The need for bridging therapy with a subcutaneous or intravenous anticoagulant before and after the procedure depends on the thromboembolic risk of the patient. How soon an anticoagulant can be restarted after surgery depends on the bleeding risk associated with the surgery. Some guidelines have been created by the American College of Chest Physicians (Table 69-3), but individual risk assessment of a patient and good communication between the health care provider managing the patient's anticoagulants and the surgeon is typically needed for optimal periprocedural anticoagulation planning.

Pregnancy and Anticoagulants

Prophylactic or full-therapeutic doses of anticoagulants may be indicated in the pregnant woman with (1) a strong thrombophilia but no previous thromboembolism, (2) previous thromboembolism or a mechanical heart valve, or (3) a history of recurrent early pregnancy losses or one or more late pregnancy losses as a result of thrombophilia. Warfarin can be teratogenic when taken during pregnancy weeks 6 to 12, but this risk is low; coumarin embryopathy occurs in only 0.6% of pregnancies in which women received oral vitamin K antagonists between weeks 6 and 12. However, warfarin taken at any time during pregnancy may lead to bleeding complications in the fetus. Discontinuation of warfarin and institution of LMWH or unfractionated heparin is, therefore, the anticoagulant management strategy of choice during pregnancy. The heparin can either be started as soon as pregnancy is confirmed and before week 6 of pregnancy, or before conception.

Warfarin is not detectable in the breast milk of mothers who take warfarin, but only a limited number of women taking warfarin have been studied. These data cannot exclude the passage of small amounts of warfarin into breast milk, but such doses are unlikely to cause bleeding

in the newborn. It, therefore, appears safe for the woman taking warfarin to breast-feed. There are very limited data in the medical literature on other coumarin drugs (see Table 69-1), and it is, therefore, not known, whether they are also safe. Phenindione and anisindione (see Table 69-1) do appear in breast milk. Unfractionated heparin and LMWH are not secreted in breast milk and can be safely administered to nursing mothers.

Patient Education

Treatment with anticoagulants and antiplatelet agents is associated with a significant risk for bleeding, and lack of appropriate treatment with these drugs can lead to significant morbidity and mortality. The therapy recommended and prescribed by health care providers may be optimized by having an educated patient. Patients can find information about anticoagulant drugs, as well as the diseases treated with these drugs, at websites listed in the "Additional Resources" section of this chapter.

Avoiding Treatment Errors

Of premier importance for the optimization of safety and efficacy of anticoagulant and antiplatelet agents is an accurate assessment in each patient about the indication or lack thereof for the use of anticoagulants, based on established treatment guidelines as well as the patient's individual risk factors for thromboembolism and bleeding. Treatment algorithms should be used for unfractionated heparin and oral anticoagulant management whenever possible. Patients taking oral anticoagulants should be followed by a specialized anticoagulation service or, at least, through a systematic management approach. Awareness of a patient's renal status and weight is important to avoid inappropriate LMWH and fondaparinux dosing. HIT should be considered in any patient who develops thrombocytopenia or a new thrombotic event while being treated with a heparin product.

Future Directions

More efficacious, safer, and easier to use anticoagulant agents are under development. Several promising oral agents that may not require monitoring of their anticoagulant effect and will, therefore, be less cumbersome to use and are presently being tested in phase 2 and 3 clinical trials (e.g., dabigatran, rivaroxaban, apixaban). Local delivery of anticoagulants or genes modulating anticoagulant control at sites of increased thrombogenicity, such as in diseased arteries, is a promising treatment modality that may decrease systemic bleeding problems. Much about the initiating pathophysiologic events leading to venous thrombotic disease needs to be elucidated before such local therapy can be tested in the venous vasculature. While waiting for better anticoagulants to become clinically available, patient management with the existing drugs needs to be improved by instituting coordinated anticoagulation services, promoting patient self-monitoring and self-management, and improving patient and health care provider education on the use of anticoagulant drugs.

Bleeding Disorders

Introduction

The coagulation system is based on an intricate set of checks and balances between procoagulant and anticoagulant proteins, all interacting with platelets and the vascular endothelium. The end result is protection from bleeding and inhibition of excessive thrombosis. A great deal is known about many of the proteins in this system as well as the structure and function of platelets. This knowledge enables the internist to approach bleeding disorders with diagnostic and therapeutic sophistication.

Etiology and Pathogenesis

Congenital Bleeding Disorders

Von Willebrand's Disease

Von Willebrand's Disease (vWD) is a common congenital bleeding diathesis. Both quantitative and qualitative abnormalities have been described in the von Willebrand protein, which allows platelet adherence to the endothelium and provides factor VIII stability. The most common variant of vWD is type I, which is autosomal dominant in inheritance. Patients have a quantitative decrease in vWD protein to 30% to 50% of normal. Type II variants are defined by qualitative differences in the multimeric structure of the von Willebrand protein. At least eight different type II variants have been described. They are labeled alphabetically as types IIa to IIh. Inheritance is either autosomal dominant or recessive.

Hemophilia A

Hemophilia A is the most common inherited bleeding disorder. The inheritance is X linked, so this disorder is seen almost exclusively in males. Affected individuals have reduced factor VIII levels. Patients with severe hemophilia have no detectable factor VIII activity. Those with mild hemophilia have 1% to 5% factor VIII activity (Fig. 70-1).

Acquired Bleeding Disorders

Disseminated intravascular coagulation (DIC) is a multi-system process resulting in bleeding and thrombosis in the microvasculature. DIC occurs in the setting of life-

threatening disorders, including sepsis and massive trauma, that overwhelm the clotting cascade, leading to excessive amounts of activated thrombin. This, in turn, causes fibrin deposition with activation of the lytic system and depletion of clotting factors (see Chapter 68, Fig. 68-1).

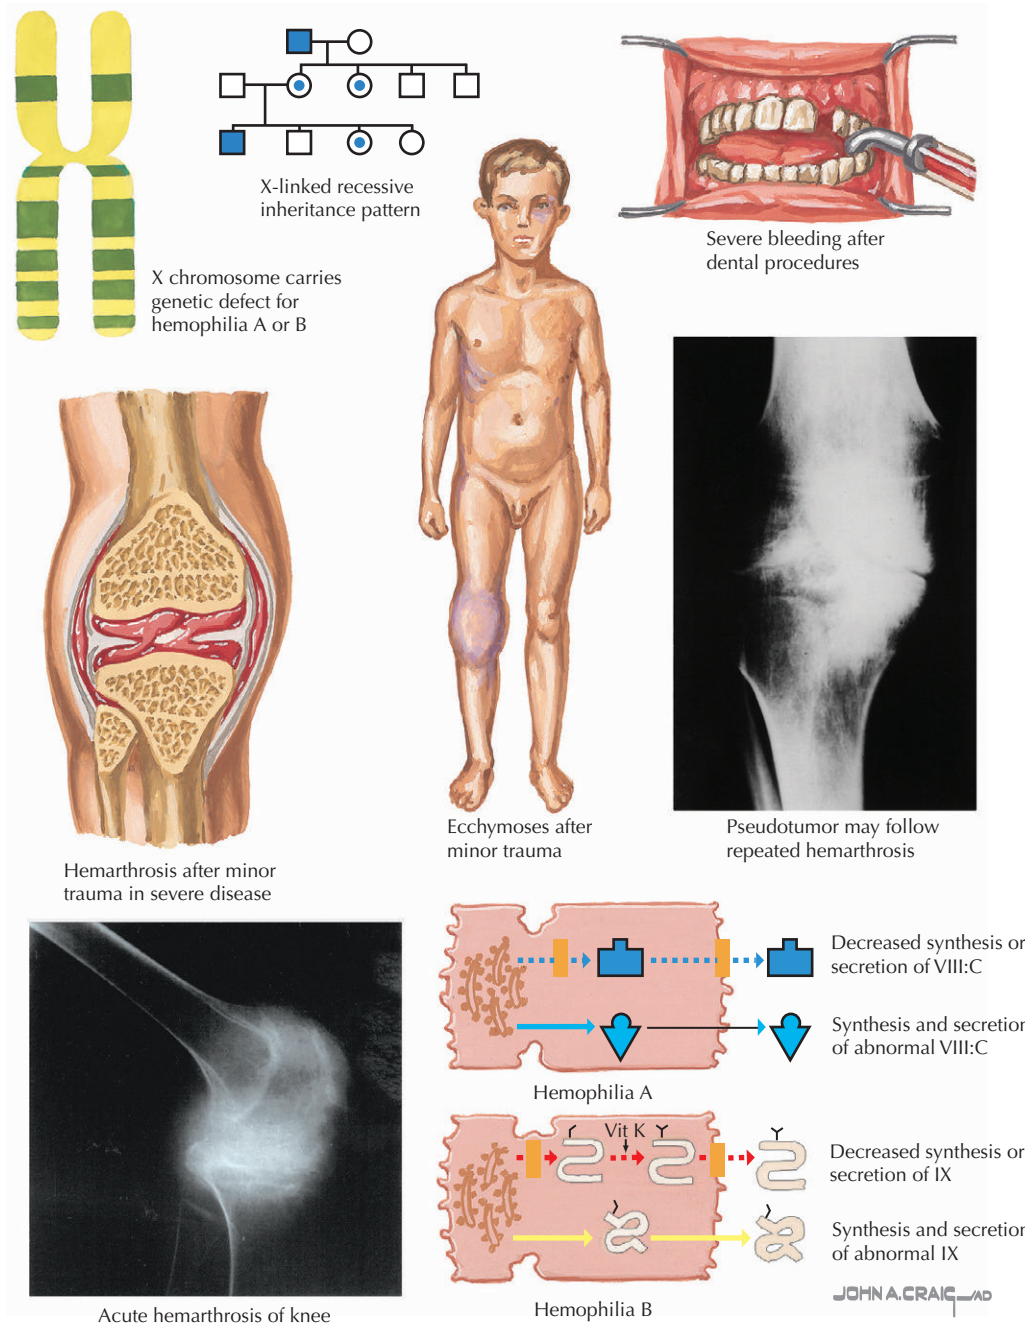

Immune thrombocytopenic purpura (ITP) is an autoimmune process in which patients generate antibodies directed to surface proteins on platelets. The antibody-coated platelets are then prematurely destroyed in the reticuloendothelial system. ITP occurs spontaneously or as a manifestation of an autoimmune disease or B-cell neoplasm.

Thrombotic thrombocytopenic purpura (TTP) is characterized by platelet clumping in the microcirculation. This results in thrombocytopenia, microangiopathic hemolytic anemia, and varying degrees of organ dysfunction, particularly in the brain and kidney.

Qualitative Disorders of Platelets

Platelets follow a multistep sequence to form a platelet plug over a site of damaged vascular endothelium. The sequence begins with platelet adherence, followed by platelet aggregation and activation. Activation is dependent in part on cyclooxygenase-induced release of intracellular granules. Once the platelet plug is formed, coagulation factors are then activated, resulting in fibrin deposition and hemostasis. Both congenital and acquired qualitative platelet disorders have been recognized. Glanzmann's thrombasthenia is a congenital disorder in which the platelets have a defect in the glycoprotein IIb/IIIa complex, altering platelet aggregation. A number of congenital storage granule disorders have been described. The most common

Figure 70-1 Hemophilia A and B.

acquired defects are seen with the use of aspirin and non-steroidal anti-inflammatory drugs (NSAIDs). Both inhibit cyclooxygenase; aspirin's effect is irreversible, whereas NSAIDs cause reversible inhibition.

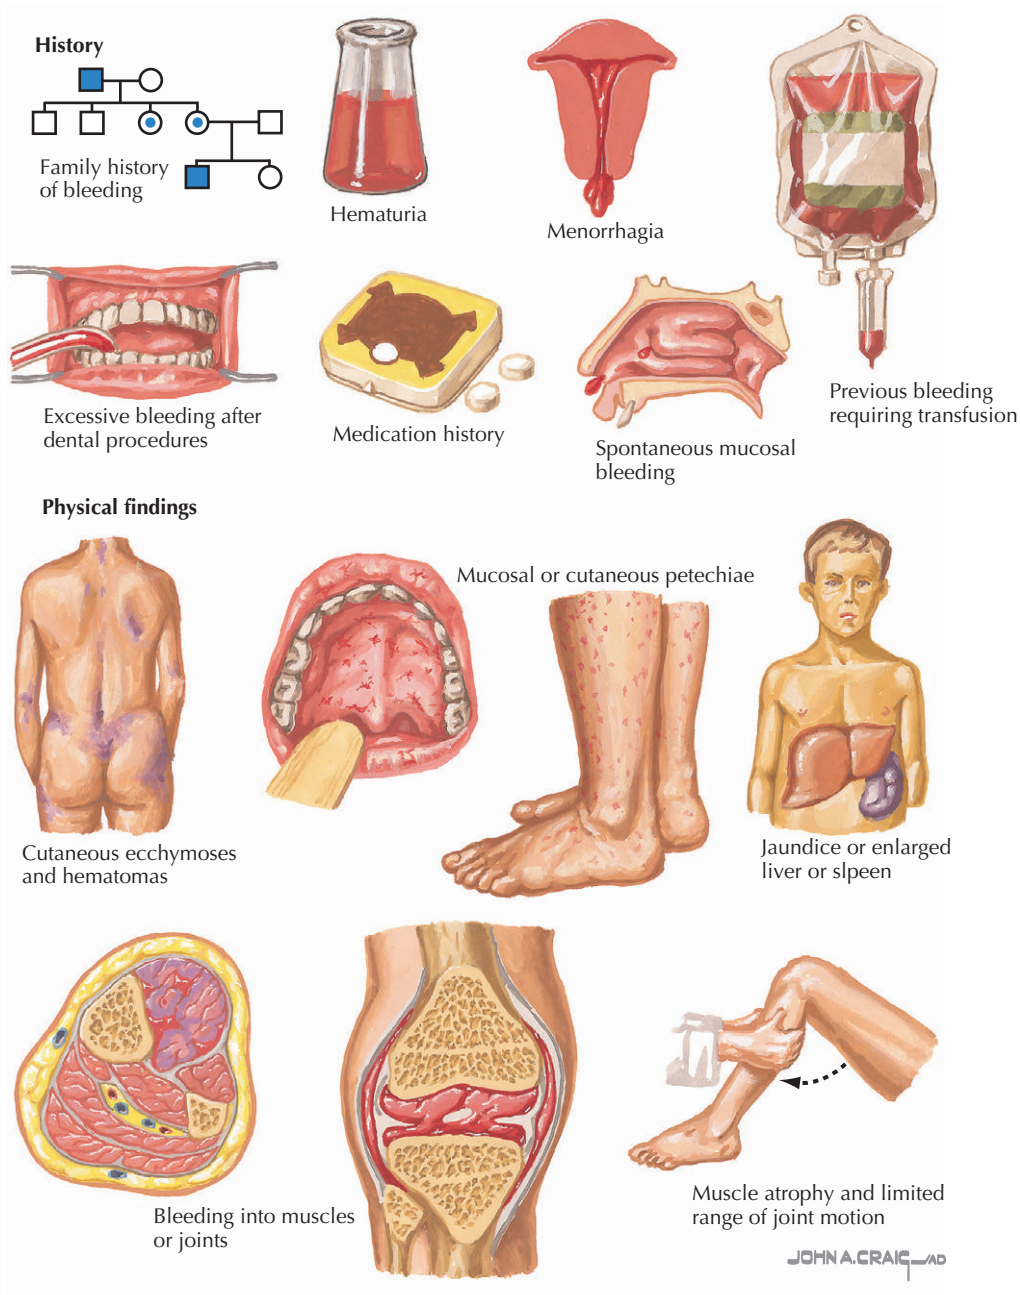

Liver Disease

The liver is the site of synthesis of most clotting proteins. In addition, activated factors are cleared from the circulation by the liver. Any disease that causes impaired liver function will lead to decreased synthesis of clotting factors

and a DIC-type picture because of the prolonged half-life of activated thrombin. The liver is also the site of vitamin K-dependent modulation of factors II, VII, IX, and X, a process that is also impaired with significant liver disease and results in decreased factor activity.

Clinical Presentation and Differential Diagnosis

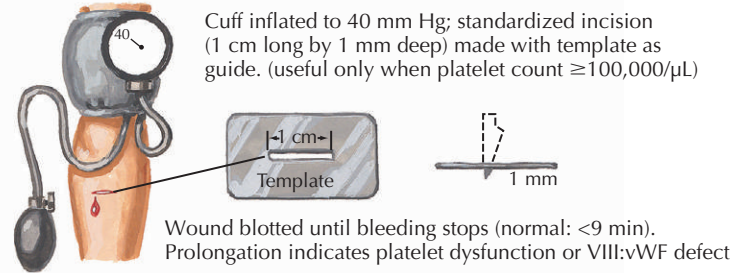

Congenital bleeding disorders may present in childhood or in adults (Fig. 70-2). Patients with hemophilia A have

Figure 70-2 Clinical Presentation of Patients with Bleeding Disorders.

bleeding beginning in infancy. As these patients mature, spontaneous hemarthroses are common. Any trauma will result in localized hemorrhage. Patients with von Willebrand's disease (vWD) usually present later in life, and most often with easy bruisability, heavy menses, or significant bleeding secondary to dental work or surgery. Hemarthroses are rare.

With acquired bleeding disorders, there are several key findings. Patients with ITP or thrombocytopenia associated with DIC usually have petechiae on the lower extremities. The lesions are small parafollicular

erythematous macules and are seen at platelet counts less than $50,000/\mu\text{L}$. Oozing from any puncture site, such as from intravenous sites, blood-drawing sites, and surgical scars, is common. TTP has been described in patients with *Escherichia coli* sepsis and in patients taking certain drugs (quinine, mitomycin C, cisplatin, gemcitabine, clopidogrel). These patients also have neurologic findings, evidence of a hemolytic anemia, and renal abnormalities. Patients with qualitative platelet disorders or liver disease generally have an increased tendency to bruise.

Figure 70-3 Hemostasis Tests.**Platelet count****Bleeding time****Prothrombin time (PT): extrinsic pathway****Activated partial thromboplastin time (aPTT): intrinsic pathway****Mixing studies: prolonged PT or aPTT**

With all bleeding problems, there is a great deal of overlap in findings, and none is pathognomonic for a particular disease process. With any of the above findings, the physician should have a low threshold to evaluate the coagulation system.

Diagnostic Approach

Several tests are readily available and will significantly narrow the diagnostic possibilities (Fig. 70-3). The prothrombin time (PT) and activated partial thromboplastin

time (aPTT) measure the activities of all clotting factors. Prolongations indicate significant factor deficiency, which is seen in hemophilia, vWD, DIC, and the coagulopathy of liver disease. The platelet count detects quantitative platelet problems (alterations in platelet number), and the bleeding time detects qualitative platelet problems (alterations in platelet function). Table 70-1 shows specific differences in these tests for the common coagulopathies.

Following the results of screening tests, more specific assays can be done. Tests are available for factor VIII and von Willebrand protein. Measurement of other factors and

Table 70-1 Diagnostic Studies in Common Coagulations

Disorder	PT	aPTT	Platelet Count	Bleeding Time
Hemophilia A	Normal	Prolonged	Normal	Normal
vWD	Normal	Prolonged	Normal	Prolonged
DIC	Prolonged	Prolonged	Decreased or normal	Normal

5. Fever

fibrinogen can be helpful for the diagnosis of DIC. The D-dimer assay, which measures lytic system activity, is often used in DIC. The diagnosis of ITP is usually a diagnosis of exclusion. Assays for platelet antibodies are available but have poor specificity (see Fig. 70-3). The diagnosis of TTP is dependent on a pentad of findings shown in Box 70-1.

Management and Therapy**Congenital Bleeding Disorders: Optimum Treatment***von Willebrand's Disease*

Type I disease can be treated with desmopressin (DDAVP) for mild bleeding and preoperative prophylaxis. The drug can be administered intravenously or subcutaneously and will increase levels of von Willebrand protein in several hours. For more significant bleeding, purified concentrates containing von Willebrand protein should be administered intravenously. Type II disease is treated similarly, except the IIb variant, in which DDAVP is contraindicated.

Hemophilia A

The treatment of choice for significant bleeding is administration of recombinant factor VIII intravenously. The target factor VIII level depends on the severity of bleeding. For isolated hemarthroses, in which the target level is 30% to 50%, patients can be taught to self-administer factor VIII.

With treatment, inhibitors to factor VIII develop in 10% to 15% of patients. A variety of approaches can be

used in this situation, depending on the severity of the bleeding and the level of the inhibitor.

Acquired Bleeding Disorders: Optimum Treatment*Disseminated Intravascular Coagulation*

In patients with DIC, the primary focus should be to treat the underlying condition causing the coagulopathy. Until this is done, there will be no substantial improvement. This usually takes hours to several days. In the interim, fresh frozen plasma and cryoprecipitate can be given to replace clotting factors and fibrinogen. Platelets are also given if the platelet count is less than 50,000/ μ L with active bleeding. If there is no bleeding related to a surgical procedure, a lower platelet count can be tolerated without transfusion. The use of heparin is controversial because of its bleeding risk. In general, it is given if treatment of the underlying condition and replacement therapy do not appear to be working.

Immune Thrombocytopenic Purpura

At presentation, most patients are treated with prednisone (1 mg/kg body weight per day), which will normalize the platelet count in 3 to 7 days. The process is chronic, and an attempt at tapering steroids will often result in a decrease in the platelet count. Patients then must undergo splenectomy, which produces a complete response in 70% to 80% of cases. Intravenous immunoglobulin (IVIg) is an alternative to prednisone that improves the platelet count in days. Whether there is any advantage to IVIg compared with prednisone is not clear, nor is it clear that the combination of prednisone and immunoglobulin is superior to either alone. For patients who continue with significant thrombocytopenia after splenectomy, there are a number of options, including chemotherapy, high-dose pulse steroids, or chronic daily steroids. Responses are quite individualized.

Thrombotic Thrombocytopenic Purpura

TTP is a life-threatening emergency with a mortality rate of greater than 90%, if not treated. The mainstay of treat-

ment is exchange of the patient's entire plasma volume with normal donor plasma. Corticosteroids are also used in doses similar to the treatment of ITP.

Liver Disease: Optimum Treatment

Because many patients have irreversible liver pathology, the coagulopathy is usually a chronic process. Repeated doses of vitamin K may be helpful. Otherwise, patients are treated for acute bleeding with fresh frozen plasma, which will transiently raise factor levels.

Avoiding Treatment Errors

Patients with type IIb vWD should not receive DDAVP. This may cause aggregation of platelets and thrombocytopenia. Platelet transfusions are contraindicated in TTP. There are case reports of acute worsening and even death after platelets were given to these patients.

Future Directions

Patients with newly diagnosed ITP may respond to rituximab. In TTP, deficiency of a metalloproteinase that cleaves von Willebrand factor has been observed in patients with recurrent TTP. Protein C infusions have been shown to be effective in the purpura fulminans variant of DIC.

Anemias

Introduction

Anemia, a hemoglobin concentration below the normal range for a standard complete blood count (CBC), is a common finding in internal medicine patients. Most anemias have a specific etiology. Defining the cause is critical for determining therapy and for uncovering other significant associated disease processes. Although these anemias are familiar to most clinicians, understanding them continues to be a dynamic process because new information is always emerging.

Etiology and Pathogenesis, Differential Diagnosis

Iron Deficiency

This common anemia should be considered in any patient presenting with a microcytic anemia and a low or normal reticulocyte count. Because adults have several grams of iron in circulating red blood cells and another gram in storage iron, the diagnosis of iron deficiency requires searching for a source of blood loss. The sequence of findings in iron deficiency is loss of storage iron, followed by development of anemia, and finally by development of microcytosis.

Thalassemia

This disorder is a common anemia in certain areas of the world, including the Mediterranean, India, Southeast Asia, and Africa. A high prevalence has also been observed in Western countries in individuals descended from those regions where thalassemia is common. At a molecular level, there are hundreds of globin abnormalities leading to either α -chain underproduction (α -thalassemia) or β -chain underproduction (β -thalassemia). The phenotype is similar. The underproduction of either α or β chains results in a microcytic red blood cell. There is also hemolysis because the imbalance results in excess globin chains, which are oxidized and precipitate on the surface of the red blood cell, resulting in premature red blood cell removal in the spleen. The bone marrow partially compensates by increasing the number of reticulocytes.

Vitamin B₁₂ and Folate Deficiency

The folate metabolic pathway is responsible for thymidine synthesis. Thymidine is then incorporated into DNA. Vitamin B₁₂ is a cofactor in this pathway. Vegetables and fruits are rich in folates, but vitamin B₁₂ is only found in foods from animals. The absorption of folate occurs in a straightforward pathway in the jejunum. Vitamin B₁₂ absorption is more complex, requiring intrinsic factor production in the stomach, pancreatic secretion, and then passage through the mucosa of the terminal ileum.

The hematologic findings in folate and vitamin B₁₂ deficiency are identical. Because nuclear maturation is arrested, red blood cells are macrocytic. Reticulocytes are low or normal. The folate–vitamin B₁₂ pathway is also present in neutrophils and platelets, so deficiencies can result in reductions in all three cell lines. Neutrophils are often hypersegmented.

Vitamin B₁₂ deficiency can also lead to neurologic findings as a consequence of demyelination. These include peripheral neuropathy with decreased proprioception, optic atrophy, and dementia. These abnormalities may precede hematologic changes and may not improve after B₁₂ replacement when recognized late in the disease course.

Anemia of Chronic Disease

A normocytic anemia with a suboptimal reticulocyte response may develop in patients with a variety of chronic inflammatory diseases, infections, or neoplastic diseases. Because a precise cause has not been found, this anemia is

called the *anemia of chronic disease* and is the most common cause of anemia in hospitalized patients. One theory is that elevated levels of cytokines induce blockage of the release of storage iron into circulating iron. Another theory is that elevated levels of cytokines result in decreased endogenous erythropoietin levels. There are no specific diagnostic tests, so the diagnosis is made by careful clinical observation and by excluding other causes of anemia.

Sickle Cell Anemia

Sickle cell anemia is an inherited hemoglobinopathy secondary to a single amino acid substitution in the β -globin chain. In the homozygous state, sickle hemoglobin becomes insoluble when deoxygenated. This results in a loss of red

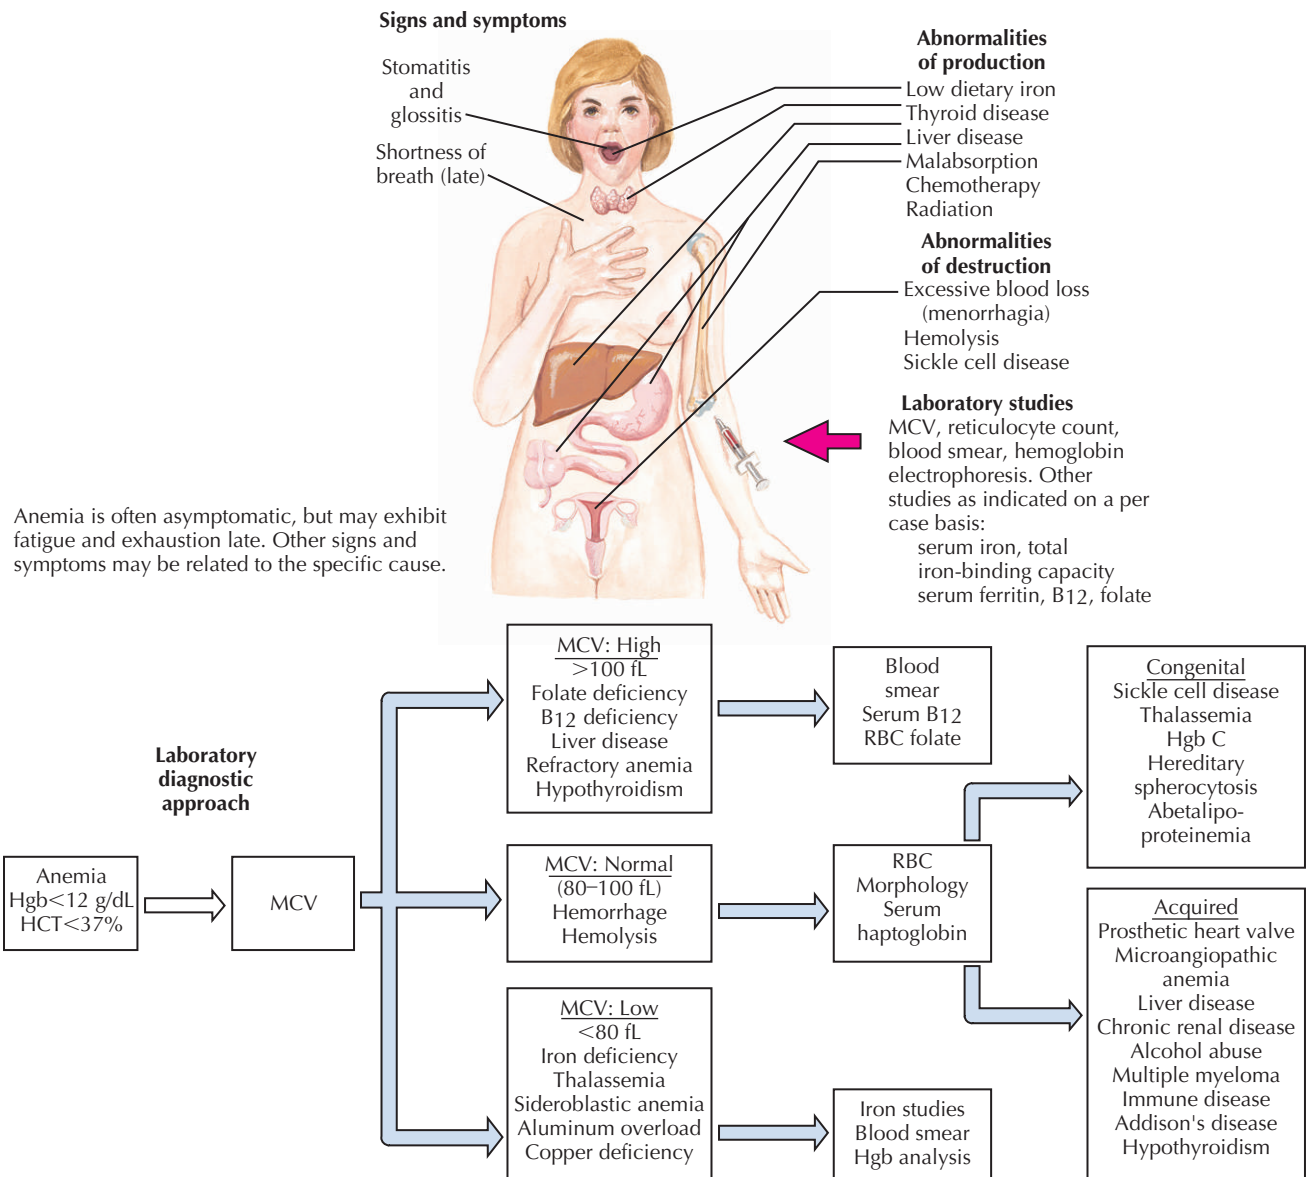

cell deformity, which in turn causes vaso-occlusion in the microcirculation and a shortened life span of these erythrocytes. The prevalence for the gene that encodes hemoglobin S is 8% in the African American population. There are about 50,000 patients with sickle cell anemia in the United States. There are also sickle variants that combine hemoglobin S with another abnormal hemoglobin such as sickle thalassemia (hemoglobin S- β -thalassemia) or hemoglobin C (hemoglobin SC disease). These variants have a similar phenotype to sickle cell anemia but are less severe.

Clinical Presentation

Patients with anemia may or may not be symptomatic (Fig. 71-1). Key factors include the degree of anemia and how

Figure 71-1 Anemia.

Box 71-1 Crises in Sickle Cell Anemia

Vaso-occlusive
Aplastic
Splenic sequestration
Hyperhemolytic

rapidly it develops. In general, symptoms develop at a hemoglobin level of 8.0 to 9.0 g/dL, when the anemia develops over hours to a few days. A slower evolving process will allow the patient to compensate hemodynamically, so patients with hemoglobin values below 7.0 g/dL may have few symptoms. All patients will have symptoms at a hemoglobin level of 5.0 to 6.0 g/dL.

Early symptoms of anemia include fatigue and dyspnea on exertion. As the anemia worsens, patients will experience organ ischemia, often presenting with angina pectoris or focal neurologic findings. Shock is common with acute blood loss. In the setting of ischemic symptoms or shock, patients should undergo an emergency transfusion before a cause for the anemia is investigated.

Almost all sickle cell patients are diagnosed in childhood. In adult patients, the recognition of acute and chronic complications is the major challenge for the internist. An acute vaso-occlusive crisis is the most common acute presentation. Patients present with pain in the back and extremities, anywhere the small-sized arterioles become occluded. The average number of crises per year per patient is two, and the average duration of each crisis is 7 days. Hypoplastic or aplastic crises are the next most common presentation. Patients present with signs and symptoms of worsening anemia. This is due to parvovirus B19 infection of red cell precursors, which causes reticulocytopenia. Other types of crises are listed in Box 71-1.

Sickle cell patients have an average hemoglobin level of 7 to 8 g/dL. This degree of anemia plus chronic vaso-occlusion leads to widespread organ damage. A dilated cardiomyopathy is found in 50% of adults. Pulmonary hypertension occurs in 30% and carries a mortality rate of 50%. All adult patients are asplenic, resulting in susceptibility to infection with encapsulated organisms. Pregnancy complications occur more frequently than in the general population, and cholelithiasis with cholecystitis is common. Additional complications are listed in Box 71-2.

Diagnostic Approach

Because there are many causes of anemia, a selective diagnostic approach is recommended. A prudent place to begin is to categorize the anemia based on the mean corpuscular volume (MCV) of the patient's red blood cells and the reticulocyte count (see Figs. 71-1 and 71-2). Dividing the red blood cells into microcytic (MCV <80 μ L), normocytic (80 to 100 μ L), or macrocytic (>100 μ L) will greatly narrow the diagnostic possibilities. The reticulocyte count gives

Box 71-2 Complications of Sickle Cell Anemia

Cholelithiasis
Acute chest syndrome
Hematuria
Priapism
Osteomyelitis
Stroke
Pulmonary hypertension
Spontaneous abortion

additional information regarding the status of the bone marrow. If the bone marrow's red blood cell productive mechanism is intact, anemia will result in an increased production of reticulocytes. A low or even normal reticulocyte count in the anemic patient (3% or less) indicates that the marrow is not responding appropriately, and a search for a marrow abnormality will define the cause of the anemia. A word of caution about interpreting reticulocyte counts is warranted. They are usually reported as a percentage of the red blood cells, a relative value. To convert this to an absolute value, the patient's percentage of reticulocytes should be multiplied by the ratio of the patient's hematocrit and a normal hematocrit value (ratio = the patient's hematocrit divided by a normal hematocrit value).

Figure 71-2 illustrates how the MCV and reticulocyte count can be used to categorize anemias. After the anemia has been categorized by MCV and the reticulocyte count, more specific tests can be done.

Iron Deficiency

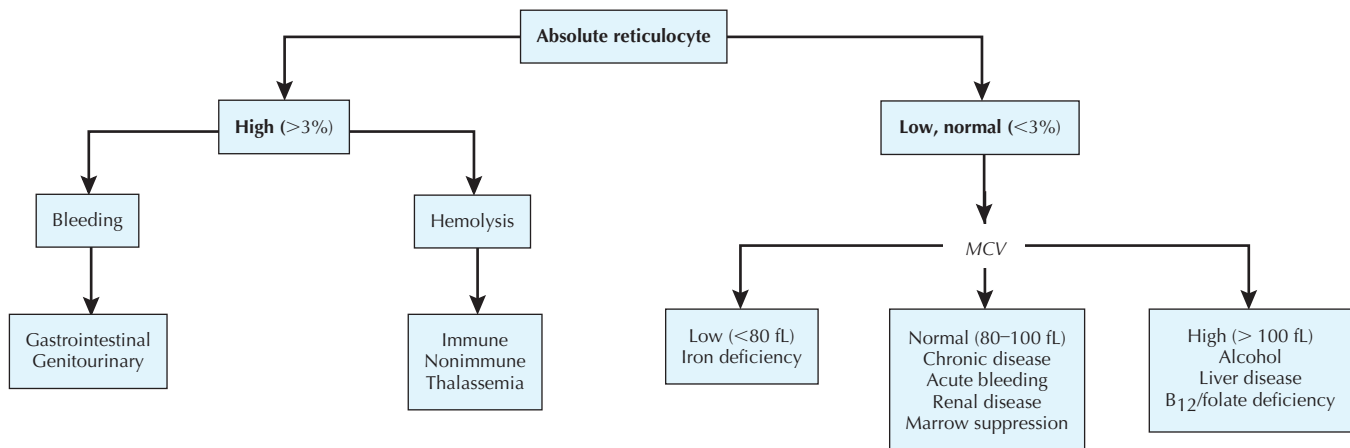

A number of diagnostic tests are useful for diagnosing iron deficiency. Serum markers include serum iron, total iron binding capacity, and ferritin. A low serum ferritin (<18 μ g/L) has a positive likelihood ratio over 40, and a serum ferritin of 19 to 45 μ g/L has a positive likelihood ratio of about 3. A transferrin saturation (Fe/total iron binding capacity) of 0.05 has a positive likelihood ratio of 16.5. However, a transferrin saturation of 0.06 to 0.08 only has a positive likelihood ratio of 1.43. The gold standard for iron deficiency is a Prussian blue stain of the bone marrow, indicating the presence or absence of iron. Because bone marrow aspiration is an invasive procedure, the morbidity must be considered on an individual basis. When the diagnosis remains unclear, a trial of iron can be diagnostic. The response will take weeks, and patient compliance is necessary. The diagnostic approach, whether serologic markers, bone marrow aspiration, or a trial of iron, depends on the severity of illness.

Thalassemia

Because the erythrocytes underproduce hemoglobin in individuals with thalassemia, microcytosis is universally

Figure 71-2 Categorizing Anemia Based on Reticulocyte Count.

MCV, mean corpuscular volume.

present. This underproduction also results in hemolysis. The combination of microcytosis and increased reticulocytes seen in thalassemia is unique and thus can be used to make the diagnosis. Further information can be obtained from a hemoglobin electrophoresis, which in β -thalassemia shows increased hemoglobin A₂ and increased hemoglobin F.

Vitamin B₁₂ and Folate Deficiency

The diagnosis of folate deficiency is made when there is a macrocytic anemia with or without pancytopenia in clinical settings that could lead to folate deficiency. These settings include pregnancy, poor nutrition, hemolysis, and malabsorption. A serum folate assay may be helpful, but it should be noted that levels increase quickly with proper diet. A red blood cell folate assay that does not change with refeeding can confirm the diagnosis. The diagnosis of vitamin B₁₂ deficiency is usually made by measuring serum vitamin B₁₂. Current assays have high sensitivity but are only moderately specific. Assays of homocysteine and methylmalonic acid are helpful in that they both increase with vitamin B₁₂ deficiency. The Schilling test, in which a patient ingests radiolabeled vitamin B₁₂ with or without intrinsic factor, is rarely done because of the difficulty in obtaining an adequate urine collection and the reduced sensitivity of the test in early vitamin B₁₂ deficiency.

Sickle Cell Anemia

The findings of a normochromic, normocytic anemia with reticulocytosis and sickle forms on peripheral smear is diagnostic of sickle cell disease. Microcytosis suggests sickle thalassemia. A person with sickle cell trait has no abnormalities on physical examination or of the CBC. The gold standard for diagnosis is hemoglobin electrophoresis. Unless there is suspicion of a variant phenotype, electrophoresis is not necessary.

Management and Therapy

Optimum Treatment

Iron Deficiency

Patients need sufficient iron to restore erythrocyte as well as storage iron. The standard treatment is ferrous sulfate, 325 mg orally 3 times a day for 6 months. Other iron preparations are also available and equally efficacious, with the exception of enteric-coated products. These reduce gastrointestinal toxicity but have poor absorption. Iron can also be given intravenously if a patient cannot tolerate oral iron. A single total replacement dose is given. This carries a small risk for anaphylaxis. Transfusions also provide intravenous iron, 250 mg per unit of packed red blood cells.

Thalassemia

Patients with heterozygous α - or β -thalassemia have a mild hemolytic anemia. Folic acid daily (1 mg orally) will more than meet the increased demands resulting from the increased red blood cell turnover. A severe anemia develops in patients with homozygous thalassemia, which requires transfusions, usually beginning in childhood.

Vitamin B₁₂ and Folate Deficiency

The most common cause of vitamin B₁₂ deficiency is pernicious anemia, in which loss of intrinsic factor does not allow vitamin B₁₂ absorption; vitamin B₁₂ must be given intramuscularly. At diagnosis, 1 mg of vitamin B₁₂ is given weekly for 4 weeks followed by monthly injections. The same treatment is applicable for other causes of vitamin B₁₂ deficiency such as gastric achlorhydria from protein pump inhibitors and diseases of the terminal ileum. The treatment of all causes of folate deficiency is daily oral folate, 1 mg. If the patient cannot take oral folate, it can be given intravenously.

Anemia of Chronic Disease

If improvement of the underlying condition occurs, an improvement in the anemia will follow. This is not always the case in conditions that are chronic. Measurement of the endogenous erythropoietin level is recommended. If the level is less than 500 mU/mL, patients are candidates for recombinant human erythropoietin, given weekly by subcutaneous injection. An increase in the hemoglobin is usually seen in 4 to 8 weeks. Administration is maintained as long as the chronic condition is present.

Sickle Cell Anemia

The management of an acute vaso-occlusive crisis includes pain relief, hydration, and treatment of any precipitating infection. Narcotics are often required for pain control. Management of chronic complications such as pulmonary hypertension and cardiomyopathy are the same for the sickle cell patient and any other patient with these medical problems. Adult patients are given hydroxyurea daily, which reduces sickling by increasing hemoglobin F. There is no role for ongoing transfusions in sickle cell patients. Exchange transfusions are done for life-threatening complications such as acute chest syndrome, stroke, and acute hepatic failure.

Avoiding Treatment Errors

A diagnosis of iron deficiency in an adult requires that a source of blood loss be found. In premenopausal females, menstruation is the most likely cause. In postmenopausal females and men, a bleeding site in the gastrointestinal tract should be thoroughly evaluated. For all causes of

vitamin B₁₂ deficiency the treatment must be lifelong because storage B₁₂ will only suffice for several months.

Future Directions

Vasodilators and antiproliferative agents have been tried in sickle cell patients with pulmonary hypertension. Recent studies have shown that sildenafil can reduce pulmonary arterial pressure and improve exercise tolerance. Two oral iron chelators, deferiprone and deferasirox, have been used in patients with sickle cell anemia, β -thalassemia, and the anemia of chronic disease. These agents appear to have similar efficacy and toxicity to deferoxamine. Further trials are ongoing.

The authors present a definitive review of the causes and treatments of anemia.

Bone Marrow Failure States

Introduction

Bone marrow failure refers to any condition in which peripheral blood cell counts are low because of failure of the marrow to produce adequate numbers of circulating cells. Marrow failure is due to many different causes but is broadly classified as aplastic anemia (fatty bone marrow), myelodysplasia (disordered hematopoiesis), and agnogenic myeloid metaplasia and myelofibrosis (fibrosis).

Despite different etiologies, the signs and symptoms of all bone marrow failure syndromes are similar (Fig. 72-1). Patients with anemia may present with fatigue, dyspnea, or pallor. Thrombocytopenia can lead to petechiae, bruising, or bleeding. Infections are the hallmark of neutropenia. Most deaths are due to complications of bleeding, infection, transfusion-associated complications such as iron overload, or progression to acute leukemia.

Aplastic Anemias

Etiology and Pathogenesis

Aplastic anemia is an acquired or inherited disorder with multiple- or single-lineage cytopenia. Although adults are more likely to have acquired aplastic anemia, some congenital forms (Fanconi's anemia, dyskeratosis congenita) may not be diagnosed until adulthood because up to half of affected people may not have typical physical anomalies.

Most cases of aplastic anemia are idiopathic, but it can also occur secondary to exposure to radiation, chemicals, drugs, infections, or immunologic diseases (Box 72-1).

Clinical Presentation

Patients usually present with a history of infection, bleeding, or symptomatic anemia. There is a bimodal age distribution with peaks at 20 years of age and again in the fifth decade.

Differential Diagnosis

The differential diagnosis for cytopenia is very broad. During initial workup, it is important to rule out reversible

causes (drugs, infection, and thymoma). Testing for acquired causes such as paroxysmal nocturnal hemoglobinuria (PNH) is also important because of a higher risk for progression to acute leukemia and the possible need to change treatment decisions. If clinically indicated, diseases such as cirrhosis, cancer, systemic lupus erythematosus, and tuberculosis should be considered.

Diagnostic Approach

Examination of the peripheral blood smear and bone marrow biopsy specimens is required to diagnose aplastic anemia. The blood smear shows few abnormalities except a decrease in the numbers of white blood cells, red blood cells, and platelets. Examination of the bone marrow specimen reveals a hypocellular marrow that is replaced by variable amounts of fat. Other diagnostic tests include cytogenetic analysis, which is usually normal; flow cytometry to look for the coexpression of the CD55/59 antigens (diagnostic of PNH); and testing for antibodies for parvovirus. A chest x-ray should be performed to screen for thymoma, and a subsequent computed tomography scan of the neck and chest is performed if indicated.

Figure 72-1 Bone Marrow Failure: Clinical Presentation.

Symptoms of anemia (pallor, dyspnea, and tiredness) are common to **aplastic anemias**, **myelodysplasia** (when it affects the red cell line), **agnogenic myeloid metaplasia**, and **myelofibrosis**

Examination of peripheral blood smear:
Aplastic anemia: Decrease in overall number of platelets, white and red cells

Myelodysplasia: Anisocytosis is common with both microcytic and macrocytic red blood cells present in most cases

Agnogenic myeloid metaplasia and myelofibrosis: Immature granulocytes, nucleated red cells, and teardrop-shaped red cells

Hepatomegaly routinely present in the **agnogenic myeloid metaplasia syndromes**

Replacement of the bone marrow by fatty tissue is seen in **aplastic anemia**. **Myelofibrosis** is characterized by the presence of diffuse fibrotic tissue replacing the bone marrow

Peripheral edema is another sign seen in patients with **agnogenic myeloid metaplasia** and **myelofibrosis**

Patients with **agnogenic myeloid metaplasia** present with night sweats; low-grade fever; digestive symptoms such as early satiety and diarrhea; marked splenomegaly

Ecchymoses and petechiae are common findings in those conditions that affect platelet production, such as **aplastic anemia**, and **myelodysplasia**

Examination of the bone marrow smear:
Myelodysplasia: Most marrow biopsies are hypercellular, and abnormal cytogenetics are important prognostic markers found in 50% of these patients

Agnogenic myeloid metaplasia and myelofibrosis: Fibroblasts, reactive myelofibrosis, dysplastic-megakaryocyte hyperplasia, osteosclerosis, and dilation of marrow sinusoids with intravascular hematopoiesis

Histopathology of normal and abnormal marrow states

Normocellular marrow

Hypercellular marrow

Hypocellular marrow

Management and Therapy

Management involves a combination of supportive care and immunosuppressive therapy and, for selected individuals, bone marrow transplantation (BMT). Patients commonly need medical support with antibiotics and blood transfusions. Blood products should be depleted of white blood cells before infusion to reduce the risk for alloimmunization. Cytokines such as granulocyte colony-stimulating factor (G-CSF), granulocyte-macrophage colony-stimulat-

ing factor, and erythropoietin may be helpful in patients with recurrent infections or profound anemia.

Immunosuppressive therapy with cyclosporine and antithymocyte globulin (ATG) is frequently used and has an overall response rate of about 70%. Response to immunosuppressive therapy is correlated with long-term survival (Box 72-2). However, partial responses with late relapses of disease or development of secondary malignancies, including myelodysplasia and acute leukemia, are frequent.

Box 72-1 Classification of Aplastic Anemias and Single Cytopenias**Causes of Aplastic Anemia****Acquired**

Radiation
 Drugs and chemicals
 Cytotoxic agents, benzene
 Idiosyncratic reactions: chloramphenicol, nonsteroidal anti-inflammatory drugs, antiepileptic drugs, gold, other drugs and chemicals

Viruses

Epstein-Barr virus (infectious mononucleosis)
 Hepatitis (non-A, non-B, non-C hepatitis)
 Human immunodeficiency virus (HIV)
 Parvovirus

Immune Diseases

Eosinophilic fasciitis
 Hypoimmunoglobulinemia
 Thymoma and thymic carcinoma
 Graft-versus-host disease after transplantation or blood transfusion
 Paroxysmal nocturnal hemoglobinuria
 Pregnancy
 Idiopathic—the most frequent diagnosis

Inherited

Fanconi's anemia
 Dyskeratosis congenita
 Schwachman-Diamond syndrome
 Reticular dysgenesis
 Amegakaryocytic thrombocytopenia
 Familial aplastic anemias
 Nonhematologic syndromes (Down's, Dubovitz's, Seckel's)

Causes of Cytopenias**Acquired**

Anemias
 Pure red blood cell aplasia
 Idiopathic
 Thymoma

Allogeneic transplantation is generally used as initial therapy for patients younger than 40 years who have a matched sibling donor or for other patients after failure of immunosuppressive therapy. Transplant-related mortality and morbidity are significant, however, and increase dramatically in patients older than 40 years, those with an unrelated donor, and those with multiple prior transfusions. Despite these risks, allogeneic transplantation offers a benefit over immunosuppressive therapy because the risk for disease relapse or progression to acute leukemia or PNH is much smaller in this group. These clonal diseases develop in 15% to 20% of patients within 10 years after immunosuppressive therapy but are rare after allogeneic transplantation.

Optimum Treatment

Treatment decisions are influenced by severity of disease and patient age. Patients with severe (absolute neutrophil count [ANC] = $0.2-0.5 \times 10^9/L$) and very severe (ANC $<0.2 \times 10^9/L$) aplastic anemia should be considered for immunosuppressive therapy or, if they are younger than 40 years with a matched sibling donor, for BMT. Patients with nonsevere aplastic anemia (ANC $>0.5 \times 10^9/L$), those older than 40 years, and those lacking a matched related sibling donor should be treated with supportive care (growth factors, transfusions) and immunosuppression.

Myelodysplasia**Etiology and Pathogenesis**

Myelodysplasia is a clonal disorder of hematopoietic progenitor cells, which results in ineffective hematopoiesis. The marrow is usually hypercellular, but stem cells are unable to differentiate into mature cells that leave the marrow cavity and function normally in the peripheral blood. Myelodysplastic syndromes are classified into five categories (Table 72-1). Myelodysplasia is generally an

Table 72-1 World Health Organization Criteria for Myelodysplastic Syndromes

Syndrome	Cytopenia	Dysplasia in Bone Marrow	Ringed Sideroblasts	Blasts Peripheral Blood	Blasts Bone Marrow	Auer Rods
Refractory anemia	Anemia	Erythroid	<15%	No	<5%	No
Refractory anemia with ringed sideroblasts	Anemia	Erythroid	≥15%	No	<5%	No
Refractory cytopenia with multilineage dysplasia	Bi- or pancytopenia; monocytes <1000/μL	≥10% in two or more myeloid cell lines	<15%	Rare	<5%	No
Refractory cytopenia with multilineage dysplasia and ringed sideroblasts	Bi- or pancytopenia; monocytes <1000/μL	≥10% in two or more cell lines	≥15%	Rare	<5%	No
Refractory anemia with excess blasts-1	Cytopenia; monocytes <1000/μL	Single- or multiple-lineage dysplasia		<5%	5%-9%	No
Refractory anemia with excess blasts-2	Cytopenia; monocytes <1000/μL	Single- or multiple-lineage dysplasia		5%-19%	10%-19%	±
Myelodysplastic syndrome (MDS), unclassified	Cytopenia	Dysplasia in granulocytes or megakaryocytes		Rare	<5%	No
MDS with 5q deletion (5q-syndrome)	Anemia; normal or increased platelets	Megakaryocytes normal or increased with hypolobated nuclei		<5%	<5%	No

idiopathic acquired process, but it has been associated with exposure to chemicals (solvents, pesticides), chemotherapy, and radiation therapy.

Clinical Presentation

As with all bone marrow failure syndromes, presentation depends on which cell line is primarily affected (see Fig. 72-1). Patients can present with fatigue, dyspnea, bleeding, petechiae, or recurrent infection; asymptomatic patients may be diagnosed after routine blood work. Although initial cytopenia may be mild, progressive pancytopenia usually occurs over several years.

Differential Diagnosis

The differential diagnosis of pancytopenia in myelodysplastic syndrome (MDS) patients includes hypersplenism, aplastic anemia, congenital causes, PNH, viral marrow suppression, marrow infiltration, and anemia of chronic disease. Dysplastic changes in the bone marrow can also be caused by vitamin deficiency (B₁₂, folate), drugs (antibiotics, diphenylhydantoin, and chemotherapy), ethanol, benzene, lead, and viral infections (HIV).

Diagnostic Approach

Diagnosis requires examination of the peripheral blood smear and the bone marrow biopsy specimen. The peripheral blood smear may show macrocytic red blood cells, hypogranular neutrophils (pseudo-Pelger-Huët anomaly), and giant platelets. Bone marrow evaluation shows normal or increased cellularity, megaloblastic red blood cell precursors, ringed sideroblasts, and immature myeloid cells, often with an increase in myeloblasts.

Cytogenetic analysis is important for determining the biology and prognosis of the disease. Half of all cases of myelodysplasia include a cytogenetic abnormality. Complex abnormalities are associated with an aggressive course and rapid progression to acute leukemia. However, those with an isolated deletion of chromosome 5 (5q-syndrome) have a more benign course that includes a tendency to develop an isolated anemia without other cell lines being involved; the median survival of patients with 5q-syndrome is longer than 5 years, and only 25% experience progression to acute leukemia (Tables 72-2 and 72-3).

Management and Therapy

Supportive care includes the administration of hematopoietic cytokines and growth factors, especially the

Table 72-2 International Prognostic Scoring System for Myelodysplastic Syndromes

Survival and Acute Myeloid Leukemia Evolution Score Value					
Prognostic variables	0	0.5	1.0	1.5	2.0
Marrow blasts (%)	<5	5-10	—	11-20	21-30
Karyotype	Good	Intermediate	Poor	—	—
Cytopenia	0-1	2-3	—	—	—

Karyotypes: good = normal, -Y, del(5q), del(20q); poor = complex (>3 abnormalities) or chromosome 7 anomalies; intermediate = other abnormalities. Cytopenias: neutrophils <1800/ μ L, platelets <100,000/ μ L, hemoglobin <10 g/dL.

Modified from Greenberg P: *Aplastic anemia*. In Hoffman R, Benz EJ Jr, Shattil SJ, et al (eds): *Hematology: Basic Principles and Practice*, 3rd ed. New York, Churchill Livingstone, 2000, p 298.

Table 72-3 Survival by International Prognostic Scoring System

Risk Category	Combined Score	Median Survival (yr)
Low	0	5.7
Intermediate		
1	0.5-1.0	3.5
2	1.5-2.0	1.2
High	\geq 2.5	0.4

Note: Median age at diagnosis is the seventh decade, with a 3 : 2 proportion favoring men. Many patients progress to acute myeloid leukemia (AML). This can range from 5% transformation in refractory anemia with ringed sideroblasts (median survival, 73 months) to 40% to 50% in refractory anemia with excess blasts (median survival, 12 months) and refractory anemia with excess blasts in transformation (median survival, 5 months), respectively. AML following evolution of myelodysplastic syndrome (MDS) is an especially aggressive form of leukemia that is difficult to treat and is fatal in 90% of the one third to one half of MDS patients in whom it develops. Reprinted with permission from Heaney ML, Golde DW: *Myelodysplasia*. *N Engl J Med* 340:1651, 1999.

combination of erythropoietin and G-CSF. Patients with less than 20% blasts in their marrow can be given a trial of 5-azacytidine or decitabine to induce differentiation and maturation of the abnormal cells. Lenalidomide warrants consideration in patients with a 5q deletion because complete cytogenetic responses with decreased splenomegaly and transfusion requirements have been seen with this therapy. Other management options include chemotherapy and stem cell transplantation. Immunomodulation may be promising. In a pilot study of 25 patients, 11 patients, most of whom had the HLA-DR15 haplotype, became transfusion independent after treatment with ATG (Table 72-4).

Patients who develop blast counts greater than 20% are frequently treated with standard induction regimens for acute leukemia. Results have been disappointing, with a remission rate of 50% to 60% and a relapse rate of 90% for anthracycline-cytarabine combinations. Although BMT is the only curative therapy for such patients and

should be undertaken when feasible, patients often fare poorly because of their advanced age and resistant disease.

Optimum Treatment

Care of patients with myelodysplasia is directed at symptom control with growth factor support including G-CSF and erythropoietin plus blood transfusions when necessary. Lenalidomide is the recommended therapy in patients with 5q-syndrome; azacitidine or decitabine can be used in other MDS patients. If a patient progresses to acute leukemia, standard leukemia chemotherapy regimens are implemented. For younger patients, BMT should be considered as the only potentially curative option; the optimal timeframe for BMT is when the disease is progressing but before leukemic transformation has occurred.

Agnogenic Myeloid Metaplasia and Myelofibrosis

Etiology and Pathogenesis

Fibrosis of the bone marrow (myelofibrosis) is divided into primary (idiopathic) and secondary processes. Myelofibrosis can be caused by infiltration of the bone marrow by a neoplastic process, granulomatous infections, and metabolic abnormalities.

Malignant disorders associated with myelofibrosis include agnogenic myeloid metaplasia, polycythemia vera, chronic myeloid leukemia, essential thrombocytosis, acute myelofibrosis, acute myeloid leukemia, hairy cell leukemia, acute myelodysplasia with myelofibrosis, multiple myeloma, non-Hodgkin's lymphoma, and metastatic carcinoma.

Nonmalignant conditions associated with myelofibrosis include tuberculosis, histoplasmosis, renal osteodystrophy, vitamin D deficiency, hypoparathyroidism, hyperparathyroidism, gray platelet syndrome, systemic lupus erythematosus, scleroderma, radiation exposure, osteopetrosis, Paget's disease, benzene exposure, thorotrast exposure, and Gaucher's disease.

Table 72-4 Myelodysplasia and Therapies

	(G-CSF) + Epo vs. Epo Alone	Azacitidine vs. Best Supportive Care	Decitabine vs. Best Supportive Care	Lenalidomide
Overall response rate	73.3% vs. 40% (erythroid response)	60% vs. 5% (response in at least one blood cell line)	17% vs. 0% (all cell lines improved, and a 50% decrease in bone marrow blasts)	56% Overall; 83% 5q-syndrome; 57% normal cytogenetics; 12% abnormal cytogenetics (erythroid response)
Median time to event (AML or death)	Not available	21 mo vs. 12 mo ($P = 0.007$)	12 m vs. 6.8 m ($P = 0.03$) (in the subgroup of patients with IPSS Int-2/high-risk MDS)	Not available
Overall survival	Not available	20 mo vs. 14 mo ($P = 0.10$)	Not available	Not available

AML, acute myeloid leukemia; G-CSF, granulocyte colony stimulating factor; Epo, erythropoietin; IPSS, International Prognostic Scoring System; MDS, myelodysplastic syndrome. Data from Balleari E, Rossi E, Clavio M, et al: *Ann Hematol* 85:174-180, 2006; Kantarjian H, Issa J PJ, Rosenfeld CS, et al: *Cancer* 106:1794-1880, 2006; List A, Kurtin S, Roe DJ, et al: *N Engl J Med* 352:549-557, 2005; and Silverman LR, Demakos EP, Peterson BL, et al: *J Clin Oncol* 20:2429-2440, 2002.

Clinical Presentation

Patients present with marked splenomegaly, progressive anemia, and constitutional symptoms including fatigue, weight loss, night sweats, fever, early satiety, diarrhea, and peripheral edema. Upon examination, they have pancytopenia, leftward shift in the granulocyte count, and increased levels of lactate dehydrogenase as a result of extramedullary hematopoiesis and accelerated marrow cell turnover. Complications can include portal hypertension or splenic infarction, as well as symptoms from extramedullary hematopoiesis associated with lymphadenopathy, ascites, pleural effusions, pneumonia, hematuria, or compression of the spinal cord and nerve roots. Median age at diagnosis is 65 years, with no definitive gender distribution.

Differential Diagnosis

The differential diagnosis includes other hematologic malignancies such as chronic myelogenous leukemia, lymphoma, multiple myeloma, Hodgkin's disease, hairy cell leukemia, and myelodysplastic syndromes. Solid tumors such as metastatic breast, prostate, or lung cancer can also cause this syndrome.

Diagnostic Approach

The diagnosis is made through examination of the peripheral blood smear and the bone marrow. The peripheral blood smear shows immature granulocytes, nucleated red cells (leukoerythroblastosis), and teardrop-shaped red blood cells. Biopsy of the bone marrow shows fibroblasts in the marrow space with reactive myelofibrosis along with dysplastic-megakaryocyte hyperplasia. Cytogenetic studies

are most useful for excluding chronic myelogenous leukemia and identifying those patients at risk for rapid transformation to acute leukemia.

The diagnosis of myelofibrosis with myeloid metaplasia is based on the following combinations: two necessary criteria plus any two optional criteria when splenomegaly is present, or two necessary criteria plus any four optional criteria when splenomegaly is absent.

Necessary criteria: (1) diffuse bone marrow fibrosis, and (2) absence of Philadelphia chromosome or *BCR-ABL* rearrangement in peripheral blood cells

Optional criteria: splenomegaly, anisopoikilocytosis with teardrop erythrocytes, circulating immature myeloid cells, circulating erythroblasts, clusters of megakaryoblasts and dysplastic megakaryocytes in bone marrow sections, myeloid metaplasia

Management and Therapy

Median survival is 3 to 6 years (Table 72-5). Death is usually due to complications of thrombocytopenia (bleeding) or neutropenia (infection). Transformation to acute leukemia is uncommon, occurring in less than 5% of cases. Prognostic factors associated with shortened survival include advanced age, anemia, hypercatabolic symptoms, leukocytosis, leukopenia, circulating blasts, increased numbers of granulocyte precursors, thrombocytopenia, and abnormalities in karyotype.

Management and therapy of myelofibrosis are largely palliative. Androgen preparations and corticosteroids are used to alleviate anemia. Hydroxyurea or thalidomide can be used to control leukocytosis, thrombocytosis, and organomegaly. Alternative treatments include interferon-

Table 72-5 Lille Scoring System for Predicting Survival in Myelofibrosis with Myeloid Metaplasia

No. of Adverse Prognostic Factors	Risk Group	Median Survival (mo)
0	Low	93
1	Intermediate	26
2	High	13

Note: Adverse prognostic factors were hemoglobin count less than 10 g/dL and white blood cell count less than 4 or greater than $30 \times 10^9/L$. Data from Barosi G: Myelofibrosis with myeloid metaplasia: Diagnostic definition and prognostic classification for clinical studies and treatment guidelines. *J Clin Oncol* 17(9):2961, 1999.

α and cladribine. In anemic patients with low serum erythropoietin levels, darbepoetin or epoetin alfa injections may be helpful.

Splenectomy is recommended for patients with hydroxyurea-resistant symptomatic splenomegaly, overt portal hypertension, and progressive anemia requiring transfusion. For patients with contraindications to surgery, splenic irradiation can be effective. Allogeneic stem cell transplantation is an option in young patients and is the only potentially curative therapy.

Optimum Treatment

The goal of therapy is to minimize symptoms while avoiding treatment-related toxicities. Therefore, patients with mild cytopenia and minimal symptoms do not require treatment. As the disease progresses, stem cell transplantation is a good option in young patients. Otherwise, treatment with either hydroxyurea or thalidomide is an acceptable option, with responses seen in up to half of patients. For patients with massive symptomatic splenomegaly, splenectomy or splenic irradiation should be considered.

Avoiding Treatment Errors

All patients with marrow failure syndromes should be referred to a hematologist. Before subjecting patients to intensive therapy or BMT, easily reversible causes of disease must be ruled out. For any patients who have the potential for proceeding to BMT, blood transfusions should be minimized because a history of multiple blood transfusions is associated with worse outcomes after transplantation. Additionally, patients who have received multiple blood transfusions (>20 to 30 units) should be monitored for iron overload, with possible initiation of iron chelation to prevent long-term complications. Every patient, even those who obtain a complete response to therapy, must be closely monitored for relapse or progression of disease and transformation to acute leukemia or, in patients with aplastic anemia, to PNH.

Future Directions

Aplastic Anemias

Future directions for the therapy of aplastic anemia include nonablative BMT, growth factors (megakaryocyte growth factors, stem cell–stimulating factors, and other cytokines), high-dose cyclophosphamide, recombinant humanized anti–interleukin-2 receptor antibody–directed therapy, and gene therapy for identifiable lesions such as Fanconi’s anemia.

Myelodysplasia

Future directions include nonablative BMT, immunomodulation, and molecular genetic approaches. Thalidomide and arsenic trioxide have also shown some benefit in treating patients with MDS, but more data are needed. Long-term outcomes with methylation-altering agents such as 5-azacytidine and decitabine or immunomodulating agents like lenalidomide remain to be determined.

Agnogenic Myeloid Metaplasia and Myelofibrosis

Future directions for therapy include lenalidomide, antifibrotic therapy, cytokine-directed approaches, and safer, more effective methods of allogeneic transplantation.

1. Deeg HJ, Gooley TA, Flowers MED, et al: Allogeneic hematopoietic stem cell transplantation for myelofibrosis. *Blood* 102:3912-3918, 2003.

Allogeneic transplantation can lead to long-term relapse-free survival.

2. Marchetti M, Barosi G, Balestri F, et al: Low-dose thalidomide ameliorates cytopenias and splenomegaly in myelofibrosis with myeloid metaplasia: A phase II trial. *J Clin Oncol* 22:424-431, 2004.

Thalidomide therapy can lead to decreased splenomegaly, cytopenia, and fatigue.

Blood Component Therapy

Introduction

The transfusion of blood was the first successful transplantation of living tissue in humans. Today, transfusion of blood components is so common and safe that it is rarely thought of as a transplantation. In 2001, for allogeneic transfusions within the United States alone, it is estimated that 13,898,000 units of whole blood/red blood cells, 2,614,000 units of whole blood-derived platelets, 1,264,000 units of apheresis platelets, and 3,926,000 units of plasma were administered. For red blood cell-containing products alone, this equates to 1 unit transfused every 2.3 seconds. A basic understanding of compatibility, indications, and the risks of blood component therapy are essential both for optimal patient care and for providing patients with information for a truly informed decision.

Basic Immunohematology

Pretransfusion testing confirms compatibility between the blood component and the recipient and detects unexpected but clinically significant antibodies that might harm the recipient or compromise the survival of the transfused cells. Red blood cell serologic testing depends on *in vitro* hemolysis or agglutination resulting from red blood cell antigen-antibody interaction. ABO typing involves testing of the recipient's red blood cells with potent anti-A and anti-B typing reagent (forward typing) and reaction of the recipient's plasma or serum with A1 (the major subtype of group A) and B red blood cells (reverse typing). Typically, ABO antibodies are immunoglobulin M antibodies and are reactive at room temperature. Rh typing tests the recipient's red blood cells with a chemically modified immunoglobulin G anti-D antibody that is reactive at room temperature.

Antibody screening for unexpected red blood cell antibodies requires testing of serum or plasma with group O reagent red blood cells selected to express all commonly occurring clinically significant antigens. Clinically significant antibodies present in serum or plasma are detected after 37° C incubation or after the addition of antihuman globulin (an indirect antihuman globulin test or indirect Coombs' test). If an unexpected antibody is detected, further serologic testing to identify the antigen specificity

of the antigen is performed. A nonreactive antibody screen allows for the rapid selection of red blood cells that require only a confirmation of ABO compatibility. The presence of unexpected antibodies requires the more time-consuming identification of antigen-negative units and a full crossmatch. A full crossmatch requires testing the recipient's serum or plasma with red cells from the units to be transfused, incubation at 37° C, and testing with antihuman globulin.

With the exception of infants, the lack of expression of either the A or B antigen results in the formation of anti-B or anti-A, respectively. A group O individual lacks both the A and the B antigens and thus forms both anti-A and anti-B. The ABO antigens, their antibodies, and compatibility of red blood cell and plasma components are summarized in Table 73-1.

Platelets can be thought of as bags of plasma, and ideally one would transfuse platelets with the compatibility of plasma. However, because of the short shelf life of platelets (5 days, or 7 days for some apheresis products), platelets are frequently transfused across ABO compatibility barriers. Cryoprecipitate due to the limited volume transfused is also frequently transfused across ABO plasma compatibility barriers. Group O is a universal red blood cell unit. Group AB is a universal plasma unit.

Table 73-1 ABO Types and Compatibility of Red Cells and Plasma

ABO Type (Antigens Expressed)	Percentage of Population	ABO Red Blood Cell Compatibility	Plasma Compatibility
O	45	O	O, A, B, AB
A	40	A, O	A, AB
B	11	B, O	B, AB
AB	4	AB, A, B, O	AB

Rh-negative (D-negative) red blood cells and platelets (which account for only 15% of the donor base) are reserved principally for female recipients of childbearing potential, and thus at risk for hemolytic disease of the newborn with pregnancy. To preserve an inventory of Rh-negative units, trauma cases involving males, in which the type is not initially known, are frequently transfused with Rh-positive red blood cells.

Blood Components and Indications for Transfusion

Individual institutions must have guidelines for the transfusion of blood components. These guidelines are based on the scientific literature and local practice and serve as the basis for the focused review of transfusion practices. Although guidelines represent institution consensus, they cannot substitute for clinical judgment and the need for flexibility in practice, and should not be considered a mandate to transfuse or not to transfuse.

Before the administration of blood or blood components, the indications, risks, and benefits of a blood transfusion and possible alternatives must be discussed with the patient and documented in the medical record. Transfusions should be documented in the patient's record, including both indications and outcome. Specific notations should be made when exceptions to the institutional guidelines exist.

Red Blood Cells

The purpose of red blood cell transfusion is to provide oxygen-carrying capacity and to maintain tissue oxygenation when the intravascular volume and cardiac function are adequate for perfusion. One unit of red blood cells should increase the patient's hemoglobin (Hgb) level by 1 g/dL or the hematocrit by 3% in a 70-kg recipient. Red blood cell transfusion should only be used when time or underlying pathophysiology precludes other management (e.g., iron, erythropoietin, and folate).

Criteria are as follows: (1) Hgb <8 g/dL in an otherwise healthy patient; (2) Hgb <11 g/dL in cases of increased risk for ischemia (e.g., pulmonary disease, coronary artery disease, cerebral vascular disease); (3) acute blood loss resulting in blood loss >15% of total blood volume (750 mL

in 70-kg male) or with evidence of inadequate oxygen delivery (e.g., electrocardiographic signs of cardiac ischemia, tachycardia, cyanosis); (4) symptomatic anemia in a normovolemic patient (e.g., tachycardia, mental status changes, electrocardiographic signs of cardiac ischemia, angina, shortness of breath, lightheadedness or dizziness with mild exertion); or (5) regular predetermined therapeutic program for severe hypoplastic or aplastic anemia or for bone marrow suppression for hemoglobinopathies. The post-transfusion Hgb should not exceed 11.5 g/dL (12.5 g/dL in those cases of increased risk for organ/tissue ischemia).

It is not acceptable to use red blood cell transfusions to increase wound healing or merely to take advantage of readily available predonated autologous blood without an acceptable medical indication.

Platelets

Platelets are used for patients suffering from or at significant risk for hemorrhage due to thrombocytopenia or platelet dysfunction. One unit of whole blood-derived platelets (a random unit) should increase the platelet count by 7 to $10 \times 10^9/L$ in a 70-kg recipient. Dosing is generally a pool of 4 to 6 U. A single donor apheresis platelet transfusion should increase the platelet count by 40 to $60 \times 10^9/L$ in a 70-kg recipient. In the United States, the use of apheresis platelets has been increasing annually. In 2004, it was estimated that 77% of all therapeutic doses of platelets transfused were apheresis platelets.

Criteria are as follows: (1) platelet count $\leq 10 \times 10^9/L$ (for prophylaxis in stable, nonfebrile patients), or $< 20 \times 10^9/L$ for prophylaxis with fever or instability; (2) platelet count $\leq 50 \times 10^9/L$ in a patient with documented hemorrhage or rapidly decreasing platelet count or planned invasive or surgical procedure; (3) diffuse microvascular bleeding in a patient with disseminated intravascular coagulation or following a massive blood loss (>1 blood volume) with a platelet count not yet available; or (4) bleeding in a patient with platelet dysfunction.

Unacceptable indications for platelet transfusion include patients with the following syndromes, but no evidence of bleeding or coagulopathy: thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), or idiopathic thrombocytopenic purpura; empiric use during

massive transfusion in which the patient does not exhibit a clinical coagulopathy; and extrinsic platelet dysfunction, such as in renal failure, hyperproteinemia, or von Willebrand's disease.

Plasma

This component contains adequate levels of all soluble coagulation factors. Plasma is available as fresh frozen plasma (FFP), plasma frozen within 24 hours, and thawed plasma. These products are indicated for the correction of multiple or specific coagulation factor deficiencies, or for the empiric treatment of TTP or HUS. One unit contains about 220 mL, and the usual starting dose is 5 to 15 mL/kg (2 to 4 U in a 70-kg recipient).

Criteria for transfusion include treatment or prophylaxis of multiple or specific coagulation factor deficiencies (prothrombin time [PT] or partial thromboplastin time [PTT] >1.5 times the mean normal value). Congenital deficiencies (antithrombin III; factors II, V, VII, IX, X, XI; plasminogen; or antiplasmin) or acquired deficiencies related to warfarin therapy, vitamin K deficiency, liver disease, massive transfusion (>1 blood volume in 24 hours), and disseminated intravascular coagulation are acceptable indications for the transfusion of plasma. Plasma is also indicated in patients with a suspected coagulation deficiency (PT/PTT pending) who are bleeding, or at risk for bleeding, from an invasive procedure. Unacceptable criteria are empiric use during massive transfusion in which the patient does not exhibit clinical coagulopathy, nutritional supplementation, or volume replacement.

Cryoprecipitate

Cryoprecipitate is a cold insoluble fraction of FFP; each bag contains about 80 to 100 U of factor VIII and 250 mg of fibrinogen. It also contains factor XIII and von Willebrand's factor. The usual starting dose is one concentrate per 7 to 10 kg. In a 70-kg male, 10 U would be expected to raise the fibrinogen 40 mg/dL. Cryoprecipitate may also be applied topically, with an equal volume of bovine thrombin, taking advantage of its adhesive, hemostatic, and sealant properties. Single units are appropriate as a fibrin sealant or glue.

Appropriate indications for cryoprecipitate use include treatment or prevention of bleeding associated with certain known or suspected clotting factor deficiencies (factor VIII, von Willebrand's factor, factor XIII, or factor I) and of a prolonged bleeding time or fibrinogen of less than 150 mg/dL or other specific coagulation factor assay-documented deficiency. Cryoprecipitate may also be used for the treatment of surface oozing and the maintenance of tissues in tight apposition to each other or the sealing of leaking spaces (fibrin glue). The use of desmopressin acetate may frequently be a preferred or acceptable alternative to use of cryoprecipitate for patients with type I von

Willebrand's disease, mild hemophilia A (factor VIII deficiency), or certain platelet dysfunctional disorders.

Other Blood-Derived Products

Other blood-derived products, such as intravenous immunoglobulin preparations, normal serum albumin, and coagulation factor concentrates, are beyond the scope of this chapter. Their use is covered in other relevant chapters.

Risks of Blood Products

Infectious Disease

Although blood products today are considered safer than ever, a truly zero-risk blood supply is probably unattainable. Currently, blood donations in developed countries are screened for HIV types 1 and 2, hepatitis C, hepatitis B, and syphilis. Recently, many countries have begun testing for hepatitis C and HIV with nucleic amplification testing (NAT). Knowledge of the current risk for disease transmission (summarized later) is a prerequisite for proper informed consent for transfusion (Table 73-2).

Table 73-2 Risk for Infectious Disease

Infectious Agent	Estimated Risk/Unit (with Nucleic Amplification Testing)
Virus	
HIV types 1 and 2	1 : 400,000-1 : 2,400,000
Human T-cell lymphotropic virus types I and II	1 : 256,000-1 : 2,000,000
Hepatitis B	1 : 58,000-1 : 147,000
Hepatitis C	1 : 872,000-1 : 700,000
West Nile virus	<1 : 2,000,000 but in flux, with regional, temporal, and testing variation
Bacteria	
Red blood cells	1 : 1000 (contaminated) <1 : 1,000,000 (fatal)
Platelets screened with Gram stain, pH, or glucose concentration	1 : 2000-1 : 4000 >40% result in clinical sequelae
Platelets screened with aerobic culture	<1 : 10,000
Syphilis	<1 : 10,000,000
Parasites	
Malaria, <i>Babesia</i> species	<1 : 1,000,000

Note: The high risk for bacterial contamination of platelets is due to the required storage at 20° C to 24° C; 1 : 2500 per pool of 6 or 1 : 13,400 single donor apheresis platelets result in clinical sepsis (without a bacterial detection screen). The related mortality is about 1 : 17,000 for random donor pools and 1 : 16,000 for single donor apheresis platelets (nonscreened for bacteria). Modified from Brecher ME (ed): *Technical Manual, 15th ed.* Bethesda, MD, American Association of Blood Banks, 2005, p 700.

Table 73-3 Noninfectious Complications of Transfusion

Type	Rate
Acute (≤24 Hours of Transfusion)	
Immunologic	
Hemolytic	1 : 38,000-1 : 70,000
Nonhemolytic (febrile, chills)	1 : 100-1 : 200
Transfusion-related acute lung injury	1 : 5000-1 : 190,000
Allergic (mild)	1 : 33-1 : 100
Anaphylactic	1 : 20,000-1 : 50,000
Angiotensin-converting enzyme inhibitor—mediated hypotension	Dependent on clinical setting
Nonimmunologic	
Fluid overload	<1%
Air embolism	Rare
Citrate toxicity (hypocalcemia)	Dependent on clinical setting
Pseudohemolytic	Unknown
Delayed (>24 Hours after Transfusion)	
Immunologic	
Delayed hemolytic	1 : 5000-1 : 11,000
Graft-versus-host disease	Rare
Post-transfusion purpura	Rare
Nonimmunologic	
Iron overload	After >100 units of red blood cells

Modified from Brecher ME (ed): *Technical Manual*, 15th ed. Bethesda, MD, American Association of Blood Banks, 2005, pp 634-638.

Noninfectious Disease

The greatest risk of transfusion involves noninfectious complications. The most common noninfectious cause for death is the transfusion of ABO-incompatible allogeneic red blood cells (with the administration of ABO-incompatible red blood cells at a rate of 1 : 38,000 units and a fatality rate of 1 : 1,300,000 units transfused). These events are invariably due to human error, classically, the misidentification of a patient or sample. It is because of the recognition of this avoidable source of error that blood banks and transfusion services have very stringent policies regarding patient and sample identification. Noninfectious complications of transfusion can be divided into acute (≤24

hours of transfusion) and delayed (>24 hours after transfusion) (Table 73-3).

Future Directions

Future directions for blood component therapy include additional initiatives to reduce the risk for infectious disease such as wider application of NAT testing, use of viral and bacterial inactivation technologies, or both. Currently, the use of bacterial culture of apheresis platelets is allowing a transition to a 7-day extended storage. Red blood cell “substitutes” made from polymerized Hgb are currently in clinical trials. Such products with a prolonged shelf life will not require compatibility testing and may provide transient (24 to 48 hours) oxygen-carrying capacity in patients for whom transfusion of red blood cells is not an option (e.g., trauma patients in the field) or allow extensive acute normovolemic hemodilution in the operative setting.

Malignant Lymphomas

Introduction

Lymphomas arise from a malignant transformation of lymphoid cells (B-, T-, or natural killer cells) and are classified as Hodgkin's disease (HD) or non-Hodgkin's lymphoma (NHL). HD is divided into five subtypes that share many characteristics, while NHL comprises a heterogeneous group of more than 20 malignancies that are distinct not only from HD, but in many cases from one another (Box 74-1). NHL can be divided broadly into low-, intermediate-, and high-grade malignancies based on their clinical aggressiveness. Low-grade NHL is associated with long survival but, in most instances, is not curable. In contrast, although the median survival for intermediate- and high-grade NHL is shorter, they often can be cured. With current therapy, HD is curable in most patients.

In developed areas, the incidence of HD is about 3 of 100,000 persons. A bimodal age distribution is seen, with a first peak occurring in the third decade and a second peak after the age of 50 years. NHL is more common than HD, representing 4% of all new cancer diagnoses in the United States. In 2006, it is estimated that there will be 58,700 new cases of NHL diagnosed in the United States, in contrast to 7800 new cases of HD. The 5-year survival rates for HD and NHL during the period from 1974 to 1976 were 71% and 47%, respectively, but have since increased to 85% and 60% during the period from 1995 to 2001, which is testimony to the significant advances made in the therapy for these diseases.

Etiology and Pathogenesis

Several factors support a possible role for Epstein-Barr virus (EBV) in the pathogenesis of HD as evidenced by the fact that patients with a history of infectious mononucleosis have a twofold to threefold increased risk for developing HD, and that EBV is found in the tumor cells of about half of cases. Patients with HIV are at increased risk for the development of HD. Furthermore, there appears to be a slight genetic predisposition to the development of HD, in that about 1% of patients have a family history of HD, with first-degree relatives and monozygotic (compared with dizygotic) twins being at increased risk.

Whereas HD is typically cytogenetically normal, in NHL nonrandom chromosomal translocations are frequently encountered and play important pathogenic roles. Notable examples include translocations involving chromosome 8q24, which lead to overexpression of *c-Myc* in Burkitt's lymphoma (BL); t(14;18), which leads to overexpression of the B-cell survival factor, *Bcl-2*, in follicular lymphoma; and t(11;14), which results in up-regulation of the cell cycle regulator, cyclin D1, in mantle cell lymphoma.

Several risk factors for NHL have been identified, including primary immunodeficiency syndromes (e.g., ataxia-telangiectasia, Wiskott-Aldrich syndrome) and secondary immunodeficiency from pharmacologic immunosuppression of organ transplant recipients or HIV infection. Other infectious agents associated with an increased risk for NHL include hepatitis C virus (splenic marginal zone lymphoma), human T-cell leukemia virus type I (adult T-cell leukemia and lymphoma), EBV (primary central nervous system [CNS] lymphomas and BL), human herpesvirus-8 (primary effusion lymphoma), *Helicobacter pylori* (gastric mucosa-associated lymphoid tissue [MALT] lymphomas), and *Chlamydia psittaci* (ocular adnexal MALT lymphomas). Autoimmune and chronic inflammatory disorders associated with an increased risk for NHL include celiac sprue (enteropathy-type intestinal T-cell lymphomas), rheumatoid arthritis (large granular lymphocytic leukemia), Sjögren's disease (extranodal marginal zone lymphomas), autoimmune thyroid disease (thyroid lymphomas), and inflammatory bowel diseases. Finally, exposure to pesticides and radiation has been associated with an increased risk for NHL.

 Systemic anaplastic large cell lymphoma
 Primary cutaneous anaplastic large-cell lymphoma
 Subcutaneous panniculitis-like T-cell lymphoma
 Enteropathy-type intestinal T-cell lymphoma
 Hepatosplenic T-cell lymphoma

Hodgkin's Lymphoma

Nodular lymphocyte predominant Hodgkin's lymphoma
 Classic Hodgkin's lymphoma
 Nodular sclerosis
 Lymphocyte-rich type
 Mixed cellularity
 Lymphocyte depleted

Clinical Presentation

Patients with HD and NHL typically have adenopathy that is firm, nontender, and mobile. Contiguous spread of disease to adjacent lymph node chains is the rule in HD, and supradiaphragmatic presentations involving the neck, supraclavicular fossa, or axilla are most common, whereas sites of involvement are more varied in NHL because of its predilection for early hematogenous spread. Disease limited to areas below the diaphragm is less frequent in HD, as is epitrochlear, Waldeyer ring, or extranodal

involvement. Mediastinal involvement is common in HD, but may be seen in NHL as well, particularly primary mediastinal large cell and lymphoblastic lymphomas, and is commonly heralded by symptoms of chest pain, cough, and dyspnea. Constitutional symptoms in HD and NHL are common and can include fever, night sweats, weight loss, fatigue, and pruritus. In HD, rare manifestations include pain in affected nodes after drinking alcohol and Pel-Ebstein fever, which builds to a peak over several days, lasts several weeks, wanes, and then begins anew. Patients with low-grade NHL may have several years of waxing-waning adenopathy before seeking medical attention and tend not to have systemic symptoms or extranodal involvement until disease is more advanced. Low-grade NHL can transform into intermediate- or high-grade NHL, which declares itself as a disproportionately increasing nodal mass or the rapid acceleration of symptoms. With intermediate- and high-grade NHL, symptoms develop over weeks to months, and extranodal involvement, such as of the gastrointestinal tract, bone marrow, or CNS, can occur even in early-stage disease. CNS involvement may manifest as spinal cord compression from epidural lesions, focal neurologic deficits from intraparenchymal brain lesions, or headaches, mental status changes, neck pain and stiffness, cranial neuropathies, or radicular symptoms from leptomeningeal involvement.

Hematologic abnormalities most commonly include anemia, although leukopenia and thrombocytopenia can be seen, especially with bone marrow involvement or hypersplenism from splenic infiltration. Liver test abnormalities can be seen with hepatic involvement, and an increased creatinine might be seen in patients with bilateral ureteral obstruction from bulky retroperitoneal lymphadenopathy. Lactate dehydrogenase (LDH) is frequently elevated in patients with advanced HD and NHL and is reflective of significant tumor burden. Hypercalcemia can be seen in the presence of bony involvement or through the increased conversion of 25-hydroxy-vitamin D to 1,25-hydroxy-vitamin D. Tumor lysis syndrome (hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and renal failure) may occur in high-grade NHL, most notably BL and lymphoblastic lymphoma, and occasionally in intermediate-grade NHL, even before the initiation of treatment, but is rare in HD.

Differential Diagnosis

The differential diagnosis for adenopathy is broad and should prompt consideration of infectious etiologies, autoimmune processes, hypersensitivity reactions, and other malignancies (Table 74-1).

Diagnostic Approach

For patients with adenopathy and no constitutional symptoms, a period of close observation for a few weeks, possi-

Table 74-1 Differential Diagnosis of Lymphadenopathy

Infectious	
Bacterial	Streptococcal infections, secondary syphilis, Lyme disease, cat-scratch disease, tularemia
Viral	Infectious mononucleosis, cytomegalovirus, HIV, hepatitis B
Fungal	Cryptococcosis, histoplasmosis, coccidioidomycosis
Mycobacterial	Tuberculosis, atypical mycobacterial infections
Protozoal	Toxoplasmosis
Malignancy	Solid tumors (e.g., lung, breast, head and neck)
Endocrine	Thyroid disease, Addison's disease
Autoimmune	Rheumatoid arthritis, systemic lupus erythematosus, Wegener's granulomatosis, Still's disease, Churg-Strauss syndrome, dermatomyositis
Immunologic	Serum sickness, other hypersensitivity reactions (e.g., phenytoin)
Other	Sarcoidosis, Kikuchi's disease, Rosai-Dorfman disease, amyloidosis, Castleman's disease, the histiocytoses, Kawasaki's disease, Whipple's disease

bly with a course of antibiotics, is usually reasonable, provided that the involved area is not growing at a rapid rate. Empiric use of steroids should be avoided because steroids are lympholytic and can make interpretation of a future lymph node biopsy difficult. Regression of adenopathy does not rule out a malignant process because nodes may wax and wane. Patients with persistent or progressive adenopathy, especially in the presence of unexplained constitutional symptoms; abnormal screening laboratory studies including anemia; elevations of the erythrocyte sedimentation rate, liver function tests, or LDH; abnormal chest radiographs, or those at high HIV risk, should be considered for prompt referral for biopsy.

An incisional or excisional biopsy is usually required to diagnose lymphoma, and the most accessible node is targeted. If there is concern for transformation of a low-grade lymphoma, the most symptomatic or suspicious node should be removed. Standard hematoxylin and eosin staining is supplemented with flow cytometry, immunohistochemistry, cytogenetic analysis, or DNA testing (e.g., immunoglobulin or T-cell receptor gene rearrangement studies) to establish the diagnosis of lymphoma and the correct subtype. Needle aspiration is not adequate in most cases because the neoplastic Reed-Sternberg cells in HD can make up 1% or less of the total cell population, and the nodal architecture used in histologic classification of lymphomas is lost.

Staging of Hodgkin's Disease and Non-Hodgkin's Lymphoma

In addition to a careful history and physical examination, management of HD and NHL depends on accurate staging (Fig. 74-1). Staging is typically accomplished with the use of computed tomography (CT) of the neck, chest, abdomen, and pelvis. [¹⁸F]-2-fluoro-2-deoxy-D-glucose positron emission tomography (FDG-PET), particularly when combined with CT, is a highly sensitive technique for detecting metabolically active lymphoma. Bone marrow aspiration and biopsy remain an essential part of staging given the limitations of CT and FDG-PET in the detection

of marrow involvement. The staging laparotomy, once commonly used in the workup of HD, is infrequently performed today, but might be considered in favorable-prognosis, stage I and II HD if a negative result would dictate the use of radiation therapy without chemotherapy. Certain subtypes of NHL (BL, lymphoblastic lymphoma, or diffuse large B-cell NHL with bone marrow involvement, extensive extranodal involvement, or in HIV patients) have a predilection for spreading to the CNS, and a lumbar puncture at diagnosis is warranted to exclude CNS involvement. Patients are staged according to the Ann Arbor classification system (see Fig. 74-1). However, clinical factors other than stage play an important role in determining prognosis from HD and NHL. To better determine long-term outcomes and treatment, scoring systems have been devised for HD and NHL (Table 74-2).

Management of Hodgkin's Disease

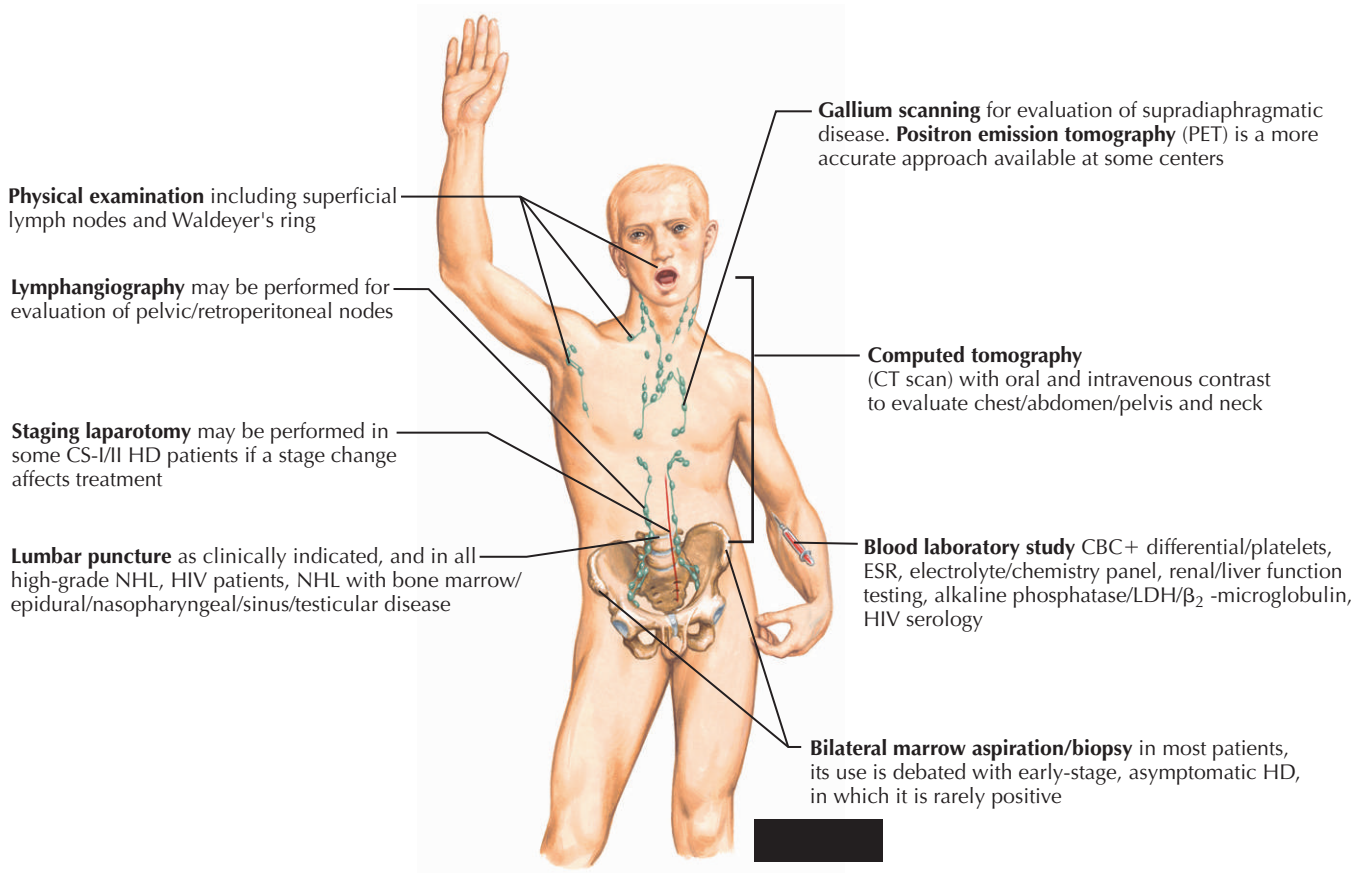

Optimum Treatment

Favorable-prognosis, stage I, and II classic HD: Patients with supradiaphragmatic, laparotomy-staged disease may receive primary radiation therapy, and enjoy a 75% to 85% relapse-free survival rate and a 90% 20-year survival rate because many relapsed patients are successfully salvaged with chemotherapy. Patients with clinical stage I or II disease with favorable prognostic factors may receive extended-field radiation therapy that includes para-aortic and splenic fields, but are more commonly treated with combined-modality chemotherapy and radiation therapy. Patients with unfavorable prognostic factors are also treated with combined-modality therapy, which includes the use of four to six chemotherapy cycles, followed by involved-field radiation therapy (IFRT) at lower doses than those used when primary radiation therapy is employed.

Advanced, stage III, and IV classic HD: Most stage III and IV patients receive six to eight cycles of combination chemotherapy. Radiation is used in select instances, such as for patients with bulky masses at presentation,

Figure 74-1 Malignant Lymphomas—Staging.

CBC, complete blood count; ESR, erythrocyte sedimentation rate; HD, Hodgkin's disease; HIV, human immunodeficiency virus; LDH, lactate dehydrogenase; NHL, non-Hodgkin's lymphoma.

**Ann Arbor Classification****Stage I**

Involvement of a single lymph node region (I) or of a single extralymphatic organ or site (IE)

Stage II

Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of extralymphatic organ or site and of one or more lymph node regions on the same side of the diaphragm (IIE)

Stage III

Involvement of lymph node regions on both sides of the diaphragm (III), which may also be accompanied by localized involvement of extralymphatic organ or site (IIIE) or by involvement of the spleen (IIIS) or both (IIISE)

Stage IV

Diffuse or disseminated involvement of one or more extralymphatic organs or tissues with or without associated lymph node enlargement

Certain symptoms are commonly associated with lymphoma:

- * Night sweats
- * Temperature $> 38.5^{\circ}\text{C}$
- * Weight loss $> 10\%$

These are called "B" symptoms and are included in the stage designated to a patient. For instance, a patient with involved lymph nodes in the neck and under the arms only, and without any of the "B" symptoms, has stage IIA disease. The same patient with night sweats has stage IIB disease.

Table 74-2 Prognostic Scoring Systems for Malignant Lymphomas**A. The International Prognostic Index for Diffuse Large Cell Lymphoma**

Score	Risk Group	Complete Response Rate	5-Year Overall Survival
0 to 1	Low	87%	73%
2	Low-intermediate	67%	51%
3	High-intermediate	55%	43%
4 to 5	High	44%	26%

1 point is assigned for each of the following clinical parameters: age >60 years, serum lactate dehydrogenase (LDH) > the normal range, an Eastern Cooperative Oncology Group (ECOG) performance status of ≥ 2 , Ann Arbor stage III or IV disease, and >1 extranodal site of disease.

B. The Follicular Lymphoma International Prognostic Index

Score	Risk Group	5-Year Overall Survival	10-Year Overall Survival
0 to 1	Low	90.6%	70.7%
2	Intermediate	77.6%	50.9%
≥ 3	High	52.5%	35.5%

1 point is assigned for each of the following clinical parameters: age >60 years, serum LDH > the normal range, Ann Arbor stage III or IV disease, number of nodal sites >4, hemoglobin <12 mg/dL.

or for those whose disease has not completely regressed radiographically after chemotherapy. Freedom from relapse in stage IIIB and IV disease can occur in up to 70% of cases, with an overall survival rate of more than 80%. The most common regimens include ABVD (Adriamycin, bleomycin, vinblastine, and dacarbazine) or MOPP (mechlor-ethamine, oncovin, procarbazine, and prednisone). ABVD is generally preferred because it is associated with a decreased risk for myelodysplasia or secondary leukemia, is better tolerated, and improves the chance of preserving fertility.

Nodular lymphocyte-predominant HD: Most patients present with early-stage disease, and radiation therapy, sometimes with more limited fields, is a consideration given their good prognosis.

Relapsed HD: Relapsed HD is curable in many instances. Most patients who received radiation as initial treatment undergo combination chemotherapy. For those who underwent chemotherapy initially and had a long remission (>1 year), repeat chemotherapy, often combined with radiation therapy for those with limited disease at relapse, is reasonable; but after a brief or no remission, patients should be considered for salvage chemotherapy followed by autologous stem cell transplantation.

Late toxicities of radiation therapy vary, in part, with the radiation field used, but may include hypothyroidism,

accelerated atherosclerosis, solid tumors (lung, breast, gastrointestinal, thyroid, soft tissue, and skin), and hematologic malignancies, including myelodysplasia, acute myeloid leukemia, and NHL. Chemotherapy (especially alkylating agents and topoisomerase II inhibitors) further increases the risk for myelodysplasia and acute myeloid leukemia. Congestive heart failure can occur as a result of anthracycline exposure, especially in those who have received a higher cumulative dose, are older, or have received prior radiation therapy to the chest. Bleomycin can cause an acute hypersensitivity pneumonitis or, more commonly, a subacute or chronic fibrosing alveolitis, which is more likely in those who have received chest radiation.

Management of Non-Hodgkin's Lymphoma

The histologic type and stage are taken into account in making treatment recommendations. General guidelines for follicular and diffuse large cell lymphomas, the most common NHLs, are presented next.

Low-Grade, Follicular Lymphomas

Optimum Treatment

Low-grade, follicular lymphomas are incurable with standard chemotherapy, and there is no evidence that early treatment prolongs survival. A watchful waiting approach is reasonable for asymptomatic patients. For many with systemic symptoms, chemotherapy can effectively decrease tumor burden and symptoms, often for long periods of time, although relapse is inevitable.

Early, stage I, and II disease: Although stage I or limited stage II disease at presentation is uncommon, these patients are candidates for radiation therapy, which may be curative in some. Whether this approach is better than observation alone for patients with early-stage, asymptomatic disease is debatable.

Advanced, stage III, and IV disease: Watchful waiting is still appropriate for most asymptomatic patients, whereas symptomatic patients are candidates for systemic chemotherapy. Options for cytotoxic chemotherapy include chlorambucil or cyclophosphamide, alone or with prednisone (these are oral regimens but expose patients to alkylating agents, which confer a risk for myelodysplasia and secondary leukemia); fludarabine-based chemotherapy (higher response rates, but more immunosuppressive); or the combination regimen CHOP (cyclophosphamide, doxorubicin, oncovin, and prednisone) or CVP (cyclophosphamide, oncovin, and prednisone). Rituximab is a monoclonal antibody directed against the CD20 antigen on B cells and has significant activity against low-grade B-cell lymphomas. In combination with cytotoxic chemotherapy regimens and as maintenance therapy after completion of chemotherapy,

rituximab has been shown to improve remission durations for patients with follicular lymphoma. Rituximab can also be used as single-agent therapy, especially for those who are medically unfit to receive conventional chemotherapy. More recently, radioisotope-conjugated anti-CD20 antibodies have emerged for the treatment of follicular lymphoma and have demonstrated impressive response rates in newly diagnosed and relapsed disease.

Relapsed disease: When patients experience relapse, they can usually be treated with another of the many available chemotherapeutic modalities. Autologous and allogeneic transplantation remains investigational.

Diffuse Large B-Cell Lymphomas

Optimum Treatment

Early, stage I, and II disease: Three cycles of CHOP chemotherapy followed by IFRT is associated with a 70% to 80% progression-free and overall survival rate at 5 years. Rituximab is typically given with chemotherapy and will likely improve survival further, given its successful use in more advanced disease.

Advanced, stage III, and IV disease: Six to eight cycles of CHOP produces complete response rates in up to 60% of cases, but therapy is curative in less than 50%. The addition of rituximab to CHOP has improved the overall survival from this disease and is now routinely incorporated into therapy. Autologous stem cell transplantation is sometimes used for patients with high-risk disease as defined by the International Prognostic Index score (see Table 74-2), which has been shown to improve disease-free survival but has not led to a consistent improvement in overall survival compared with chemotherapy alone.

Relapsed disease: Relapsed disease is treated with salvage chemotherapy, followed in most cases by autologous stem cell transplantation, with intent to cure. Patients who are not eligible for transplantation are treated with non-cross-resistant chemotherapy regimens, palliative radiation therapy, or both, and are rarely cured.

Avoiding Treatment Errors

Decisions regarding the use of radiation therapy, chemotherapy, or a combination of the two, and the choice of chemotherapy agents used critically depend on a thorough staging evaluation and accurate pathologic diagnosis for both Hodgkin's and non-Hodgkin's lymphoma. Furthermore, aggressive supportive care is crucial to the successful outcome of a chosen therapy, requires a thorough understanding of the toxicity profiles of the therapeutics used, and may include the use of hematopoietic growth factors (e.g., erythropoietin for malignancy-related anemia, granulocyte colony-stimulating factor for prevention of febrile neutropenia), antiemetics for acute and delayed chemo-

therapy-induced nausea and vomiting, and prophylactic antibiotics for specific infections (e.g., *Pneumocystis carinii* pneumonia prophylaxis for patients receiving fludarabine-based chemotherapy).

Future Directions

Ongoing studies in HD and NHL will determine whether more extended chemotherapy can effectively replace radiation therapy in the management of early-stage HD, thereby decreasing long-term radiation-associated morbidity and mortality. Fueled by the success in NHL, current and future studies in HD will incorporate antibody-based treatment strategies into current standards of care (e.g., anti-CD30 antibodies). Ongoing and future studies in NHL will clarify the efficacy and role of immunotherapy (anti-idiotype vaccine strategies, novel antibody-based therapies, radioimmunotherapy). Finally, our increased understanding of the molecular pathogenesis of lymphomas has paved the way for the development and incorporation of targeted pharmacologic agents into current management strategies for these diseases.

This phase 3 study established ABVD as the standard of care chemotherapy regimen for patients with advanced HD, and the ABVD regimen remains in use today.

Coiffier B, Lepage E, Briere J, et al: CHOP chemotherapy plus rituximab compared with CHOP alone in elderly patients with diffuse large-B-cell lymphoma. *N Engl J Med* 346(4):235-242, 2002.

This phase 3 study demonstrated an improvement in overall survival for elderly patients with diffuse large B-cell lymphoma who received the anti-CD20 monoclonal antibody, rituximab, with their CHOP chemotherapy, and defined the current standard of care for this disease.

Leukemias

Introduction

The leukemias are a group of disorders characterized by neoplastic transformation of hematopoietic cells, with resultant accumulation of these cells in the bone marrow and commonly, although not universally, in the peripheral blood. Leukemias may arise from lymphoid or from myeloid cells and are generally classified as acute if the cells are arrested early in differentiation (blasts or early progenitors), or as chronic if the cells are mature. Most leukemias are characterized by chromosomal or cytogenetic abnormalities that contribute to the assessment of overall prognosis. Risk factors for leukemia include exposure to ionizing radiation, previous chemotherapy, and increasing age.

Acute Myeloid Leukemia

Etiology and Pathogenesis

Acute myeloid leukemia (AML) arises in a stem cell capable of giving rise to granulocytes, monocytes, red blood cells, and platelets. Malignant transformation occurs at different stages of differentiation, giving rise to subtypes that can be distinguished by morphology, histochemistry, and specific surface markers using a panel of monoclonal antibodies (flow cytometry). The subtypes of AML have been codified in a French-American-British classification system that divides the leukemias into eight groups (M0-7) based on the myeloid phenotype. Because cells accumulate at a very immature stage of development, they replace the bone marrow and cause anemia and thrombocytopenia. Many cytogenetic abnormalities have been described that lead to the production of specific proteins that cause the leukemias. Of these, the translocation of a portion of chromosome 17 onto the long arm of chromosome 15 in acute progranulocytic or M3 leukemia is the best understood. The resulting aberrant gene product contains a portion of the nuclear retinoic acid receptor, and clinical remissions in this disorder can be achieved with pharmacologic doses of all-*trans*-retinoic acid. This vitamin A derivative binds to the receptor and overcomes the block in differentiation, allowing maturation of the leukemic cells into neutrophils.

Clinical Presentation

Patients present with symptoms related to anemia (fatigue, pallor, and dyspnea), neutropenia (infection), or thrombocytopenia (petechiae, bleeding). Different subtypes may have specific manifestations. Acute progranulocytic leukemia (M3) may present with disseminated intravascular coagulation and bleeding or purpura. Leukemias derived from monocytes (M4 and M5) may present with skin, gum, or lung infiltration. AML may also develop from preexisting myelodysplasia that is characterized by a period of low blood counts, frequently requiring blood product support.

Differential Diagnosis

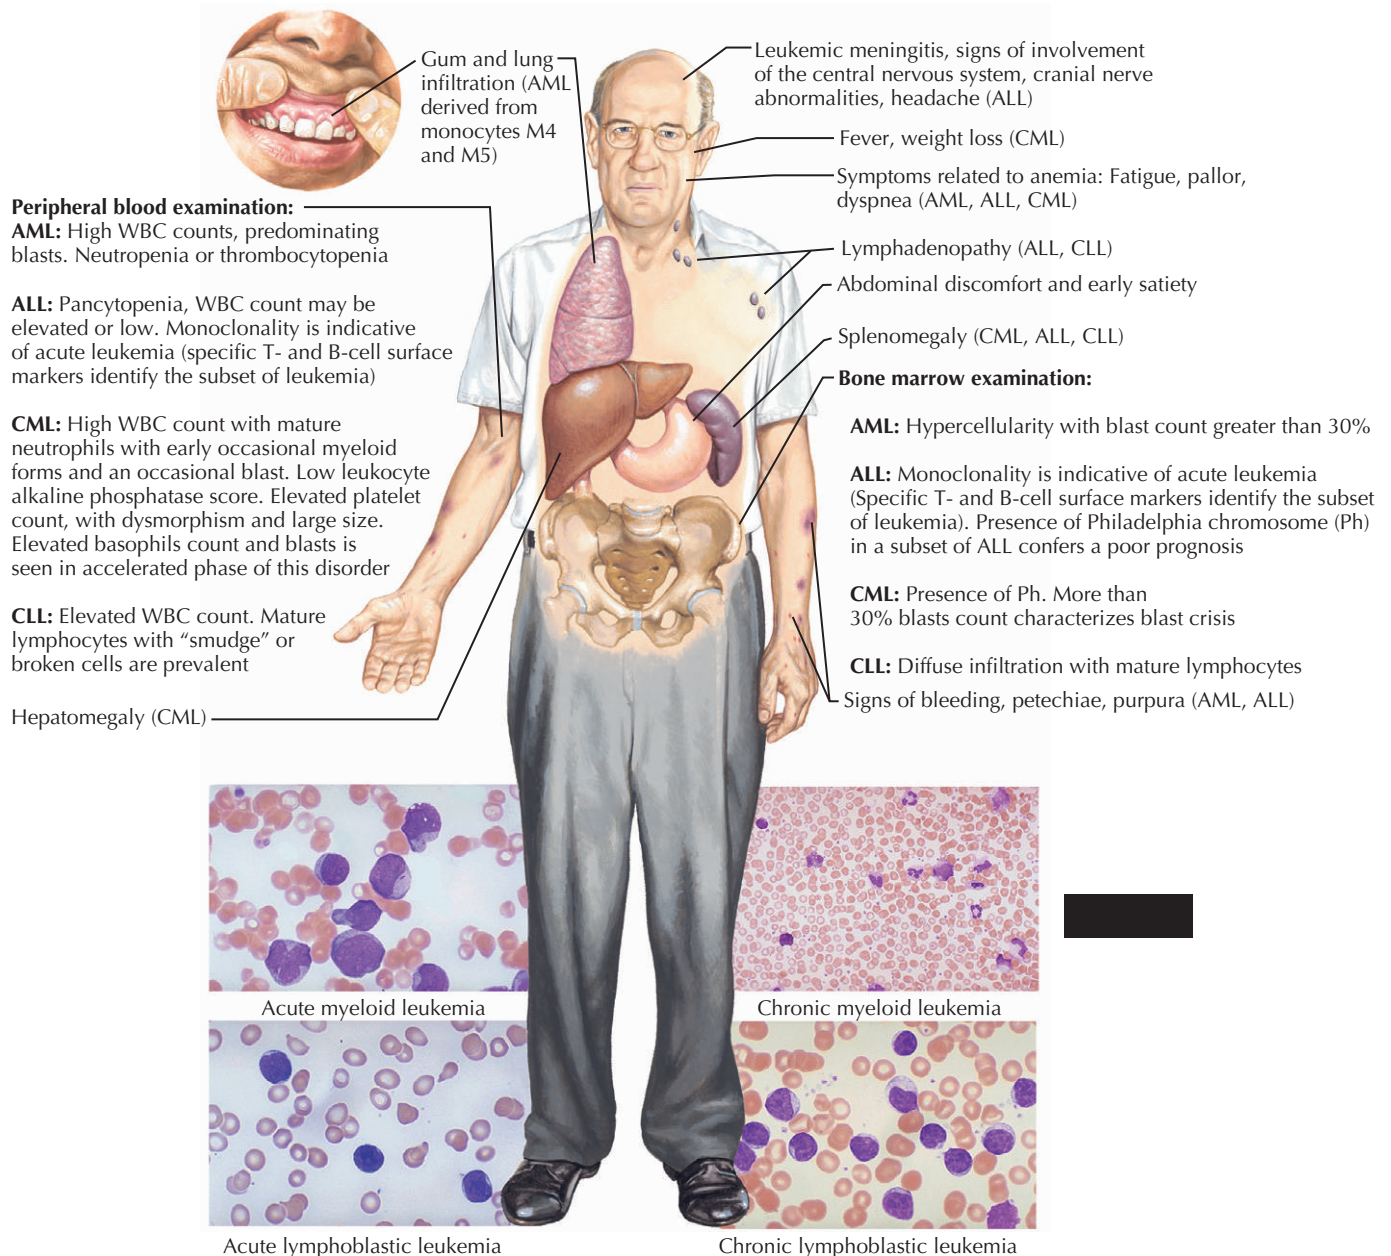

Patients presenting with high white blood counts consisting predominantly of blasts are easily diagnosed based on examination of the peripheral blood smear (Fig. 75-1). Patients with pancytopenia may have acute leukemia on the basis of blasts in the bone marrow only. The differential diagnosis includes aplastic anemia, myelodysplasia, marrow infiltration with fibrosis or tumor, or, rarely, hypersplenism.

Diagnostic Approach

Examination of the peripheral blood smear is always warranted. A bone marrow aspiration and biopsy should be

Figure 75-1 Leukemias: Clinical Presentation of Leukemias.

AML, acute myeloid leukemia; ALL, acute lymphoblastic leukemia; CML, chronic myelogenous leukemia; CLL, chronic lymphocytic leukemia.

performed with requests for flow cytometry and cytogenetics. Bone marrow specimens are generally hypercellular, and a blast count of greater than 30% is diagnostic of acute leukemia.

Management and Therapy

Optimum Treatment

Patients with AML are treated with combination chemotherapy in an attempt to empty the bone marrow of malig-

nant cells and allow normal progenitors to repopulate the marrow. Patients are generally hospitalized for 3 to 4 weeks and require intensive blood product and antibiotic support. Following the induction of remission (less than 5% blasts in the marrow), patients are treated with several cycles of high-dose chemotherapy as consolidation of the remission. Patients with cytogenetic abnormalities portending a poor prognosis or who relapse are candidates for bone marrow transplantation. The overall survival rate is 30% to 40% at 3 to 5 years, with most deaths due to relapse of the disease.

Avoiding Treatment Errors

Because treatment regimens are markedly different for AML and acute lymphoblastic leukemia (ALL), it is critical to definitively classify the leukemic blasts as either myeloid or lymphoid before initiating therapy.

Acute Lymphoblastic Leukemia

Etiology and Pathogenesis

ALLs are associated with cytogenetic abnormalities and translocations. Most frequently they occur in immunoglobulin or T-cell receptor loci that undergo recombination in the normal course of lymphoid maturation and are regions of active transcription. These diseases may also be subcategorized as of pre-T-, T-, pre-B-, or B-cell origin based on their surface markers. The presence of a Philadelphia chromosome (a translocation between chromosomes 9 and 22) occurs in some patients with ALL and has a poor prognosis.

Clinical Presentation

As with AML, ALL presents with anemia and thrombocytopenia (see Fig. 75-1). The white blood cell count may be elevated or low, and blasts have a lymphoid morphology. In contrast to AML, patients with ALL more frequently have lymphadenopathy and splenomegaly. The disease may also involve the central nervous system and present with cranial nerve abnormalities and headache. Lumbar puncture is indicated to make a diagnosis of leukemic meningitis in such cases.

Differential Diagnosis

Toxoplasmosis or acute viral infections such as cytomegalovirus and infectious mononucleosis may present with a reactive lymphocytosis that is difficult to distinguish from an acute leukemia. Appropriate antibody titers in conjunction with suspicion of an infectious etiology should establish the appropriate diagnosis. The leukemic phase of certain lymphomas and the occasional lymphoid blast crisis of chronic myelogenous leukemia are also in the differential diagnosis.

Diagnostic Approach

Examination of the peripheral blood and bone marrow by morphology, cytogenetics, and flow cytometry should establish the diagnosis. Specific T- and B-cell surface markers identify the subset of leukemia. Monoclonality is indicative of an acute leukemia, as opposed to a reactive lymphocytosis, and can be determined by finding identical rearrangements of the immunoglobulin or T-cell receptor loci in all cells.

Management and Therapy

Optimum Therapy

The treatment of ALL consists of intensive induction chemotherapy with multiple drugs and consolidation treatment that is carried out over 1 to 2 years. The regimens are very intensive and include prophylactic intrathecal administration of chemotherapy drugs such as methotrexate and cytosine arabinoside. Although most patients enter remission, patients may relapse years after treatment, and the overall cure rate with chemotherapy alone in adults is roughly 20%, with a worse prognosis for individuals older than 50 years. Childhood ALL has a far better prognosis, with an overall cure rate of more than 80%.

Avoiding Treatment Errors

The management of patients with both AML and ALL requires meticulous supportive care and clinical familiarity with the many complications of therapy; therefore, if possible, patients should be referred to a tertiary care center for treatment. Because patients with acute leukemia can experience a rapid decline in their clinical status, prompt attention to any new or worsening signs or symptoms, such as fever or dyspnea, is warranted.

Chronic Myelogenous Leukemia

Etiology and Pathogenesis

The hallmark of chronic myelogenous leukemia (CML) is the presence of the Philadelphia chromosome (Ph), involving a reciprocal translocation between chromosomes 9 and 22. This leads to the formation of a fusion protein between the bcr region of chromosome 22 and the c-abl tyrosine kinase on chromosome 9. The fusion protein has increased kinase activity and is sufficient to cause the disease in transgenic mice. The disease frequently undergoes progression to a blast crisis form by a progression of genetic changes that have not been well characterized.

Clinical Presentation

CML presents with a high white blood count that may be detected on routine complete blood cell count and splenomegaly in 90% of cases. Patients may complain of generalized fatigue or abdominal discomfort and early satiety. Occasionally, patients present with hypermetabolic symptoms of fever and weight loss. Hepatomegaly is also common. The peripheral blood smear shows mature neutrophils with occasional earlier myeloid forms and an occasional blast (see Fig. 75-1). The platelet count is frequently elevated, and platelets may appear somewhat large and dysmorphic on peripheral smear. An accelerated phase of the disorder is a harbinger of blast crisis and is characterized by progressive splenomegaly and elevation of the white blood cell (WBC) count with basophils and an

increasing percentage of blasts. Blast crisis occurs in untreated patients at a mean of 3 to 4 years from diagnosis and is characterized by more than 30% blasts in the bone marrow of either myeloid or lymphoid type.

Differential Diagnosis

Reactive leukocytosis, resulting most commonly from infection, malignancy, or drug reaction, is the most common entity to be differentiated from CML. Other myeloproliferative disorders, including polycythemia vera and myelofibrosis, also present with elevated WBC counts and splenomegaly. The blast crisis of CML must be distinguished from de novo forms of AML and ALL.

Diagnostic Approach

The Ph, as ascertained from cytogenetic analysis of the peripheral blood or bone marrow, definitively distinguishes CML from both infectious causes of a high WBC count and from other myeloproliferative diseases. ALL may also be associated with a Ph. A leukocyte alkaline phosphatase score may be obtained on peripheral WBCs and is generally high in reactive leukocytosis and low in CML.

Management and Therapy

Optimum Therapy

Patients presenting with a very high WBC count may require initial therapy with hydroxyurea, which controls the blood counts but does not prolong overall survival.

A drug that specifically inhibits the tyrosine kinase activity of the bcr-abl fusion protein (imatinib) is highly effective in inducing hematologic remissions with normalization of blood counts in more than 90% of patients. Unfortunately, many patients develop resistance to imatinib over time. A second bcr-abl tyrosine kinase inhibitor (dasatinib) has recently been approved for patients who are either intolerant of, or have disease resistance to, imatinib. In this setting, dasatinib produces hematologic remissions in about 60% of patients. Because the long-term efficacy of these new tyrosine kinase inhibitors is unknown, the optimum strategy for integrating tyrosine kinase inhibitors and bone marrow transplantation is evolving; however, imatinib and dasatinib offer the least toxicity and highest response rate of any therapy developed to date.

Avoiding Treatment Errors

Imatinib and dasatinib have markedly improved the outlook and quality of life of patients with CML. However, they have also made treatment of young patients with CML increasingly complex. Because the optimal way to integrate these advances into clinical practice is somewhat uncertain, consultation with a physician specializing in malignant hematology is now warranted.

Chronic Lymphocytic Leukemia

Etiology and Pathogenesis

Chronic lymphocytic leukemia (CLL) is the most common type of leukemia, frequently occurring in patients older than 50 years. This disorder involves the accumulation of slowly dividing mature B, or rarely T, lymphocytes in the peripheral blood and bone marrow. The molecular basis for this disorder remains obscure, although a number of different cytogenetic abnormalities have been described. It appears to be associated with an increase in the anti-apoptotic or anti-cell death proteins, such as bcl-2, that characterize the indolent lymphomas.

Clinical Presentation

Patients most commonly present with an elevated WBC count on routine complete blood count (CBC). Most cells are mature lymphocytes (see Fig. 75-1). Other less common presentations include lymph node enlargement, recurrent infections because of the associated hypogammaglobulinemia, or immune-mediated hemolytic anemia or thrombocytopenia. A simple Rai staging classification, which has prognostic import, defines the stage of the disease (Table 75-1).

The anemia and thrombocytopenia in CLL result from decreased production due to bone marrow involvement. In addition to clinical stage, the intracellular tyrosine kinase ZAP-70 has been shown to be useful in further defining the prognosis of CLL. Patients with ZAP-70 expression require treatment an average of 6 years earlier than those with ZAP-70-negative CLL. Whether early treatment in ZAP-70-positive patients alters their accelerated clinical course is not yet known.

Differential Diagnosis

Viral infections, the leukemic phase of non-Hodgkin's lymphoma, and hairy cell leukemia, an unusual lymphoproliferative disease characterized by pancytopenia,

Table 75-1 Rai Staging Classification for Chronic Lymphocytic Leukemia

Stage	Features	Median Survival (yr)
0	Lymphocytosis only ($>5 \times 10^9/L$)	>15
I	Lymphocytosis and lymphadenopathy	8
II	Lymphocytosis and splenomegaly	6
III	Lymphocytosis and anemia (hemoglobin ≈ 1 g/dL)	3
IV	Lymphocytosis and thrombocytopenia (platelets $<100 \times 10^9/L$)	2

splenomegaly, and a distinctive surface marker phenotype, are in the differential diagnosis.

Diagnostic Approach

Examination of the peripheral blood reveals mature lymphocytes, frequently with “smudge” or broken cells characteristic of lymphoproliferative diseases. Bone marrow transplantation may be indicated in patients presenting with cytopenia. Flow cytometry is a useful diagnostic tool in difficult cases. A serum protein electrophoresis and Coombs’ test with reticulocyte count are indicated in patients with recurrent infections and anemia, respectively.

Management and Therapy

Optimum Treatment

Patients with stage 0, I, or II disease can be observed at 3- to 6-month intervals with physical examination and CBC to assess disease progression. Patients with stable disease can be observed annually. Initial therapy for patients with stage III or IV disease is either intermittent treatment with an alkylating agent and prednisone or therapy with fludarabine, a nucleoside analogue. Although fludarabine results in a higher remission rate and longer disease-free intervals, overall survival is similar with the two regimens. Fludarabine results in prolonged immunosuppression, and patients should be monitored for opportunistic infections. Patients with more aggressive CLL or who have failed primary therapy are candidates for combination chemotherapy. Monoclonal antibodies against B-lymphocyte antigens CD20 (rituximab) and CD52 (alemtuzumab) also have activity against CLL, and alemtuzumab has been approved for use in refractory CLL.

Richter’s syndrome represents a transformation of the disease into a more aggressive lymphoma and confers a poor prognosis. Patients with recurrent infections and hypogammaglobulinemia should receive intravenous immunoglobulin. Immune-mediated hemolysis or thrombocytopenia requires treatment of the underlying disease for a good response.

Avoiding Treatment Errors

Consultation with an experienced hematopathologist is critical to ensure the correct diagnosis of CLL, which can be difficult to distinguish from other chronic lymphoproliferative disorders such as hairy cell leukemia. Although ZAP-70 shows promise as a way to select patients who might benefit from more intense therapy early in their disease course, current best evidence still supports watchful waiting until the onset of disease progression or symptoms.

Future Directions

Progress in treating the acute leukemias has been slow. New approaches include the combined use of monoclonal antibodies with chemotherapeutic drugs and stimulation of the host immune system to leukemia-associated antigens. As new molecular mechanisms of oncogenesis are discovered, they will become subjects for specific targeting by pharmacologic agents. CML has opened a new era of tumor-specific therapies that should revolutionize the current approaches to leukemia treatment.

Multiple Myeloma

Introduction

Multiple myeloma is a malignant clonal disorder of plasma cells typically found in the bone marrow. About 15,000 new cases are diagnosed yearly in the United States, with a prevalence of approximately 50,000 patients, making myeloma the second most common hematologic malignancy. The peak incidence occurs in the sixth decade of life, but this disease can also be found in older and younger patients. Certain exposures, such as to radiation or to some chemicals, may modestly increase the risk for developing myeloma, but most patients have no such exposure history. In most patients, multiple myeloma is sporadic, but its incidence in African Americans is twofold higher than in whites, suggesting the possibility of an influence from genetic factors.

Presentation and Evaluation

Patients with multiple myeloma have varied presentations, but common manifestations include bony pain, anemia, renal dysfunction, hypercalcemia, recurring infections, and peripheral neuropathy. Evaluation of any patient begins with a careful history and physical examination (Box 76-1). Bone pain develops secondary to lytic bony lesions or pathologic fractures, including vertebral compression fractures. Fatigue and dyspnea are consequences of anemia caused by marrow involvement, anemia of chronic disease, or in a few cases, high paraprotein levels causing hyperviscosity. Elevation of serum viscosity may also induce mental status changes, congestive heart failure, coagulopathy, and changes on examination of the optic fundus. Serum viscosity measurements aid in the diagnosis of this syndrome, which is a clinical emergency that can be rapidly reversed by plasmapheresis and exchange. Renal insufficiency of varying degrees is seen in up to 40%, and hypercalcemia can occur as a result of osteoclast activation by the myeloma cell and its microenvironment. Recurring infections, especially of the sinopulmonary tract, present as complications of functional hypogammaglobulinemia, as well as granulocytopenia and impaired cell-mediated immunity. Peripheral neuropathies may develop as a result of compression fractures or localized masses of plasma cells, known as *plasmacytomas*, which can induce nerve root impingement. Some patients may present with amyloidosis, which can also cause peripheral neuropathy and other clinical problems, including nephrotic syndrome, congestive

cardiomyopathy, hepatomegaly, macroglossia, carpal tunnel syndrome, periorbital purpura, and malabsorption. Of note, 20% of patients are asymptomatic and come to medical attention because of an abnormality in a laboratory or radiographic evaluation performed for another indication.

The diagnosis of myeloma is ultimately based on laboratory findings, with the hallmark being identification of a monoclonal paraprotein on electrophoresis or immunofixation of the serum or urine (Box 76-2). Most commonly, patients have immunoglobulin G (IgG), IgA, or light chain disease, but IgM, IgD, and IgE myelomas are also seen, as is oligosecretory or nonsecretory disease. This last category means that even patients without a monoclonal protein can have myeloma, and they are diagnosed with a bone marrow aspiration and biopsy. Marrow sampling is important to evaluate the extent of involvement and for cytogenetic studies, including routine karyotyping and fluorescence in situ hybridization. Patients with at least 10% clonal marrow plasmacytosis, a serum or urine paraprotein, and signs of end-organ damage have symptomatic multiple myeloma. Those patients who have no disease-related symptoms have asymptomatic myeloma. Finally, patients with a lower-level paraprotein, lesser marrow involvement, and no symptoms have monoclonal gammopathy of undetermined significance (MGUS). If amyloidosis is suspected, Congo red staining of the marrow can be performed but has a sensitivity of only 50%. More reliable diagnostic tests include biopsies of the kidney, rectum, or gingiva and abdominal fat pad aspirates.

Box 76-1 Diagnostic Evaluation of a Plasma Cell Dyscrasia

Complete history and physical exam
 Complete blood cell count with differential and platelets
 Examination of peripheral blood smear for rouleaux formation
 Creatinine, blood urea nitrogen, and electrolytes
 Calcium and albumin; obtain ionized calcium in the setting of hypercalcemia
 Quantitative immunoglobulins
 Serum protein electrophoresis and immunofixation, with monoclonal protein quantitation
 Random urine collection for protein electrophoresis and immunofixation
 Twenty-four-hour urine collection for total protein, light chain quantitation, and creatinine clearance
 Myeloma skeletal survey, including evaluation of the spine, pelvis, skull, humeri, and femurs; in some patients, magnetic resonance imaging and/or positron emission tomography may be appropriate
 Unilateral bone marrow aspirate and biopsy, with cytogenetics both by routine karyotyping and fluorescence in situ hybridization for characteristic myeloma-associated abnormalities, immunophenotyping, and plasma cell labeling index, if available; bilateral marrow sampling may be of benefit in patients suspected of having oligosecretory or nonsecretory disease
 β_2 -microglobulin, C-reactive protein, and lactate dehydrogenase
 Serum viscosity, if clinically indicated

Box 76-2 Diagnostic Criteria for Plasma Cell Dyscrasias

Monoclonal gammopathy of undetermined significance

- Monoclonal protein in the serum <3.0 g/dL
- Clonal marrow plasmacytosis $<10\%$, if a marrow is done
- No related organ or tissue impairment (see below)
- No signs of another malignancy associated with a monoclonal protein

Asymptomatic multiple myeloma

- Monoclonal protein in the serum ≥ 3.0 g/dL
- Clonal marrow plasmacytosis, usually $\geq 10\%$
- No related organ or tissue impairment (see below)

Symptomatic multiple myeloma

- Monoclonal protein in the serum and/or urine
- Clonal marrow plasmacytosis, usually $\geq 10\%$ *and/or*,
- Documented clonal plasmacytoma
- Related organ or tissue impairment, including at least one of the following:
 - Hypercalcemia (>11.5 mg/dL; >2.65 mmol/L)
 - Renal insufficiency (serum creatinine >2 mg/dL; ≥ 177 μ mol/L)
 - Anemia (hemoglobin <10 g/dL, or 2 g/dL below lower limit of normal)
 - Bone disease (lytic lesions or osteopenia with compression fracture)
 - Symptomatic hyperviscosity
 - Amyloidosis
 - Frequent bacterial infections (>2 in previous 12 months)

Differential Diagnosis

Although one of the hallmarks of multiple myeloma is the presence of a monoclonal protein in the serum or urine, most patients with a paraprotein do not have myeloma. Other malignant entities to consider include Waldenström's macroglobulinemia, amyloidosis, indolent non-Hodgkin's lymphoma, mantle cell lymphoma, and chronic lymphocytic leukemia. Even more common is MGUS, which is generally a benign condition, although it does carry a 1.0% to 1.5% per year risk of progression to one of the hematologic malignancies described earlier. MGUS is also associated with an increased risk for developing solid tumors. Patients with adult T-cell leukemia and lymphoma can present with bony lesions and hypercalcemia reminiscent of myeloma, but often have abnormal circulating lymphocytes and generally do not have a monoclonal protein. Polyclonal increases in immunoglobulins without a paraprotein are often a result of chronic immune stimulation, such as from HIV or hepatitis C virus infection. A variety of autoimmune disorders can also produce a polyclonal increase in immunoglobulins and in some cases may be associated with a low-level monoclonal protein.

Staging and Risk Stratification

Several different staging systems have been used to stratify patients into different risk groups to better predict outcome and guide therapy. The International Staging System, which is based on serum levels of albumin and β_2 -microglobulin (Table 76-1), is superior in its ability to predict overall survival (OS) compared with older approaches. In the future, this may be modified or replaced with systems that incorporate the results of cytogenetics because chromosomal abnormalities can affect the response to, and durability of, both standard and high-dose therapies. DNA ploidy has an impact, in that patients with hypodiploid disease have a shorter survival, whereas hyperdiploid patients have an improved prognosis. Many patients with myeloma are found to have one of several recurring, non-random genetic lesions. Loss of a portion of, or an entire copy of, chromosome 13 is frequently reported and may induce cell cycle dysregulation through loss of the retinoblastoma protein. This genetic abnormality confers an inferior prognosis. Translocations in which one partner is the immunoglobulin heavy-chain locus, such as t(11;14), t(4;14) or t(14;16), and t(6;14), are also frequent, and may affect cell cycle control in part by dysregulation of *cyclin D1*,

Table 76-1 The International Staging System for Multiple Myeloma

Stage	Criteria	Median Overall Survival
I	Serum β_2 -microglobulin <3.5 mg/L and Serum albumin \geq 3.5 g/dL	62 mo
II	Neither stage I nor stage III	44 mo
III	Serum β_2 -microglobulin \geq 5.5 mg/L	29 mo

cyclin D2, or *cyclin D3*, respectively. Interestingly, t(11;14) is associated with a neutral or good prognosis, whereas t(4;14) and t(14;16) confer a poor risk. Other genetic lesions that are found include mutations of the p53 locus at 17p13, *c-myc*, *ras*, and 1q21 lesions that may involve *CKS1B*.

Management and Therapy

Optimum Initial Treatment

Patients with symptomatic multiple myeloma require treatment to reduce tumor burden, ameliorate symptoms, reduce the risk for complications, improve quality of life, and prolong survival. The choice of initial induction regimens is often guided by a decision about whether or not the patient is a candidate for high-dose chemotherapy with autologous peripheral blood stem cell transplantation (PBSCT). Factors that are weighed in this decision include the age and performance status of the patient and the presence of comorbid medical conditions and vital organ compromise. Those patients who are candidates for autologous PBSCT typically undergo initial therapy with regimens that avoid alkylating agents because these drugs damage stem cells and impair their collection in adequate numbers.

For patients who are older or who for another reason are not candidates for PBSCT, initial therapy has in the past consisted of a combination of the alkylator melphalan (Alkeran) and prednisone (MP; Fig. 76-1). Recent studies have added novel agents to the MP backbone, and results with the MPT regimen, incorporating the immunomodulatory and antiangiogenic agent thalidomide (Thalomid), have been encouraging. Two randomized trials have shown that MPT induced a higher overall and complete response rate, as well as a superior time to progression (TTP) and OS, suggesting MPT should be the standard of care for this population. Unfortunately, MPT carries with it a higher risk for toxicities, including thromboembolic and infectious complications, with the former indicating the need for concurrent prophylactic anticoagulation. MP is still, therefore, acceptable in patients of very advanced age or poor performance status and organ function. Current studies are investigating the utility of adding other agents,

such as lenalidomide (Revlimid) or the proteasome inhibitor bortezomib (Velcade), to the MP regimen. In some cases, it may also be appropriate to utilize an induction therapy more typically used in younger, transplant-eligible patients. Barring toxicity or disease progression, treatment is continued until either a complete remission is achieved or patients enter a plateau phase, with 3 months of stable disease despite continued therapy. Induction is then stopped in favor of watchful waiting, or patients may receive maintenance therapy.

In patients who are eligible for PBSCT, induction therapy with four to six cycles is pursued to reduce the disease burden before stem cell mobilization. One regimen used commonly combines infusional doxorubicin (adriamycin) and vincristine with oral dexamethasone, or a similar combination except using pegylated liposomal doxorubicin (Doxil; DVd). An oral combination of thalidomide with dexamethasone (thal/dex) appears to provide a higher overall response rate of 60% to 70% and may result in a prolonged TTP and OS in patients who do not proceed to transplantation. Lenalidomide with dexamethasone seems to improve upon these benefits further and may be less toxic than thal/dex, although both require prophylactic anticoagulation because of the risk for thromboembolic complications. Studies with hybrid regimens, such as DVd with thalidomide, have shown response rates approaching or exceeding 90%, with a high proportion of complete responses. However, these regimens are more toxic, and long-term follow-up is needed to determine whether the higher response rates will translate into a benefit after PBSCT. Bortezomib is also being actively investigated in combination with some of the agents described earlier in the front-line setting.

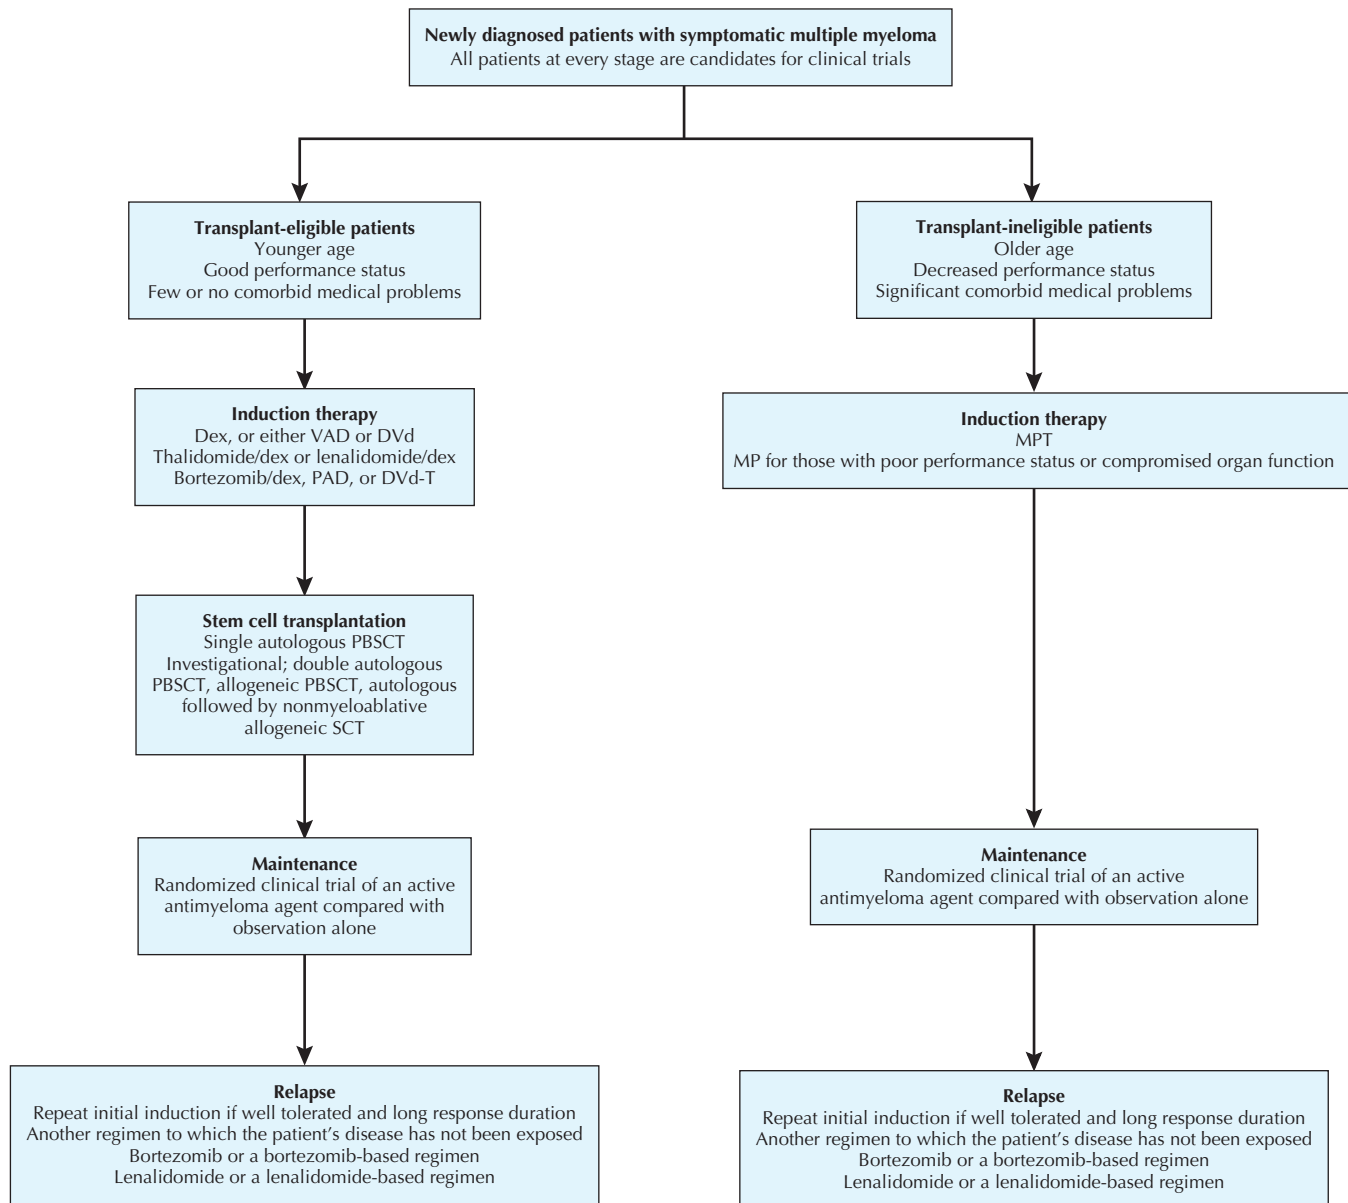

Supportive care is an important aspect of the multidisciplinary approach to multiple myeloma. Bisphosphonates, such as pamidronate (Aredia) and zoledronate (Zometa), reduce the risk for pathologic bony fractures in patients with lytic lesions or osteoporosis and compression fractures and may also affect survival. Their risks include acute flu-like infusion-related reactions, renal insufficiency, and jaw osteonecrosis with extended use. Erythropoietic agents (Aranesp, Epogen, or Procrit) affect disease- and treatment-related anemia and improve quality of life while reducing transfusion requirements, although care should be taken to not exceed a hemoglobin value of 12.0 g/dL with their use. Kyphoplasty or vertebroplasty in patients with acute vertebral compression fractures and pain can provide significant relief of pain and reduce the need for analgesics. Local radiation therapy can also be of benefit in pain control and is helpful for patients with solitary plasmacytomas as well.

Transplantation Options

High-dose chemotherapy for myeloma is employed in an attempt to extend both the event-free survival and the OS.

Figure 76-1 A Current Treatment Algorithm for Multiple Myeloma.

A current treatment algorithm for patients who are or are not suitable candidates for stem cell transplantation is presented. Further detail is provided in the text. Dex, dexamethasone; DVd, pegylated liposomal doxorubicin with vincristine and oral dexamethasone; DVd-T, DVd with thalidomide; MP, melphalan and prednisone; MPT, melphalan and prednisone with thalidomide; PAD, bortezomib with infusional doxorubicin and dexamethasone; PBSCT, peripheral blood stem cell transplantation; SCT, stem cell transplantation; VAD, infusional doxorubicin and vincristine with oral dexamethasone.

Several randomized studies comparing single autologous PBSCT after induction chemotherapy with a chemotherapy-only approach have shown an advantage for transplantation. Complete remissions can be achieved in up to 40% or more of patients, and median OS of up to 5 years or more can be seen, with a 100-day transplant-related mortality (TRM) rate of less than 2% to 3%. Some studies suggest that a tandem approach, in which two auto-

PBSCTs are performed, with the second shortly following the first, may be superior to a single transplantation. Unfortunately, most patients ultimately relapse, probably because of residual myeloma present in the patient despite conditioning with high-dose melphalan, or contamination of the stem cell product with plasma cells, or both. As a result, there has been interest in following a single auto-PBSCT with a reduced-intensity, nonmyeloablative

approach, using stem cells from a matched allogeneic donor that would not be contaminated with myeloma and would induce a graft-versus-myeloma effect. In younger patients, a fully ablative allogeneic transplant may be an option as well, but these approaches are complicated by graft-versus-host disease, and the latter is plagued by a high TRM.

Maintenance Therapy

Because front-line myeloma therapy is not curative, a maintenance approach with a lower dose of an active anti-myeloma agent is an attractive strategy to prolong the response duration. For patients treated with conventional dose regimens, no studies have shown a benefit in OS for any currently available drug when compared with observation alone. In patients who have received high-dose therapy with stem cell support, interferon was shown to improve survival by about 6 months, but its use was complicated by significant toxicities. Recently, thalidomide has been shown to improve post-transplantation event-free survival by more than 10 months, and also to improve overall survival. Lenalidomide, as well as other agents such as bortezomib, continue to be studied in this setting.

Treatment of Relapsed and Refractory Disease

Despite the use of induction chemotherapy, and even of autologous PBSCT, multiple myeloma will relapse and become symptomatic again in most patients, who then need additional therapy. In some cases, it may be appropriate to repeat whatever regimen was used previously, especially if it induced a remission of 6 to 12 months or more. Responding patients treated with such an approach typically have a remission duration one half the length of that seen previously. More commonly, patients are treated with a single-agent or combination regimen to which their disease has not been previously exposed. Bortezomib was the first new drug recently approved for therapy of relapsed and refractory disease, and in a randomized study induced a superior response rate, TTP, and OS compared with dexamethasone alone. Combination regimens based on bortezomib have even greater activity, and bortezomib with pegylated, liposomal doxorubicin has been shown to be superior to bortezomib alone. A second, newly approved agent is the novel immunomodulatory drug lenalidomide, which in combination with dexamethasone, was shown to be superior to dexamethasone alone and to improve TTP and OS.

Avoiding Treatment Errors

It is important to perform a full initial evaluation because patients with asymptomatic multiple myeloma do not

benefit from early initiation of therapy, whereas those with symptomatic disease should generally be started promptly on treatment. Careful assessment of renal function and correction of abnormalities, when possible, is important before the initiation of therapy because several of the commonly used agents, including melphalan and lenalidomide, may need to be dose-adjusted in patients with renal insufficiency. Also, cytogenetic studies and fluorescence in situ hybridization probing for myeloma-associated chromosomal abnormalities are becoming increasingly important both prognostically and in deciding on optimal therapeutic strategies. For example, patients with t(4;14) have a poor outcome after autologous stem cell transplantation and may be candidates for novel chemotherapeutic approaches or allogeneic transplantation, whereas patients with deletion 13 may respond especially well to bortezomib-containing regimens.

Future Directions

Even though multiple myeloma remains an incurable disease, recent advances that have been incorporated into the current treatment algorithm (see Fig. 76-1) have produced a significant trend toward an improving OS. Many novel agents being studied in the relapsed and refractory disease population are showing promising results, including heat shock protein 90 inhibitors and monoclonal antibodies to interleukin-6, among others. Therefore, all patients should be considered candidates for clinical trials, which offer access to new, promising drugs that usually have been extensively validated in increasingly physiologically relevant preclinical models. It is likely that our expanding knowledge of the molecular pathogenesis of multiple myeloma will lead, in the near future, to a risk-adapted and cytogenetically adapted treatment strategy that will personalize therapy for patients and bring us closer to a cure for this disease.

Hematopoietic Stem Cell Transplantation

Introduction

During the past three decades, hematopoietic stem cell transplantation (HSCT) has been established as curative therapy for hematopoietic malignancies, marrow failure syndromes, primary immunodeficiencies, and genetic disorders. Current efforts are improving the efficacy of this therapy and expanding its role in the treatment of other disorders such as the hemoglobinopathies and autoimmune diseases. Underlying the use of HSCT is the principle of dose response in regard to tumor cell kill (i.e., increasing dose overcomes drug resistance and eradicates more malignant cells). The ensuing pancytopenia following marrow-ablative therapy is abrogated by the infusion of stem cells from either an autologous or allogeneic (histocompatible donor) source (Fig. 77-1). In the autologous setting, tumors that are still responsive to standard doses of chemotherapy (chemosensitive disease) respond even better to the dose escalation used in transplantation. Additional benefits of allogeneic transplantation include the infusion of a tumor-free stem cell graft and the graft-versus-tumor (GVT) immune effect mediated by donor cells against residual host cancer cells. This concept has recently led to treatments that use lower doses of chemotherapy or irradiation, so called nonmyeloablative or reduced intensity transplantations, which focus on establishing a stable donor graft to allow for GVT with less emphasis on direct cytotoxicity from the conditioning regimen itself. Advances in the fields of immunology, infectious disease, and transfusion medicine have all contributed to the encouraging results listed in Table 77-1.

Management and Therapy

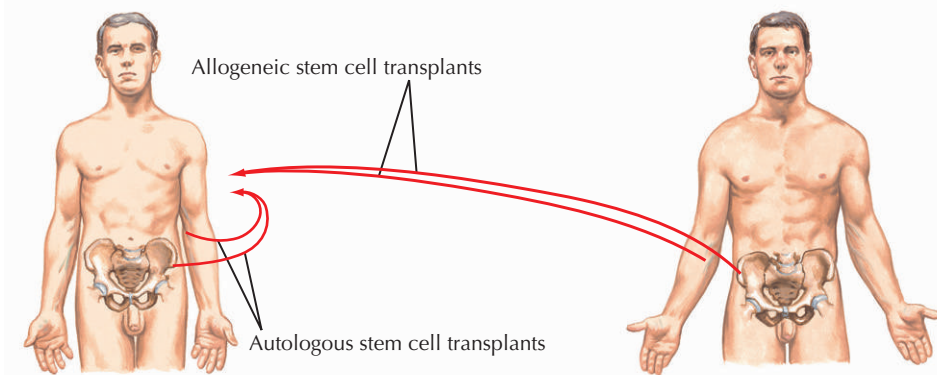

The decisions regarding application and initiation of transplantation are complex and best addressed by early referral to centers with experience in a full-range of options regarding the use of autologous versus allogeneic transplants as well as the different types of donor cells available. Maintaining good communication with the transplantation center is critical to the successful long-term management of patients after they are discharged and reintegrated into their local health care system. This is particularly important in managing allogeneic transplant recipients who may develop opportunistic infections or graft-versus-host disease (GVHD) requiring the long-term use of immunosuppressive medications.

Autologous Transplantations

Prospective trials have identified a disease-free survival and overall survival benefit for autologous transplantations over conventional therapy in relapsed Hodgkin's and non-Hodgkin's lymphoma and multiple myeloma. Numerous phase II trials also attest to the value of autologous transplantation in patients with acute myelogenous leukemia (AML) in second complete remission. Although autologous transplantation is better tolerated than allogeneic transplantation, it is not feasible in patients with significant residual disease in the marrow and is generally unsuccessful in disease that is resistant to conventional doses of chemotherapy. Although conceptually attractive, the value of removing contaminating tumor

In autologous transplantation, the patient is the source of the stem cells (the patient is the donor and the host at the same time). When the stem cells come from another person who is a histocompatible donor, this is called allogeneic transplantation

cells from reinfused products, so-called purging, remains unproved.

Allogeneic Transplantations

The decision to undergo an allogeneic transplantation depends on the underlying disease, the existing age and comorbidities of the patient, and the availability of a suitable donor. The decreased leukemia relapse rate after allo-

geneic transplantations compared with that after identical twin (syngeneic) or autologous transplantations exemplifies the advantage of a GVT response. Mild chronic GVHD enhances GVT in diseases such as chronic myelogenous leukemia (CML) and is associated with a decreased relapse rate. This immune effect is also the basis for treating recurrent disease after transplantation with infusions of lymphocytes collected from the donor (donor lymphocyte infusions). Usually, allogeneic transplantation is pref-

Table 77-1 Diseases Responsive to Hematopoietic Stem Cell Transplantation

Disease	Type of Transplantation	Timing	Clinical Results
AML	Allogeneic Autologous	CR 2 or high-risk CR 1 CR 1 or CR 2 if no donor available	OS 30%-60% OS 30%-40%
ALL (children)	Allogeneic	Second CR	OS 40%-65%
ALL (high risk)	Allogeneic	First CR	OS 50%
CML	Allogeneic	Tyrosine kinase (imatinib) resistant	OS 50%-60%
Myelodysplastic syndrome	Allogeneic	Age <65 yr	OS 40%
Aplastic anemia	Allogeneic	Individualized	OS 70%-90%
CLL	Allogeneic or autologous	Participation in clinical trial	Small series of patients with durable CR. Nonablative transplantation under investigation
Intermediate-grade NHL	Autologous	Chemosensitive relapse	OS 40%-50%
High-risk NHL	Autologous	First CR	OS 50%-60%
Low-grade NHL	Allogeneic or autologous	Chemosensitive relapse	DFS 25%-50% at 5 yr
Mantle cell lymphoma	Allogeneic or autologous	First CR	Small series with autologous durable CR rates of 25%-50%
Hodgkin's disease	Autologous	Chemosensitive relapse	15%-25% DFS
Multiple myeloma	Autologous	Chemosensitive relapse or first remission	5-yr OS 50%; DFS of 20%
Thalassemia	Allogeneic	Clinical trial	OS 75% for patients without cirrhosis
Sickle cell anemia	Allogeneic	Clinical trial	OS 75%
Autoimmune disorders	Allogeneic or autologous	Clinical trial	Small series of remissions

CR, complete response; DFS, disease-free survival; OS, overall survival; AML, acute myelogenous leukemia; CLL, chronic lymphocytic leukemia; CML, chronic myelogenous leukemia; ALL, acute lymphocytic leukemia; NHL, non-Hodgkin's lymphoma.

erable for relapsed leukemias and patients with refractory lymphomas because of the immune effect of the donor cells against residual tumor and the lack of contaminating tumor cells in the infusion product. Early identification and transplantation in patients with high-risk features who are destined to do poorly with standard therapies optimize the chance for cure in such settings.

Histocompatibility

Major histocompatibility class I (human leukocyte antigens [HLA]-A, -B, -C) and class II (HLA-D, -DR, -DQ, -DO, -DN, -DP) antigens are the HLA used to determine patient-donor compatibility. Six alleles from three HLA antigens (A, B, and DR) are used for routine typing of siblings. A six-for-six match is considered to be an HLA identical full match. Additional alleles can be evaluated for unrelated donor transplantations.

Donor Availability

Matched sibling donors are available for about 30% of patients and have historically been preferred over partially matched or unrelated donors because of the decreased risk for graft rejection and GVHD. The National Marrow Donor Program includes a registry with more than 5.5 million volunteer donors that can provide a match for

about 80% of patients overall, with the probability of finding a donor varying by the patient's racial and ethnic background. Transplantations using umbilical cord blood cells or cells from donors who are mismatched at more than one allele are available for certain patients at a limited number of centers. Virtually all patients have a haplotype or three-antigen-matched donor, provided they have a living first-degree relative. The infusion of large numbers of stem cells, depletion of T cells from the donor product, and aggressive immunosuppression may overcome the high risk for acute graft rejection and severe GVHD in these transplant recipients.

Sources of Hematopoietic Stem Cells

Bone Marrow

Marrow harvesting usually requires general anesthesia and multiple aspirations from the iliac crest. Typically, 15 to 20 mL/kg recipient body weight, yielding a minimum of 2×10^8 nucleated cells/kg, is adequate for engraftment. Donors usually go home the same day and seldom require more than oral analgesics for 1 to 2 days postoperatively.

Peripheral Blood

Low numbers of stem cells expressing the CD34 surface antigen exist in the peripheral blood under normal circumstances. This number can be markedly increased, allowing

for collection by a process called *apheresis*, following treatment with granulocyte colony-stimulating factor (G-CSF) alone, or, for autologous transplant recipients, G-CSF plus chemotherapy. Advantages over bone marrow infusions include more rapid hematopoietic recovery and decreased transplantation-related mortality. This process does, however, result in the infusion of 10 times more donor T cells in allogeneic transplants, leading to an increased risk for GVHD. This complication is offset by earlier graft recovery and a lower risk for both infection and relapse and has led to peripheral blood becoming the most common stem cell source for both related and unrelated adult allogeneic transplantations. In children, however, especially in the treatment of nonmalignant diseases such as aplastic anemia, related donor marrow may be preferred to stem cells because of the decreased risk for GVHD.

Umbilical Cord Blood

Hematopoietic stem cells are present in umbilical cord blood and can be collected from the placenta after delivery. Because neonatal lymphocytes remain immunologically naive, they are less likely to result in GVHD and permit the use of partially matched patient-donor pairs. The ability to undertake transplantation with mismatched donors and the rapid availability of frozen and stored cord blood products are the major advantages of this approach. Disadvantages include delayed engraftment and an increased risk for infection. Currently, umbilical cord transplantations are used primarily for children, but research on in vitro stem cell expansion and use of multiple cord blood products may allow for the more widespread use of this approach in adult patients.

Transplantation-Related Therapy

Conditioning Regimens

Preparative regimens given before allogeneic stem cell or bone marrow infusion are designed to eradicate the underlying disease and permit engraftment of donor stem cells without rejection. Full myeloablation of the hematopoietic system may be accomplished by total-body irradiation (TBI) or high-dose busulfan. In addition to marrow aplasia and infection, major toxicities include infertility, lung and liver toxicity, and severe mucositis. Each of these treatments is generally administered with other agents to augment both the immunosuppressive and antitumor effect of the treatment. In the autologous setting, a variety of combination regimens have been used including TBI-cyclophosphamide-etoposide and carmustine-etoposide-cytarabine-melphalan (BEAM).

There has also been interest in the integration of radioimmunotherapy (RIT) into both autologous and allogeneic transplantation conditioning regimens. RIT involves coupling radioactive isotopes to monoclonal antibodies directed at molecular targets found on the surfaces of

malignant cells. Such a therapeutic strategy permits the targeting of high levels of radiation directly to a tumor, thereby minimizing damage to adjacent, normal tissues. Iodine-131 tositumomab and yttrium-90 ibritumomab are currently approved at nonmyeloablative doses for the management of non-Hodgkin's lymphoma. In the allogeneic setting, protocols incorporating immunoconjugates directed against CD33, CD45, and CD66 are currently underway to augment therapy for patients with leukemia, myelodysplastic syndrome, and lymphoma. The toxicity of such approaches does not appear greater than with chemotherapy alone, and efficacy may be improved compared with historical controls.

Nonmyeloablative regimens consisting of immunosuppressive drugs such as fludarabine and cyclophosphamide, low-dose TBI, and most recently RIT have been used to establish a mixed-chimera hematopoietic state (both donor and host cells). In less aggressive tumors such as the chronic leukemias or indolent lymphomas, the advantages of this strategy include less toxicity and a shorter duration of pancytopenia while maintaining a GVT effect. Early efficacy data using this approach has been encouraging, with complete remission rates approaching 85% in CML, chronic lymphocytic leukemia (CLL), and the low-grade lymphomas. Also, because of the reduced acute toxicity of the nonmyeloablative conditioning regimens, stem cell transplantation is becoming a viable treatment alternative for increasing numbers of older patients. Since 1984, the number of transplantations performed for those older than 50 years has risen more than in any other age group, with such patients currently receiving nearly 20% of all allogeneic transplantations for AML, acute lymphocytic leukemia, and CML.

Immunosuppression

The main factor allowing allogeneic transplantation is the use of medications that dampen the T-cell response. Agents such as methotrexate, corticosteroids, and cyclosporine or tacrolimus are used to prevent graft rejection and GVHD during the initial period after transplantation. Additional agents such as antithymocyte globulin and alemtuzumab have also been used both before and immediately after transplantation in an effort to prevent GVHD. Both agents are clearly effective in reducing the incidence and severity of acute and chronic GVHD, but they may increase the risk for infectious complications, graft rejection, and disease relapse, depending on the particular dosing regimen used. Newer anti-inflammatory medications such as infliximab, etanercept, rituximab, and daclizumab have been successfully used in the management of established acute or chronic GVHD but also may increase the risk for infectious complications.

Transfusion Therapy

Transfusions for immunosuppressed patients require removal of leukocytes from infused blood products to

Table 77-2 Comparison of Complications between Autologous, Allogeneic, and Nonmyeloablative Transplantations

Complication	Autologous	Allogeneic	Nonablative
Bacterial infection	3+	4+	2+
Viral infections	1+	4+	4+
Fungal infections	1+	4+	4+
Graft vs. host	—	3+	2+
Graft rejection	Slow recovery 1+	2%-5%	5%-10%
Graft vs. tumor	—	2+	3+
Veno-occlusive disease	1%-3%	5%	Rare
Relapse	4+	2+	3+
Secondary myelodysplastic syndrome or acute myelogenous leukemia	5%-15%	—	—
Treatment-related mortality	5%	20%-40%	15%-25%

lower the risk for alloimmunization and cytomegalovirus (CMV) transmission. Blood products must also be irradiated after transplantation to reduce the risk for transfusion-associated GVHD. These measures should be continued as long as patients are receiving immunosuppressive medication or have evidence of GVHD.

Transplant Complications

Treatment-Related Morbidity and Mortality

Weighing the risk for disease relapse and the potential for cure with transplantation against the likelihood of treatment-related effects on quality of life are paramount considerations for both the transplantation team and patient (Table 77-2). Overall mortality rates with allogeneic transplants range from 15% to 50% in the first 1 to 2 years, depending on patient age, organ function, and quality of the patient-donor match. Early toxicity for nonmyeloablative transplant regimens is generally low, although delayed GVHD remains a significant risk, and long-term treatment-related mortality (TRM) may be similar to fully ablative regimens. TRM rates vary from 2% to 10% for autologous transplants, depending primarily on the type and stage of malignancy, age and physiologic status of the patient, and conditioning regimen used. Although complications are more common following allogeneic transplantation than autologous transplantation, the risk for relapse is substantially higher for most autologous transplant recipients. These variables lead to complex decisions that are best made by an informed patient at an experienced center where multiple options are available.

Graft-versus-Host Disease

The degree of HLA disparity is directly associated with the incidence and severity of GVHD. More severe GVHD has historically been observed with matched unrelated or mismatched donor transplants, although outcomes comparable to those of matched related donor transplants are now being reported as a result of recent advances in

immunosuppression and HLA typing. Acute GVHD by definition occurs before day 100 and develops in 10% to 70% of matched sibling transplant recipients. Chronic GVHD occurs beyond day 100 and manifests as a persistent autoimmune reaction against the host's skin, gut, and liver. Although mild GVHD is associated with a decreased relapse rate, severe GVHD conveys a poor quality of life and higher risk for TRM. The incidence of acute and possibly chronic GVHD appears to be reduced with the use of nonmyeloablative conditioning regimens compared with fully ablative protocols.

Infection

Bacterial infections occur early after transplantation during the period of neutropenia and mucosal injury. Infection with CMV and other viral pathogens, such as adenovirus, usually occurs 30 to 100 days after transplantation. The risk for bacterial, fungal, and viral infection continues with prolonged immunosuppression and can present months to years later as unexplained fevers (see Fig. 77-1). Patients requiring prolonged immunosuppression for GVHD are at risk for rapidly fatal bacterial infections with encapsulated organisms such as streptococcus and pneumococcus. Fevers in these patients must be treated aggressively with broad-spectrum antibiotics while the underlying cause is being investigated. Reactivation of varicella zoster occurs in 30% to 40% of patients, typically within 12 months of transplantation. Life-threatening dissemination may occur if not recognized and treated early with medications such as acyclovir. Fungal infections with invasive organisms such as aspergillosis or mucormycosis can also be seen in patients on long-term immunosuppressive therapy. Amphotericin B has been the mainstay of management for presumed and documented invasive fungal infections in transplant recipients but is now being replaced by newer agents such as liposomal amphotericin B, voriconazole, and caspofungin. These agents have less renal and infusion toxicity than amphotericin, with comparable or improved efficacy in most situations.

Avoiding Treatment Errors

Most HSCT recipients are closely monitored at an experienced center after transplantation. Such patients, however, do occasionally present to local physicians and emergency departments with urgent complications. It is important to realize that such patients, in particular those undergoing allogeneic procedures, may continue to demonstrate qualitative immune system dysfunction for months or even years after the recovery of their blood counts, and that this increases their risk for serious opportunistic infectious complications. Findings such as fever, cough, skin rash, and pain should be aggressively worked up because HSCT patients can rapidly decompensate. When questions do arise, local physicians are encouraged to directly contact the patient's transplantation center for additional advice.

Future Directions

Continued improvements in supportive care and expansion of the donor transplant pool through the use of cord blood cells, mismatched, and matched unrelated donors will continue to increase the number of transplantation candidates in upcoming years. Combining vaccines and other immunotherapy approaches with either autologous or allogeneic transplantation will be used to eliminate tumor cells and the risk for relapse in the future, and approaches using regulatory T-cell infusions, total lymphoid irradiation, and new immunosuppressant agents are being investigated for the prevention and treatment of GVHD.

This retrospective analysis from the United States demonstrates similar long-term outcomes between leukemia patients receiving mismatched umbilical cord stem cells and those receiving bone marrow from mismatched, unrelated, adult donors.

5. Philip T, Guglielmi C, Hagenbeek A, et al: Autologous bone marrow transplantation as compared with salvage chemotherapy in relapses of chemotherapy-sensitive non-Hodgkin's lymphoma. *N Engl J Med* 333(23):1540-1545, 1995.

This important study, also known as the Parma trial, demonstrates improved event-free and overall survival in patients with relapsed non-Hodgkin's lymphoma treated with autologous stem-cell transplantation versus traditional, salvage chemotherapy.

6. Press OW, Eary JF, Gooley T, et al: A phase I/II trial of iodine-131-tositumomab (anti-CD20), etoposide, cyclophosphamide, and autologous stem cell transplantation for relapsed B-cell lymphomas. *Blood* 96(9):2934-2942, 2000.

This important early study demonstrates the feasibility of combining radioimmunotherapy with traditional cytotoxic agents in the autologous HSCT setting for relapsed non-Hodgkin's lymphoma.

7. Tallman MS, Gray R, Robert NJ, et al: Conventional adjuvant chemotherapy with or without high-dose chemotherapy and autologous stem-cell transplantation in high-risk breast cancer. *N Engl J Med* 349(1):17-26, 2003.

This landmark trial demonstrates a lack of benefit for HSCT compared with traditional chemotherapy for high-risk breast cancer.

8. Tauro S, Craddock C, Peggs K, et al: Allogeneic stem-cell transplantation using a reduced-intensity conditioning regimen has the capacity to produce durable remissions and long-term disease-free survival in patients with high-risk acute myeloid leukemia and myelodysplasia. *J Clin Oncol* 23(36):9387-9393, 2005.

This study demonstrates that reduced-intensity transplantations are effective in producing long-term remissions of both acute leukemia and myelodysplasia, despite their reduced toxicity compared to traditional allogeneic HSCT regimens.

Lung Cancer

Introduction

Lung cancer is diagnosed in about 170,000 people annually in the United States. It is the second most common cancer in men (behind prostate) and in women (behind breast), accounting for 14% of all cancers in men and 13% in women. It is the most common cause of cancer-related death, with about 160,000 deaths annually. In men, the number of lung cancer deaths has been decreasing since the late 1980s, but it still accounts for 31% of all cancer deaths. In women, lung cancer deaths surpassed breast cancer deaths in 1986 and now account for 25% of all cancer deaths. The number of deaths from lung cancer exceeds deaths from colon, breast, prostate, and pancreatic cancer combined (Fig. 78-1).

Etiology and Pathogenesis

Smoking is the major risk factor for lung cancer. Although 85% to 90% of all patients have a history of direct exposure to tobacco, it is likely that the cause of lung cancer is multifactorial. Susceptibility clearly plays a role because most lifetime smokers do not develop lung cancer. A dose-response relationship exists between the number of cigarettes smoked and lung cancer risk. Once smoking cessation occurs, risk decreases but remains above the risk of lifetime nonsmokers for at least 18 years. More than half of all lung cancers are diagnosed in current nonsmokers. Other risk factors are shown in Box 78-1.

Lung cancer is classified into two major categories (Table 78-1): small cell lung cancer (SCLC) and nonsmall cell lung cancer (NSCLC). Each category and subtype of lung cancer has variations in the histology and degree of differentiation. About 1% to 4% of lung cancers have mixed histology consisting of both small cell and nonsmall cell. The differentiation by pathologists between SCLC and NSCLC is good (>90%). However, it is not 100%, and careful attention to the clinical presentation is necessary.

Clinical Presentation

The clinical presentation of lung cancer (Table 78-2) is generally related to symptoms referable to the disease in the chest or to disease at sites of metastasis. The most common chest symptoms are cough, dyspnea, chest pain,

and hemoptysis. Other symptoms resulting from invasion into or obstruction of vital thoracic structures may include superior vena cava syndrome, pleural or pericardial effusion, postobstructive pneumonia, and Pancoast's syndrome.

Metastatic disease may occur anywhere, but the most common sites include the liver, adrenals, bone, brain, and lymph nodes. Patients often present with symptoms referable to sites of metastases including bone pain, seizures, hemiplegia, or hepatomegaly. Generalized symptoms such as weight loss, fatigue, malaise, and anorexia are very common and occur more often with advanced disease.

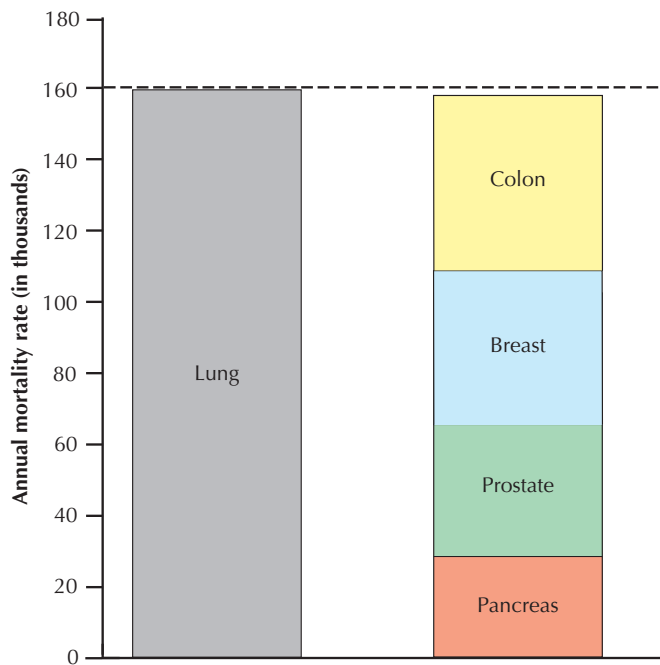

Several paraneoplastic syndromes are associated with lung cancers, including the syndrome of inappropriate antidiuretic hormone, hypercalcemia, gynecomastia, and Cushing's syndrome, and several neurologic syndromes, including Eaton-Lambert syndrome, cerebellar degeneration, peripheral neuropathy, and dementia.

Screening

The role of screening remains controversial. Table 78-3 shows trials published to date in which chest radiograph with or without sputum cytology were performed. No clear benefit was demonstrated when lung cancer mortality was the end point. These trials involved men only and really addressed less intense versus more intense screening strategies. The message is that screening has not been adequately addressed, rather than ineffective. Recent efforts have focused on the role of spiral computed

tomography (CT) scans for screening. Preliminary studies suggest that lung cancer can be found at an earlier stage, but the impact of this approach on survival remains uncertain. The results of several ongoing randomized trials are awaited and will help clarify the role of screening. The National Lung Cancer Screening Trial in the United States has randomized about 50,000 people to either plain chest x-ray or spiral CT scan. Until these results, as well as results from other similar trials, become available, routine screening cannot be recommended.

Diagnostic Approach

Histologic or cytologic confirmation is required to make the diagnosis of lung cancer. All patients should have multidisciplinary input into the optimal approach to making the diagnosis using the chest CT scan and positron emission tomography (PET) scan for direction. Options include sputum cytology, bronchoscopy, transthoracic fine-needle aspiration (TTFNA), endoscopic esophageal or bronchial ultrasound-guided fine-needle aspiration, cervical mediastinoscopy or anterior mediastinotomy, and biopsy or fine-needle aspiration of a metastatic site.

Sputum Cytology

This method is the least invasive, but accuracy depends on rigorous sample collection and optimal preservation. The

sensitivity is about 65% and highly dependent on tumor size and location (large central tumors have the highest sensitivity rates). There is a 2% false-positive rate and a 10% false-negative rate.

Bronchoscopy

The overall sensitivity of bronchoscopy is 80% to 85% in central tumors and 60% to 65% in more peripheral lesions. In tumors smaller than 2 cm, the sensitivity is less than 33%.

Transthoracic Fine-Needle Aspiration

The overall sensitivity of TTFNA is 88%, specificity is 97%, and a false-positive rate is 1%. It carries a 27% false-negative rate, so lesions highly suspicious for lung cancer should still be considered malignant even with a negative TTFNA.

Endoscopic Esophageal or Bronchial Ultrasound-Guided Fine-Needle Aspiration

Newer approaches using endoscopic transesophageal or transbronchial techniques are currently available that may be the optimal approach depending on the findings on chest CT scan. The transesophageal approach is complementary to mediastinoscopy. With careful selection of patients, the overall sensitivity is 80% or greater with rates of specificity approaching 100%.

Cervical Mediastinoscopy or Anterior Mediastinotomy

Mediastinal lymph node sampling is often the method of diagnosing lung cancer. A cervical mediastinoscopy involves an incision in the sternal notch and sampling lymph nodes with the mediastinoscope in the paratracheal and subcarinal spaces. Important stations for sampling are shown in bold in figure 78-2. A station designates a specific anatomic location of an intrathoracic lymph node as defined by the American Joint Committee on Cancer [Fig. 78-2]. In tumors arising in the left upper lobe, it is necessary to sample nodes in the aortopulmonary window through an anterior mediastinotomy. This procedure involves an incision in the left second intercostal space and direct visualization of the anteroposterior window (station 10).

Biopsy or Fine-Needle Aspiration of a Metastatic Site

Biopsy of extrathoracic sites is a strategy that can accomplish both diagnosis and staging. For example, biopsies of the liver, bones, adrenal gland, or a brain lesion will provide the diagnosis and the stage (IV in the case of brain metastasis).

Differential Diagnosis and Staging

Lung cancer should be suspected when the appropriate signs and symptoms suggest this diagnosis, particularly in a patient with a history of smoking (Table 78-4). Radiographic abnormalities often suggest the diagnosis, but new abnormalities need to be differentiated from benign pulmonary lesions including infectious, inflammatory, granulomatous, vascular abnormalities, hamartomas, and metastatic lesions.

Staging is the most important determinant of a patient's treatment plan and prognosis. All patients must be carefully staged at the time of initial presentation. Staging is done using the tumor, mode, metastasis (TNM) system briefly summarized in Table 78-5.

Clinical staging relies on physical examination and radiographic studies (Table 78-6). Pathologic staging confirms the findings of radiographic studies with biopsies of suspected areas of pathologic involvement. In general, pathologic staging is more accurate than clinical staging in defining the presence of cancer.

All patients require a complete history and physical exam, chest x-ray, and a staging chest CT (a chest CT extending all the way through the liver and adrenals). Additional testing may include a head CT or magnetic resonance imaging, radionuclide bone scan, and a PET scan. Pathologic staging may include mediastinoscopy, thoracoscopy, or biopsy of suspected metastatic lesions.

Although the TNM system should also be used for SCLC, a more simplified system has historically been limited- or extensive-stage disease. Limited-stage disease is defined as disease limited to a reasonable thoracic radiation port. This typically includes the primary tumor and N1-3 nodes. Areas of controversy include the contralateral hilar and supraclavicular nodes. Disease beyond this definition is classified as extensive-stage SCLC and includes patients with malignant pleural or pericardial effusions.

Intrathoracic Staging

Figure 78-2 shows the regional lymph node stations for lung cancer staging. The initial evaluation of the mediastinal lymph nodes should be a chest CT scan. However, the sensitivity of CT is about 65%, with a specificity of 75%. False-negative rates are 10% to 15%, with false-positive rates of 30% to 40%. PET scanning increases the sensitivity (about 84%) and specificity (93%) but still has false-positive and false-negative rates of about 7% and 16%, respectively. CT and PET should be used together in selected cases. Mediastinoscopy remains the gold standard for mediastinal evaluation. The overall sensitivity of mediastinoscopy is similar to PET (about 84%), but its specificity is 100%. It does carry a 9% false-negative rate because all the mediastinal nodal stations are not accessible by mediastinoscopy. Obviously, its false-positive rate is 0%.

Figure 78-2 Regional Lymph Node Stations for Lung Cancer Staging.

Adapted from Mountain CF, Dresler CM: Regional lymph node classification for lung cancer staging. Chest 1997; 111:1718-1723.

**Extrathoracic Staging**

Judicious use of noninvasive staging tests should be the standard for the evaluation of extrathoracic metastases. The intrathoracic clinical stage and overall signs and symptoms obtained by the history and physical examination should guide the use of such tests. The most common sites of metastases are the brain, bones, liver, adrenal gland,

and contralateral lung. Directed testing including bone scans, brain CT or magnetic resonance imaging, and CT and PET scan should be done on an individualized basis. Once stage IV disease is documented, testing can stop unless patients are having organ-specific symptoms, which need therapeutic attention (particularly brain or bone metastases).

Table 78-4 Differential Diagnosis of a Pulmonary Mass or Abnormality

Diagnostic Category	Helpful Clinical Factors
Primary lung cancer	Age, risk factors
Metastatic cancer	Medical history, number of lesions
Chronic benign lesion	
Granuloma, scar	Prior chest x-ray, diffuse calcification
Hamartoma	Prior chest x-ray, fat on fine cut computed tomography
Acute benign lesion	
Rounded atelectasis	Radiographic appearance, resolution
Pseudotumor (fluid in fissure)	Radiographic appearance, resolution
Foreign body, obstruction	Clinical history
Lung abscess	Clinical history
Bacterial pneumonia	Clinical history
Tuberculosis, atypical acid-fast bacillus	Clinical history, purified protein derivative skin test
Fungal infection	Clinical history
Pulmonary embolus	Clinical history, resolution
Vasculitis	Clinical history

Table 78-5 TNM Staging System

T Status				
T0	Primary cannot be defined			
Tis	In situ carcinoma			
T1	Lesions less than 3 cm and surrounded by lung			
T2	Lesions greater than 3 cm or invading the visceral pleura			
T3	Lesions in a structure that can potentially be resected (chest wall or pericardium)			
T4	A lesion in a vital structure that cannot be resected (aorta or heart) or a malignant pleural or pericardial effusion			
N Status				
N0	No lymph nodes involved			
N1	Lymph nodes within the lung only (peribronchial or hilar)			
N2	Ipsilateral mediastinal nodes			
N3	Contralateral mediastinal or supraclavicular nodes			
M Status				
M0	No metastatic disease			
M1	Metastatic disease

Management and Therapy

Accurate staging is essential because treatment depends on histology and stage of the disease.

Optimum Treatment of Nonsmall Cell Lung Cancer

Stage I

The standard of care is complete surgical resection through lobectomy or a more extensive procedure if needed. Systematic sampling or complete mediastinal node dissection is performed on all patients at the time of resection. The expected cure rates or 5-year survival rates range from 70% to 80% for stage IA to 50% to 65% for stage IB. The role of postoperative adjuvant chemotherapy remains controversial in stage IB but is probably justified in tumors 4 cm or greater in size. The role of adjuvant chemotherapy in stage IA remains investigational.

Stage II

Complete surgical resection by lobectomy or more if needed is standard. Systematic sampling or complete mediastinal node dissection is performed on all patients at the time of resection. The expected cure rates or 5-year survival rates range from 30% to 50% in stage II NSCLC. If a complete surgical resection is accomplished, postoperative chemotherapy is indicated. Three to four cycles of cisplatin-based chemotherapy is considered the standard of care. There is no defined role for adjuvant radiotherapy in completely resected patients.

Stage IIIA/B

Stage IIIA includes two groups: those with bulky mediastinal disease and those with nonbulky mediastinal disease. In patients with nonbulky disease, surgical resection may

Table 78-6 Types of Staging Assessments

Prefix	Concept	Definition
c	Clinical	Before initiation of any treatment, using any and all information available (including mediastinoscopy)
p	Pathologic	After resection, based on pathologic assessment
y	Restaging	After part or all of the treatment has been given
r	Recurrence	Stage at time of a recurrence
a	Autopsy	Stage as determined by autopsy

be entertained. Survival with surgery alone is poor (9% to 30% 5-year survival rate). Several small phase III studies suggest that preoperative chemotherapy improves 5-year survival rates. In resected stage IIIA patients, postoperative thoracic radiation therapy reduces local recurrences but does not improve survival. These patients have a 5-year survival rate of about 20% to 35%. Like stage II patients, they should receive adjuvant cisplatin-based chemotherapy.

In patients with unresectable stage IIIA/B NSCLC with a good performance status (PS), combined chemotherapy and thoracic radiation therapy are the standard of care. When concurrent approaches have been directly compared with sequential therapy in phase III trials, concurrent chemoradiotherapy has yielded superior survival. The 5-year survival rate is about 10% to 20%.

Stage IV

Combination platinum-based chemotherapy improves survival and palliates disease-related symptoms in most with a good pathologic stage. Studies comparing platinum-based chemotherapy versus best supportive care (BSC) show improvement in survival as a result of the chemotherapy. The 1-year survival with BSC alone is about 10%. With platinum-based chemotherapy, the 1-year survival is about 20% to 25%. Recently developed cytotoxic agents (paclitaxel, docetaxel, gemcitabine, vinorelbine, irinotecan) used with the platinum-based chemotherapies have improved the survival outcomes in stage IV NSCLC. These new agents are associated with a 1-year survival rate of 30% to 40%. Recently, the addition of bevacizumab (a monoclonal antibody to vascular endothelial growth factor [VEGF]) improved survival in combination with chemotherapy compared with chemotherapy alone in selected patients (nonsquamous histology and lack of brain metastases and hemoptysis) with advanced disease. Because stage IV disease is not curable, all patients will eventually progress. Treatment options for these patients include docetaxel, pemetrexed, and erlotinib, all of which have the potential to improve survival and palliate symptoms in patients at the time of progression.

BSC is the standard for patients with a poor pathologic stage. These patients suffer more treatment-related morbidity and mortality and show no improvement in survival as a result of treatment.

Optimum Treatment of Small Cell Lung Cancer

Limited-Stage Small Cell Lung Cancer

LS SCLC constitutes one third of all cases of SCLC. The optimal therapeutic approach is combined chemoradiotherapy. Cisplatin-etoposide is the standard regimen, and radiotherapy is given concurrently with chemotherapy early in the course. Because brain relapse is so common in patients achieving remission, prophylactic cranial irradiation is recommended to improve survival rates.

Extensive-Stage Small Cell Lung Cancer

This is a treatable but incurable disease. Although response rates to combination chemotherapy range from 60% to 80%, the 2-year survival rate is less than 10%. The median survival is 8 to 12 months. The standard regimen is either cisplatin or carboplatin in combination with etoposide.

Avoiding Treatment Errors

Because staging is the most important determinant of a patient's treatment and prognosis, errors in the staging process are the most likely to lead to errors in treatment. The presentation of each patient's clinical database to a combined team composed of a medical oncologist, a radiation oncologist, a pulmonologist, and a thoracic surgeon is the most effective mechanism to avoid treatment errors and to ensure the selection of an optimal therapeutic plan. The utilization of a team of experts takes advantage of the perspective of each of these specialists and, in the process, also leads to more efficiency in the selection of diagnostic tests. Optimal diagnostic testing increases the likelihood of accurate staging.

Future Directions

Two major growth pathways (the VEGF and epidermal growth factor pathways) have been validated as important targets in lung cancer. Several new targeted agents are being tested in advanced NSCLC. These new drugs are targeted at novel pathways, including angiogenesis, signal transduction, and apoptosis. They will likely lead to further

improvements in survival and be incorporated into treatment in earlier stages of NSCLC. New radiotherapy technologies, including three-dimensional treatment planning, intensity-modulated approaches, stereotactic radiotherapy, and the use of protective agents to ameliorate the toxicity of radiation, will likely improve the therapeutic index of radiation therapy. Chemopreventive strategies in early-stage disease are under study and may lead to a reduction in the risk for second primary tumors. Rapid spiral CT scanning has brought about a resurgence of interest in screening for lung cancer although the role of screening remains controversial. Lastly, reduction in the number of smokers would dramatically decrease the incidence of lung cancer. Strategies directed at smoking prevention and more effective smoking cessation therapies should be high priorities.

Colorectal Cancer

Introduction

Deaths due to colorectal cancer (CRC) are second only to lung cancer in site-specific mortality and constitute about 11% of the cancer-related deaths in the United States. During the past decade, advances have been made in our understanding of CRC genetics, screening, surgical techniques, adjuvant therapies, and treatment of the patient with metastatic disease. Despite these advances, the etiology of most CRCs remains ill defined, metastatic disease develops in a number of patients with localized disease at diagnosis despite adjuvant therapy, and metastatic CRC, with a few exceptions, remains fatal.

Etiology and Pathogenesis

Usually, CRC is a disease of elderly people, with incidence not rising appreciably until the fifth decade of life (Fig. 79-1). Incidence varies around the world, with rates higher in Western industrialized nations. Migrating populations tend to assume the CRC risk of the region into which they move; thus, environmental factors have long been suspected to play a role in CRC development. Epidemiologic data suggest an association between dietary constituents such as fats and risk; however, identification of the specific dietary or other environmental factors involved in CRC development has been elusive.

A family history of CRC is a strong predictor of development, with up to 20% of patients reporting a family history of the disease. Having an affected first-degree relative increases the lifetime risk to about 10%. However, defined genetic syndromes account for about 5% of CRC cases.

The sequence of molecular events leading to carcinogenesis is better described for CRC than for any other solid tumor. This is partly due to insights offered by the known inherited CRC syndromes: familial adenomatous polyposis (FAP) and hereditary nonpolyposis colorectal cancer (HNPCC).

FAP accounts for less than 1% of CRCs. It is caused by an inherited defect in one of two adenomatous polyposis coli (*APC*) genes. Affected individuals lose their only functional *APC* copy in certain somatic cells (such as colonocytes) through random deletion and develop hundreds to thousands of colorectal adenomas during adolescence.

CRC develops in nearly all these patients by 40 years of age. Spontaneous loss of both *APC* copies is thought to be a key event in the development of colorectal adenomas in most patients with sporadic CRC.

HNPCC (or Lynch's syndrome) accounts for 2% to 4% of CRC. It is due to an inherited defect in one of a family of DNA mismatch repair (*MMR*) genes and leads to an accumulation of genetic errors. CRC develops in more than 60% of affected individuals by age 50 years. About 15% of sporadic CRCs have acquired rather than inherited microsatellite instability, the genetic manifestation of *MMR* mutation.

It is believed that almost all CRC develops from adenomatous polyps. The current hypothesis of colorectal carcinogenesis suggests that CRC is caused by an accumulation of mutations. Although there is probably an order to these defects, it is the overall accumulation of abnormalities that is most important. More than 90% of cancers have two or more defects. In general, genetic changes accumulate with an initial mutation in the 5q chromosome (*APC* gene mutations) noted in polyps and followed by changes in chromosome 12 (*K-ras* oncogene) as the polyps become more dysplastic. Deletions are then noted in a chromosome 18 gene (deleted in colon cancer). Finally, *p53* (chromosome 17p) mutations appear and mark the transition from benign adenoma to malignant carcinoma.

Chronic inflammatory bowel diseases such as ulcerative colitis and Crohn's disease may lead to CRC development in up to 10% of affected individuals. Other conditions associated with an increased risk include Gardner's syndrome, Turcot's syndrome, and juvenile polyposis.

Figure 79-1 Clinical Manifestations of Colorectal Cancer.

Together, these conditions account for about 1% of CRC cases.

Clinical Presentation

It is important to remember that even advanced CRC is most often asymptomatic. When symptoms occur, they depend on the size and location of the tumor (Fig. 79-2). Typical presenting symptoms include abdominal pain, changes in bowel habits, and rectal bleeding. Colon cancers on the right side tend to be large and present with occult

bleeding resulting in anemia (fatigue, heart failure). Left-sided cancers tend to present with symptoms of bowel obstruction (e.g., cramping, change in bowel habits or stool caliber). Blood mixed with the stool is the most frequent symptom of rectal cancer. Other symptoms include mucous discharge, unsatisfied defecation, rectal discomfort, abdominal pain, and the symptoms (or signs) of anemia. Not uncommonly, patients present with signs or symptoms of metastatic disease. The liver is the most common site of CRC metastasis, but other sites can be involved.

Figure 79-2 Screening Techniques.

Differential Diagnosis

Most CRCs are adenocarcinomas; other histologic varieties account for less than 5% of cases and include carcinoid tumors, sarcomas, lymphomas, melanomas, and in patients with HIV, Kaposi's sarcoma. Locally advanced tumors from other pelvic structures can involve the rectum and present with rectal cancer symptoms. Because symptoms of CRC are nonspecific, malignancy should be included in

the differential diagnosis of nearly any chronic gastrointestinal or abdominal illness and should always be considered in the differential diagnosis of iron-deficiency anemia. Never dismiss the possibility of CRC because of a patient's age; although the incidence of CRC in the young has not increased over time, the percentage of CRC patients younger than 50 years is gradually increasing (as older patients who are screened are prevented from getting the disease).

Table 79-1 American Gastroenterological Association Screening Recommendations

- Average- or standard-risk patients, defined as the absence of any high-risk factors, should be screened annually beginning at age 50 years
- Starting at age 50 years, both men and women should have one of the following after discussion of relative merits and risks:
 - Yearly fecal occult blood test (without sample rehydration) and flexible sigmoidoscopy every 5 years; or
 - FOBT yearly; or
 - Flexible sigmoidoscopy every 5 years; or
 - Double contrast barium enema every 5 years; or
 - Colonoscopy every 10 years
- High-risk patients should begin colorectal cancer screening earlier and more often (see Fig. 79-3)
- Screening recommendations for high-risk groups are as follows:

Familial Risk Category	Screening Recommendation
First-degree relative affected with colorectal cancer or an adenomatous polyp at age ≥ 60 years, or 2 second-degree relatives affected with colorectal cancer	Same as average risk but starting at age 40 years
Two or more first-degree relatives ^a with colon cancer, or a single first-degree relative with colon cancer or adenomatous polyps diagnosed at an age < 60 years	Colonoscopy every 5 years, beginning at age 40 years or 10 years younger than the earliest diagnosis in the family, whichever comes first
One second-degree or any third-degree relative ^{b,c} with colorectal cancer	Same as average risk
Gene carrier or at risk for familial adenomatous polyposis ^d	Sigmoidoscopy annually, beginning at age 10-12 years ^e
Gene carrier or at risk for hereditary nonpolyposis colorectal cancer	Colonoscopy, every 1-2 years, beginning at age 20-25 years or 10 years younger than the earliest case in the family, whichever comes first

^aFirst-degree relatives include parents, siblings, and children.

^bSecond-degree relatives include grandparents, aunts, and uncles.

^cThird-degree relatives include great-grandparents and cousins.

^dIncludes the subcategories of familial adenomatous polyposis, Gardner's syndrome, some Turcot's syndrome families, and antibiotic-associated pseudomembranous colitis (AAPC).

^eIn AAPC, colonoscopy should be used instead of sigmoidoscopy because of the preponderance of proximal colonic adenomas. Colonoscopy screening in AAPC should probably begin in the late teens or early 20s.

Diagnostic Approach

Screening and Diagnosis

Fecal occult blood testing and sigmoidoscopy screening have been shown to decrease CRC-related mortality (Table 79-1). The concept that most cases of CRC follow the adenoma-to-carcinoma pathway has led to the important application of colonoscopy and polypectomy because more than 90% of polyps can be removed by colonoscopy. Adenoma removal has been shown to decrease the incidence of CRC by 70% to 90%. With increasing use of screening technologies, more CRCs are asymptomatic. Most cancers that present today are symptomatic because screening is still not uniformly practiced (Fig. 79-3).

Endoscopy

A rigid sigmoidoscope facilitates reliable examination of the rectum, but frequently the rectosigmoid junction cannot be negotiated; therefore, the sigmoid colon may not be visualized. Flexible sigmoidoscopy allows visualization of only the distal third of the colon. Colonoscopy provides a view of the entire colon and is more sensitive

for both early CRC and colorectal adenomas than double-contrast barium enema. Synchronous lesions are present in up to 15% of patients; thus, the entire colon should be assessed whenever possible (see Fig. 79-3).

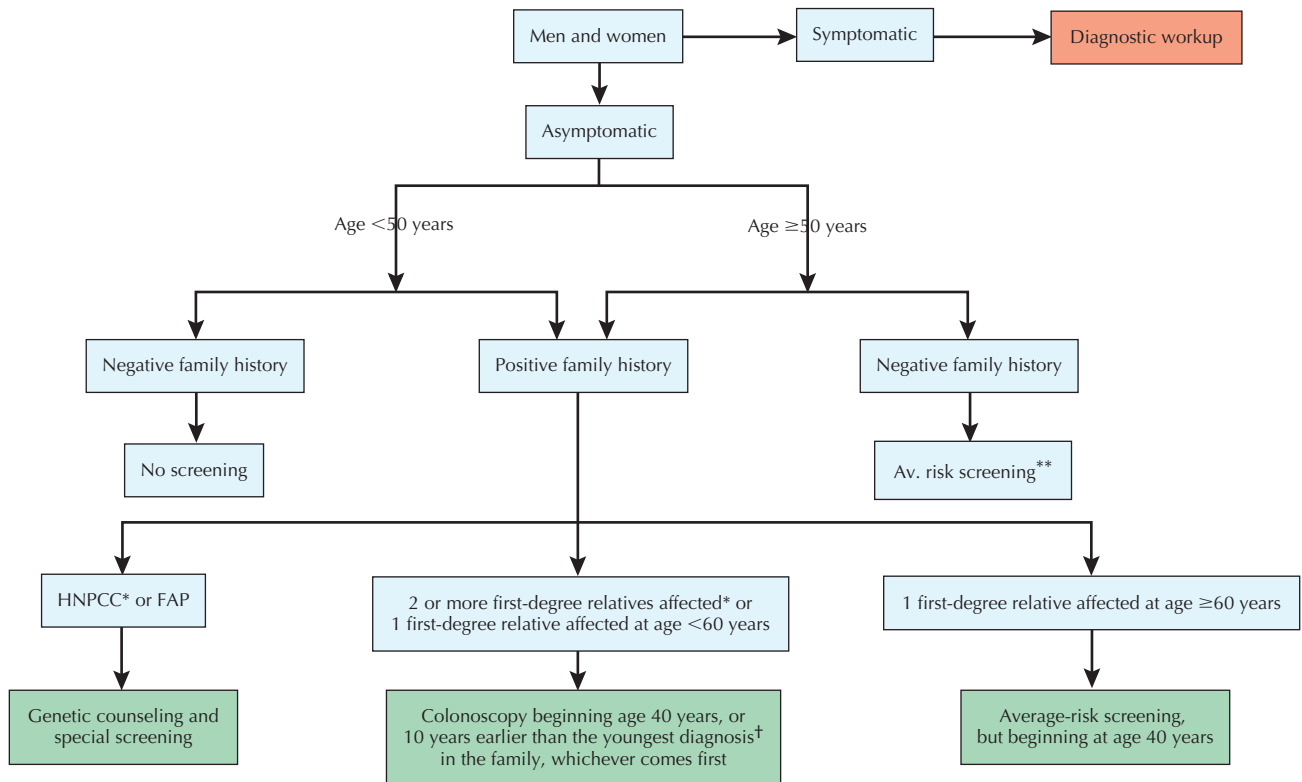

Staging

The tumor-node-metastasis classification for rectal cancer has replaced the Dukes staging system (Table 79-2). Tumor stage, determined by the depth of tumor penetration into the bowel wall, the number of regional lymph nodes involved, and the presence or absence of distant metastases, is the most important prognostic indicator of survival.

CT scanning of the chest and abdomen are commonly employed in initial staging, although intraoperative examination of the abdomen may be adequate in select cases. Transrectal ultrasound or, more recently, specialized magnetic resonance imaging scans can determine the depth of tumor invasion and the presence of pelvic lymph node metastases. It is an important rectal cancer staging tool at many institutions, particularly those where preoperative chemoradiation therapy is employed.

Routine preoperative laboratory studies, including a complete blood cell count and blood chemistry studies with liver-related tests, usually suffice. A preoperative carcinoembryonic antigen (CEA) test may be helpful in the postoperative follow-up of patients but should not be used as a screening or diagnostic test.

Management and Therapy

Optimum Treatment

Surgery

Tumor resection is the cornerstone of CRC management. The goal of surgery is the removal of all macroscopic tumor with clear surgical margins, plus areas of draining lymphatics. Most colon cancers can be treated with a one-stage resection and anastomosis. The rectum is divided into equal thirds. Tumors arising in the upper third are handled most satisfactorily by low anterior resection. A proportion of low rectal cancers and cancers of the anal canal are best managed by abdominoperineal resection of the rectum together with the anal canal and subsequent permanent colostomy. Some low mobile cancers, especially in poor operative candidates, may be best treated by transanal local excision.

Adjuvant and Neoadjuvant Therapy

Adjuvant chemotherapy with 5-fluorouracil (5-FU), leucovorin (LV), and oxilipatin for 6 months improves survival for patients with node-positive CRC. There is

increasing evidence that there may also be a survival advantage with adjuvant chemotherapy in patients with T3, N0, M0 (stage II) disease, but the absolute magnitude of this benefit is relatively small, on the order of 2% to 5%. Calculators of chemotherapy benefit are now available on the Internet and can be very useful in educating patients for decision making about therapy.

Rectal cancers (tumors arising below the peritoneal reflection) present an additional challenge. A substantial fraction of patients will have local recurrence if the tumor extends through the bowel wall (T3 disease) or if there are positive lymph nodes. Postoperative adjuvant pelvic radiation therapy is effective in controlling these local recurrences. Standard practice is to augment radiation therapy with the protracted infusion of 5-FU. It is notable also that recent advances in surgery such as sharp dissection of the entire mesorectum (total mesorectal excision or TME) may decrease the risk for local recurrence in select patients without need for radiotherapy. TME is now considered the standard operation for rectal cancer.

There has been an evolution in rectal cancer management to the delivery of chemoradiation therapy preoperatively. Benefits of this strategy include lower volume of irradiated tissue, lessening of long-term ill effects resulting from the removal of irradiated tissue at surgery, and the potential that tumor down-staging will permit more sphincter-sparing surgeries. Because a number of cases are pathologically down-staged with preoperative chemoradiation therapy, all patients treated in this manner should be considered for completion of their 6-month adjuvant chemotherapy course with additional chemotherapy postoperatively, regardless of the pathologic stage at surgery.

Follow-up includes colonoscopy 12 months postoperatively and then at 2- to 3-year intervals. Patients should be seen every 6 to 12 months for 5 years. CEA monitoring can be useful for the early discovery of disease recurrence. There is also some evidence to support routine imaging studies in the follow-up period, and American Society of Clinical Oncology guidelines now support routine imaging during surveillance.

Management of Metastatic Disease

Recurrent CRC is frequently localized to resectable organs (Fig. 79-4). The most common organ is the liver; the lung is the second most common. When confined to a resectable segment of either liver or lung, long-term survival is 25% to 40%. In select patients, liver lesions may be directly ablated by percutaneous or laparoscopic radiofrequency thermal ablation.

Patients with unresectable or widespread metastatic disease may benefit from systemic chemotherapy. Combination chemotherapy regimens are more effective than the core regimen of 5-FU/LV. The past several years have seen the addition of irinotecan (a topoisomerase I inhibi-

tor) and oxaliplatin (a DNA cross-linker) to 5-FU/LV regimens with enhanced survival, albeit with increased toxicities. Roughly half of patients respond to first-line chemotherapy.

More recently, several therapeutic antibodies have entered clinical practice, with targets that were discovered through genetic research. Of particular promise has been an antibody against the proangiogenic vascular endothelial growth factor known as bevacizumab. This antibody appears to enhance the effect of chemotherapy on survival, with limited side effects when compared with classic chemotherapeutic agents. Antibodies against the epidermal growth factor receptor have also been approved for use in colon cancer and also appear to augment the effectiveness of chemotherapy on colorectal cancers.

Avoiding Treatment Errors

Management of colorectal cancer has become increasingly complex in recent years, particularly the management of rectal cancer, which often involves multiple subspecialists. For example, sequencing of therapies can be of substantial importance. To avoid potential complications and maximize outcomes, all patients with rectal cancer and many patients with colon cancer (particularly metastatic colorectal cancer) should be managed by an organized multidisciplinary team composed of gastroenterologists, experienced surgeons, radiologists, radiation oncologists, and medical oncologists.

Another potential error in initial management is missing a second primary cancer because initial colonoscopy was incomplete (often due to an obstructing distal lesion). All patients should undergo a complete colonoscopy after appropriate recovery from surgery if the initial endoscopy was suboptimal.

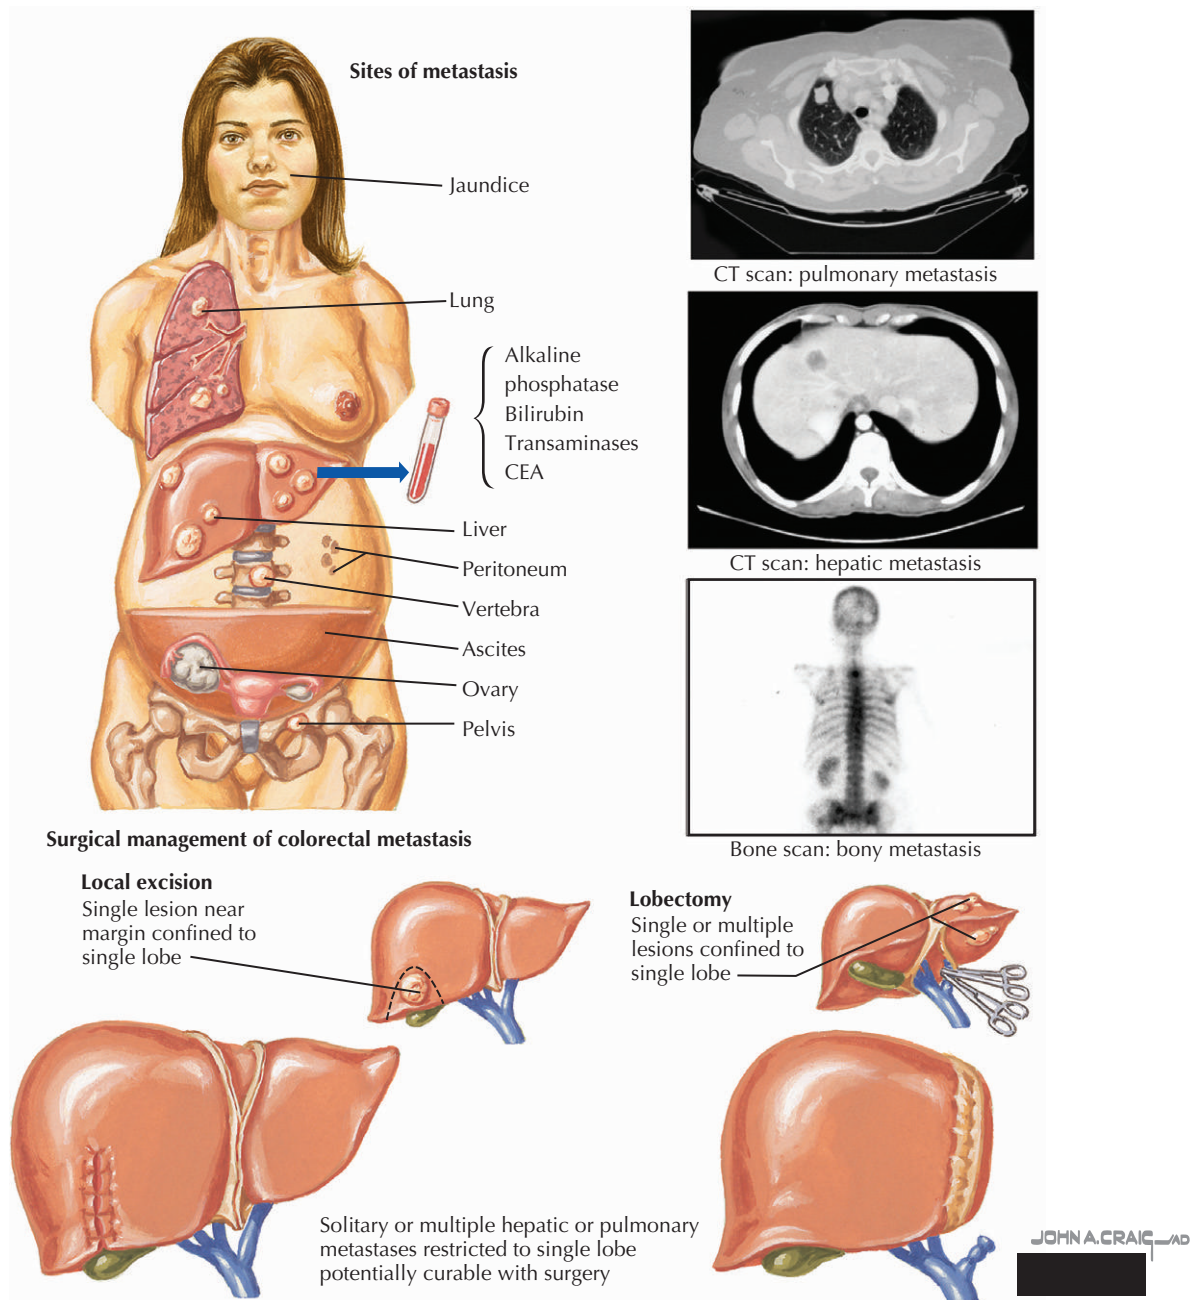

Future Directions

The future for advances in all aspects of CRC management is bright. Increasing knowledge of CRC molecular biology and genetics is pivotal in these developments. Identification of molecular targets and lesions will allow the rational design of strategies for CRC prevention, screening, and treatment.

Better identification of environmental and dietary factors will have obvious ramifications for CRC prevention. Preventive therapies remain a hot area of research, although use of the most promising class of drugs, the cyclooxygenase-2 inhibitors, has been clouded by concerns about increased cardiovascular risk. The use of aspirin, calcium supplementation, and exercise has been linked to reduced incidence of polyps and colorectal cancers. New screening modalities promise both increased sensitivity and specificity by analyzing for genetic anomalies linked to CRC (such as *K-ras* mutations) in stool

Figure 79-4 Metastasis in Colorectal Cancer.

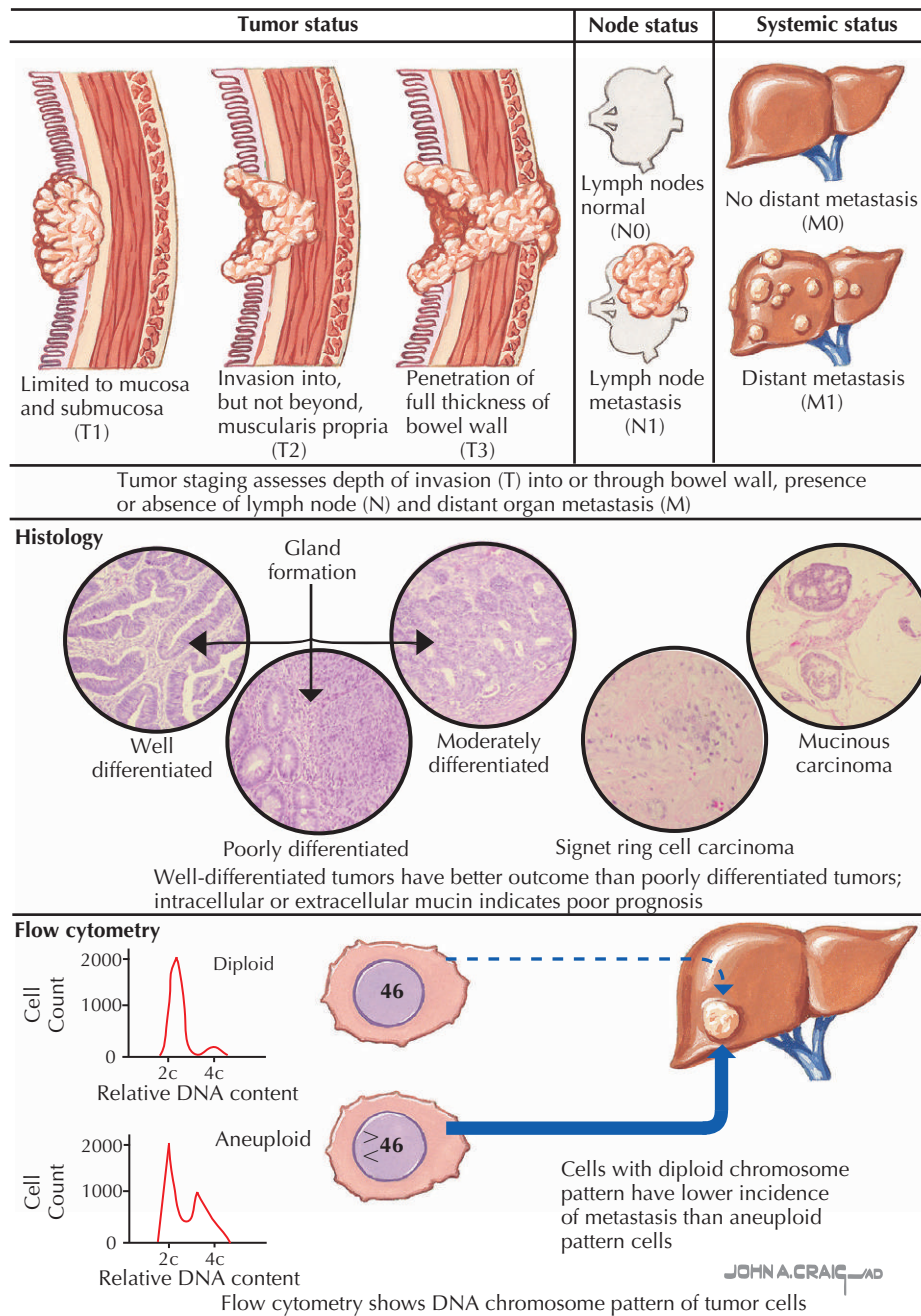

CEA, carcinoembryonic antigen; CT, computed tomography.

samples. New imaging techniques such as CT virtual colonoscopy may provide noninvasive means of detecting polyps and CRC.

Advances in adjuvant therapies will consist of both more effective regimens and improved patient selection for these treatments. Targeted therapies such as bevacizumab and cetuximab are already being studied for their potential benefits in the adjuvant setting.

Our ever-increasing understanding of CRC biology and markers of treatment responses, plus a rapidly expanding armamentarium of effective agents, will likely permit a more patient-directed approach to treatment (Fig. 79-5). As a current example, CRC with high-level thymidylate synthase (an important target of 5-FU) expression may have a poorer response to 5-FU. A host of other molecular markers may have prognostic and predictive importance.

No standardized guidelines have yet been set forth to guide the gastroenterologist in performing surveillance in patients with IBD. A panel of international experts was assembled to develop consensus recommendations for the performance of surveillance. The findings are presented herein.

5. Kaz AM, Brentnall TA: Genetic testing for colon cancer. *Nat Clin Pract Gastroenterol Hepatol* 3(12):670-679, 2006.

Colon cancer remains the third leading cause of death due to cancer in the United States, where it affected more than 145,000 individuals in 2005. Up to 30% of these cases exhibit familial clustering, which means that tens of thousands of individuals have a disease with a potentially definable genetic component. About 3% to 5% of colon cancers are associated with high-risk, inherited colon cancer syndromes. Identification of

the genes that cause these colon cancer syndromes, coupled with additional insights into their clinical course, has led to the development of specific management guidelines—and genetic tests—that can diagnose these familial disorders. These guidelines can be life saving, not only for the affected patient, but also for their family members.

6. O'Neil BH, Goldberg RM: Chemotherapy for advanced colorectal cancer: Let's not forget how we got here (until we really can). *Semin Oncol* 32(1):35-42, 2005.

Physicians and patients alike have been heartened by the recent advances in the treatment of colorectal cancer. The emergence of novel agents active in the treatment of this devastating disease, such as cetuximab and bevacizumab, has been particularly notable. However, even before these recent events, a substantial change in prognosis for patients with metastatic colorectal cancer had occurred as a result of advances in traditional chemotherapeutic agents. Refinements in dose, schedule, and sequence continue to be made that could lead to further improvements in outcomes. Additionally, new chemotherapeutic agents with promise for activity in colorectal cancer are being studied. Chemotherapy is likely to remain a central element of the treatment strategy. Our understanding of its current role is discussed in this article.

Breast Cancer

Introduction

Breast cancer will be diagnosed in nearly 178,480 U.S. women and 2,030 U.S. men in the year 2007, making it the most common malignancy in women. The lifetime risk for the development of breast cancer for an American woman is about 1 in 10, with advancing age as the strongest risk factor. Two thirds of cases occur in postmenopausal women; the disease is extremely rare in women younger than 30 years. Incidence has recently been stable, whereas breast cancer mortality within the entire population decreased about 25% during the past 10 to 20 years. About half of that improvement in mortality comes from successful screening, and the other half from improved adjuvant therapy.

Etiology and Pathogenesis

Age is the strongest risk factor for noninherited breast cancer. Women older than 65 years have a risk several-fold higher than that of 40-year-old women. At any age, a history of breast or ovarian cancer increases the risk for subsequent breast cancer. Family history is an important, but smaller, contributor to risk (about twofold to fivefold increased risk for first-degree relatives), except in those families with an inherited form of breast cancer, in whom the risk is highest. Inherited breast cancer is responsible for 5% to 10% of all breast cancers and is primarily due to mutations in the *BRCA1* or *BRCA2* gene, which are inherited in an autosomal dominant fashion. *BRCA1* or *BRCA2* mutation carriers have a 60% to 80% lifetime risk for breast cancer and an increased risk for premenopausal and bilateral disease. Identification of families with inherited breast cancer patterns is crucial because genetic testing can identify carriers of a mutation, and there are effective prevention strategies.

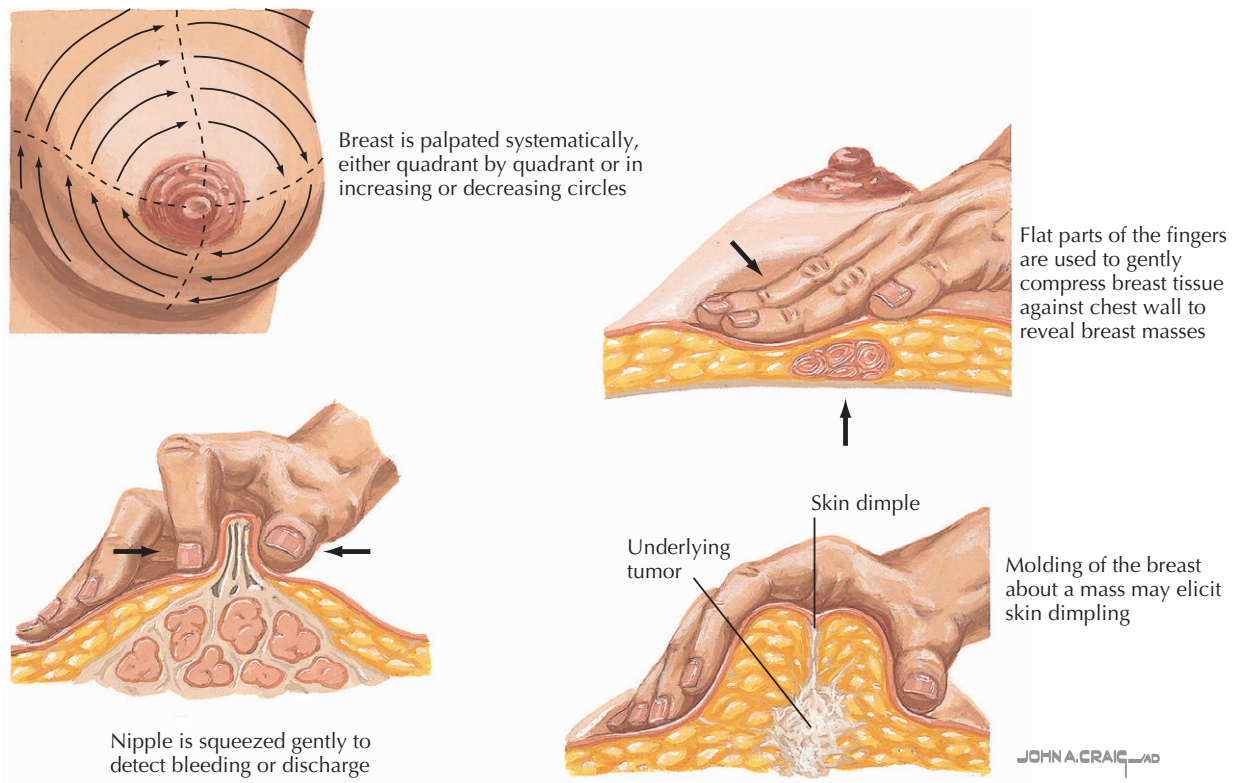

Hormonal risk factors may be broadly grouped as factors that increase the number of normal menstrual cycles in a lifetime, especially if the cycles occur before a first full-term pregnancy. They include early age of menarche, late menopause, and nulliparity or age at first pregnancy older than 30 years. Several other variables have been associated with breast cancer risk, possibly by increasing hormone levels. For example, obesity, a high-fat diet, and alcohol can all cause higher circulating estrogen levels. Certain benign breast diseases confer increased risk for breast

cancer. Atypical hyperplasia is associated with an up to 1% yearly risk of invasive breast cancer. Despite the name, lobular carcinoma in situ is not a neoplastic or preneoplastic lesion, but is a marker of increased breast cancer risk in any quadrant of either breast. This risk can approach 1.5% per year for invasive breast cancer.

Clinical Presentation

There are two major forms of primary breast cancer: invasive and noninvasive. Noninvasive breast cancer includes ductal carcinoma in situ (DCIS), which is truly a preneoplastic lesion in that up to 30% of inadequately treated DCIS cases recur or progress to invasive cancer. Most DCIS cases are detected by mammography; only 10% are palpable. Paget's disease is a rare variant of DCIS that can occur alone or at the same time as invasive disease. It appears as eczematous changes of the nipple that represent extension of the DCIS component of the cancer into the main ducts.

Invasive breast cancer usually presents as a painless mass or mammographically detected calcifications, architectural distortion, or asymmetrical density. Clinical or breast self-examination may also detect a tumor by overlying dimpling or retraction of the skin or asymmetry of the breasts (Fig. 80-1). Occasionally, breast cancer will be associated with nipple inversion or discharge. Suspicion of malignancy should be higher if the discharge is heme positive. Rarely, breast cancers present with inflammatory

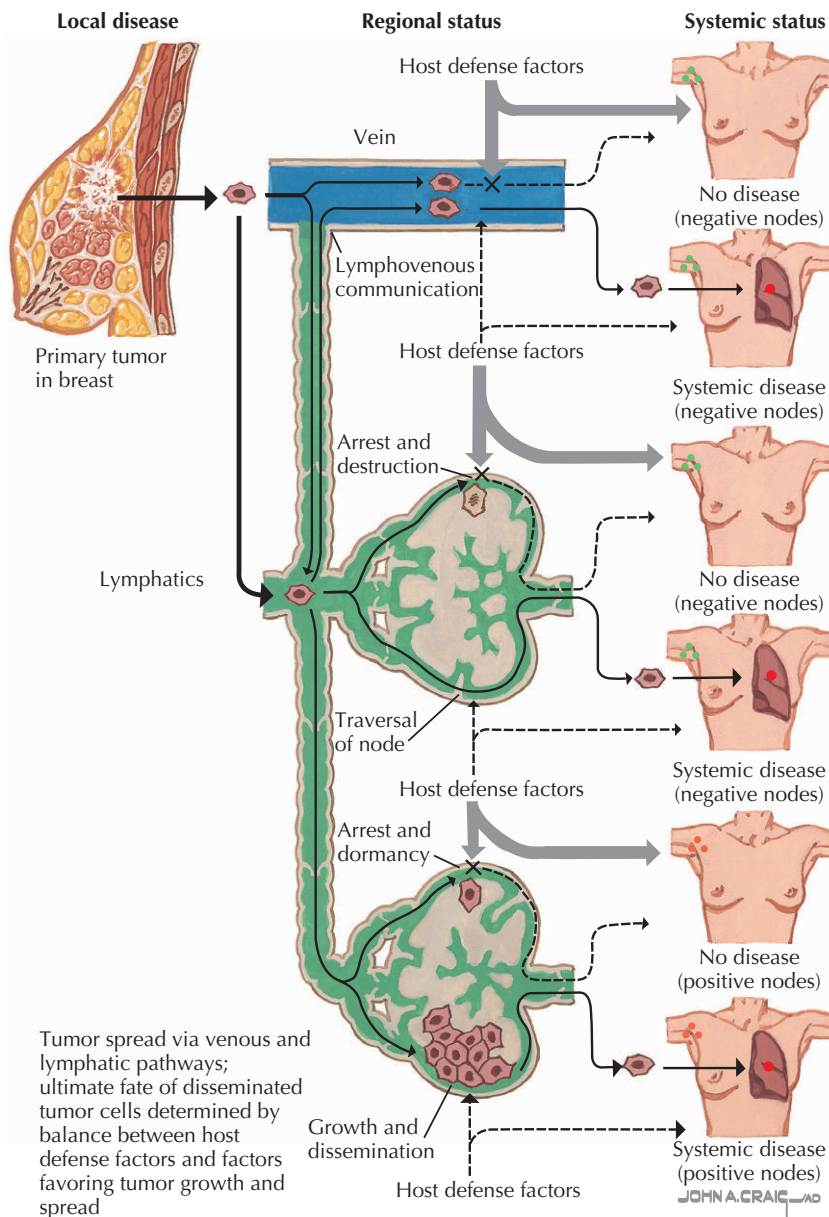

Figure 80-1 Palpation of the Breasts.

changes in the skin of the breast. Since the advent of screening, more breast cancers present at an early curable stage, with disease limited to the breast only or breast and local lymph nodes. Fewer than 10% of patients with breast cancer present with distant metastases.

Most invasive primary breast cancers are adenocarcinomas of ductal, lobular, or a mixed pattern. Less than 5% are pure tubular, colloid, mucinous, or atypical medullary type, which are considered to have a better prognosis. Clinical oncologists use several features of the patient and the tumor to gauge likelihood of recurrence. The American Joint Commission on Cancer tumor, node, metastasis (TNM) system, although imperfect, is used most commonly. *T* refers to tumor size or fixation to local structures, with larger sizes or fixed status conferring worse prognosis. *N* refers to regional lymph node metastasis; the presence of involved axillary, mammary, supraclavicular or infraclavicular lymph nodes connotes a poorer prognosis. *M* refers to distant metastasis, which is generally considered incurable. There are several prognostically relevant features of the patient or the tumor that are not included in the TNM system. Some studies suggest that high-grade tumors carry a worse prognosis. Recent research has focused on the biologic heterogeneity of breast cancer. A molecular profiling using gene expression array suggests that breast cancer actually represents several biologically distinct diseases. Although these breast cancer subtypes can only accurately be distinguished using microarray technology

that is not currently clinically available, they do differ in some easily identifiable ways using clinical assays that are routinely performed on breast cancers for the estrogen receptor (ER), progesterone receptor (PR), and receptor tyrosine kinase HER2. The presence of ER or PR identifies the luminal subtypes, which make up about 70% of breast cancers, are considered sensitive to endocrine therapies, and carry a slightly better prognosis and later recurrence. The hormone receptor–negative subtypes, which constitute about 30% of breast cancers, are about equally made up of the basal-like and HER2+/ER– subtypes, which clinically can be crudely identified as negative for all three markers (basal-like) or negative for ER and PR but positive for HER2 (HER2+/ER–). Both these subtypes are typically highly proliferative and carry a poor prognosis and a higher risk for early relapse, although the use of HER2-targeted therapy in the HER2+/ER– is altering the natural history of that subtype. Overexpression of the cell surface receptor tyrosine kinase HER2 is found not only in the HER2+/ER– subtype but also in some luminal breast cancers. As with the ER and targeted hormonal agents such as tamoxifen, HER2 predicts success of treatment with targeted anti-HER2 drugs such as the monoclonal antibody trastuzumab.

Most patients present with early-stage nonmetastatic breast cancer, at a time when prompt multimodality therapy can reduce breast cancer recurrence and death. Breast cancer recurrence as metastatic disease can occur at

Figure 80-2 Pathways of Tumor Dissemination.

any time; however, the risk is highest within the first 5 to 10 years after diagnosis. There are multiple tumor and host factors that affect a tumor's ability to exit the breast, survive in the blood and lymphatics, arrest and extravasate in a new site, and finally survive and grow in that site to become clinically evident metastatic disease (Fig. 80-2). The most common sites of recurrence are local (including conserved breast or chest wall), bone, lymph nodes, lung, and liver. Central nervous system (CNS) recurrences, rare before the era of aggressive systemic therapy, appear to be increasing, probably because the drugs used to prevent systemic relapse do not penetrate the CNS adequately. Local recurrence, particularly in a conserved breast, is curable with surgery and radiation therapy; however, it is a poor prognostic factor. Metastatic breast cancer is considered incur-

able, although a small percentage of patients live longer than 10 years, and the prognosis after metastatic diagnosis is improving.

Differential Diagnosis

Several nonmalignant conditions can mimic breast cancer. Cysts and fibroadenomas often present with palpable masses. These may be distinguished from malignancy on clinical or radiographic grounds, such as the tenderness, cyclic changes, and sonographic appearance of cysts, and the characteristic mammographic density and circumscribed feel and appearance of fibroadenomas. Papillomas or mammary duct ectasia can produce nipple discharge. Mastitis or cellulitis of the breast is very difficult to distin-

Figure 80-3 Mammograms.

Left: Mammogram depicting a partially lobulated, partially indistinct mass that proved to be infiltrating ductal carcinoma. *Right:* Mammogram depicting branching, casting, and pleomorphic calcifications that proved to be ductal carcinoma in situ. *Courtesy of Etta Pisano, MD.*

guish clinically from inflammatory breast cancer. Breast malignancies other than primary breast cancer are rare. These include sarcomas (cystosarcoma phyllodes among others), lymphomas, and chloromas as well as metastases from melanomas or other carcinomas. Breast cancer metastasis to the contralateral breast is rare. A woman with a history of breast cancer is at increased risk for developing breast cancer in the contralateral breast. In general, these represent second primary tumors.

Diagnostic Approach

About 20% to 30% of invasive and 80% of noninvasive breast cancers are not palpable; 10% of invasive cancers are not visible on mammograms. For this reason, physical examination and radiology are considered complementary (Fig. 80-3). Ultrasound may provide valuable information in evaluating palpable masses. The American Cancer Society guidelines for breast cancer screening are that women older than 20 years should perform breast self-examination every month; women should have clinical breast examination by a health professional every 3 years from ages 20 to 39 years, and yearly thereafter; and women 40 years and older should undergo annual mammography. Mammography in women between 40 and 50 years of age has been controversial, although emerging data suggest a smaller but real benefit in this age group. The benefit is smaller in younger women because breast cancer is less prevalent and mammograms are technically limited in

more glandular and dense premenopausal breasts. Recent studies suggest that screening in women at high risk or with dense breasts may be improved with digital mammography or breast magnetic resonance imaging.

Diagnosis of a palpable lesion can be made by fine-needle aspiration, core needle biopsy, or open surgical biopsy. Lesions seen by mammography or ultrasound only can be biopsied by stereotactic core needle biopsy, by ultrasound-guided needle biopsy, or by needle-localized open biopsy. A complete history and physical examination is the best screening test for systemic spread of cancer. Chest radiography, complete blood cell count, and screening liver chemistries are often performed to screen for metastatic disease; however, these tests are unlikely to be abnormal in early stage tumors. More aggressive evaluations such as bone scans and CT scans are generally reserved for symptomatic patients and those with more locally advanced or metastatic disease.

Management and Therapy

Prevention

There are both medical and surgical strategies for breast cancer prevention. In women at moderate to high risk, the selective ER modulators tamoxifen or raloxifene have been shown to reduce the risk for noninvasive and invasive breast cancer by more than 40%. Tamoxifen decreases the incidence of ER-positive breast cancer and does not appear to affect the development of ER-negative breast cancer.

Toxicity includes increased endometrial cancer risk (seen primarily with tamoxifen not raloxifene), venous thrombosis, menopausal symptoms, and a small increase in cataract progression. Surgical strategies used primarily in very-high-risk patients include prophylactic mastectomy for any woman and prophylactic oophorectomy for premenopausal women. Prophylactic mastectomy reduces the risk for breast cancer by at least 90% in high-risk patients treated by skilled surgeons. Prophylactic oophorectomy has been evaluated in *BRCA* mutation carriers, in whom it reduces breast cancer by about 50%.

Optimum Treatment

Local and Regional Therapy

Surgical options include breast conservation, which is local excision of the tumor with dissection of the level I and II axillary lymph nodes followed by radiation therapy to the breast. Breast conservation is standard of care and offers comparable 5-year survival to modified radical mastectomy. Some tumors are too large or poorly placed for conservation; for those patients, mastectomy is standard. Dissection of the ipsilateral axillary lymph nodes allows tumor debulking and prognostication. Sentinel lymphadenectomy allows surgeons to selectively identify the first draining lymph node or nodes (the “sentinel” node) from a tumor region using vital blue dye or radiolabeled colloid. In experienced hands, if this first draining lymph node does not contain tumor, the remainder of the axilla is also likely to be free of tumor and does not require dissection. Radiation therapy is required for patients who have breast conservation; otherwise, the local recurrence rate may exceed 30% with long-term follow-up. Local recurrence in conserved and radiated breasts is less than 10%. Radiation is also given to the chest wall and local lymph node groups remaining after surgery for large tumors or for some tumors with involved axillary lymph nodes.

Systemic Therapy

Systemic therapy refers to chemotherapy, hormone therapy, bisphosphonates, or biotherapy given to patients to prevent or treat metastatic disease throughout the body. Adjuvant therapy is given as an adjunct to local therapy to decrease the chance of recurrence. Neoadjuvant, or preoperative, therapy is a newer approach that involves the same drugs as in adjuvant therapy given before the surgery to decrease the tumor size, allow breast conservation and provide important data to researchers regarding the effect of drugs and combinations of drugs in the primary breast cancer. The use of adjuvant therapy, primarily chemotherapy, hormone therapy, or biologic therapy is determined by the patient’s general health, age, ER status of the tumor, and the probability of recurrence based on stage and other prognostic variables. Accurately predicting risk for recurrence has previously involved mathematic models that include these clinical variables; newer genomic models based on gene expression patterns in the tumor promise to

improve this accuracy. Chemotherapy includes several non-cross-resistant drugs, called *polychemotherapy*. Overall, adjuvant chemotherapy decreases the risk of recurrence by 23% and the risk of death by 17%. Hormone, also known as endocrine, therapy is useful only in preventing recurrence of tumors that express the ER; it is not effective in ER-negative cancer. Among hormone receptor-positive breast cancers, the selective ER modulator tamoxifen decreases the risk of recurrence by 41% and risk of death by 34%. Although there are fewer long-term data, in postmenopausal women aromatase inhibitors have better relapse-free survival than tamoxifen alone and should be considered instead of or subsequent to tamoxifen. In premenopausal patients with ER-positive tumors, oophorectomy may be a useful adjunct to tamoxifen, particularly in high-risk patients who cannot or will not take chemotherapy. Giving both chemotherapy and subsequent endocrine therapy is more effective than either strategy alone. For the 20% to 30% of patients with HER2-positive breast cancer, HER2-targeted therapy with the monoclonal antibody trastuzumab added to certain chemotherapy and after chemotherapy improves both relapse-free and overall survival compared with chemotherapy alone.

Metastatic therapy is given to women with systemic relapse. The goals of metastatic therapy are to palliate symptoms and prolong life; however, given the incurable nature of the disease at this stage, quality-of-life considerations become very important in choosing therapy. This therapy may include chemotherapy—either with one of the many single agents with documented effectiveness or polychemotherapy; hormone therapy (if hormone receptor positive—with tamoxifen or other antiestrogens; aromatase inhibitors [if postmenopausal] or ovarian ablation [if premenopausal]); bisphosphonates therapy for lytic bone metastases or targeted biotherapy such as HER2-targeted agents such as trastuzumab or lapatinib for appropriate patients. Antiangiogenics such as VEGF inhibitors improve outcome, although patient selection is a challenge. Surgery and radiation are also sometimes used for treatment of local complications. A number of clinical trials are evaluating the best combinations of chemotherapy and other drugs for adjuvant treatment and newer drugs and compounds for metastatic therapy.

Avoiding Treatment Errors

The most common errors in treating breast cancer are failures to diagnose this disease and failures to manage the disease at the time of diagnosis optimally with multimodality assessment and therapy. Failure to diagnose breast cancer can occur through ineffective screening, which often represents problems with access to health care, or poorly performed screening. Screening mammography should be performed using machinery that has met quality standards, and by experienced personnel. Therapeutic decision-making is optimized when surgical decisions are made with direct consultation with radiologists and

pathologists and adjuvant therapy decisions are made in the setting of multidisciplinary tumor boards.

Future Directions

Since 1990, breast cancer mortality in the United States has markedly decreased, largely because of aggressive efforts to detect and treat the disease at early stages. A significant additional strategy has been to develop effective preventive treatments for those at high risk. Certain groups, such as medically underserved populations in the United States and many populations in undeveloped countries, have not seen these improvements in outcome. An important accomplishment will be to provide better screening and prevention efforts to these groups. Given the improvement in outcome with mammographic screening, better imaging techniques may provide additional benefits. New strategies are at hand to determine the metastatic potential of the tumor and to refine selection of adjuvant therapy. These include examination of bone marrow or blood for evidence of micrometastases, definition of individual tumor biology through tumor markers, and classification of tumor subtypes using sophisticated molecular techniques analysis. Bisphosphonates, new hormonal approaches, and new targeted therapies are being tested in the adjuvant setting to try to improve the cure rate in early breast cancer. The success and low toxicity of tamoxifen and trastuzumab suggest that the future of breast cancer therapy is likely to involve other targeted therapies, with treatment determined by the molecular profile of the particular tumor.

Prostate Cancer

Introduction

Prostate cancer constitutes 33% of noncutaneous malignancies diagnosed in males, making it the most commonly diagnosed malignancy in men. An estimated 234,000 new cases are anticipated in the United States in 2006. These figures represent a sharp decline from the 1997 estimates of 334,500 new cases, a trend consistent with an effect from the recent adoption of prostate-specific antigen (PSA) screening for prostate cancer. Prostate cancer is the third leading cause of male cancer deaths, with 27,350 deaths anticipated in 2006. Mortality rates from prostate cancer as well as several other cancers have been decreasing since the early 1990s, although a relationship of this decrease to current screening efforts has not been established.

The incidence and mortality rates among African-American men surpass those of other racial and ethnic groups and are twice as high as those of white Americans. Risk increases sharply as men age, and men with a strong family history of prostate cancer may have several times the risk for prostate cancer as men without such a history.

Etiology and Pathogenesis

Research on men who migrate from areas of low prostate cancer mortality to areas of high mortality provides compelling evidence for unidentified environmental causes. Japanese males aged 65 to 74 years who migrated to the United States had age-specific prostate cancer mortality rates (40.2/100,000/year) intermediate between the high rate of U.S. whites (92.6/100,000/year) and Japan's lower rate (11.2/100,000/year). These studies imply that immigrants are exposed to environmental or lifestyle factors that place them at higher risk for prostate cancer. Systematic review of prostate cancer risk factors has not demonstrated consistent environmental, behavioral, or dietary risk factors amenable to primary prevention, although some studies have suggested that dietary saturated fat consumption may increase risk.

Several prostate cancer prevention strategies are under investigation. SELECT, a large randomized, controlled trial of selenium and vitamin E as nutritional cancer prevention agents, began in 2002. The Prostate Cancer Prevention Trial examined the chemoprevention of prostate cancer using finasteride, an inhibitor of 5α -reductase (the intracellular enzyme that converts testosterone to its active metabolite dihydrotestosterone). Finasteride appears to

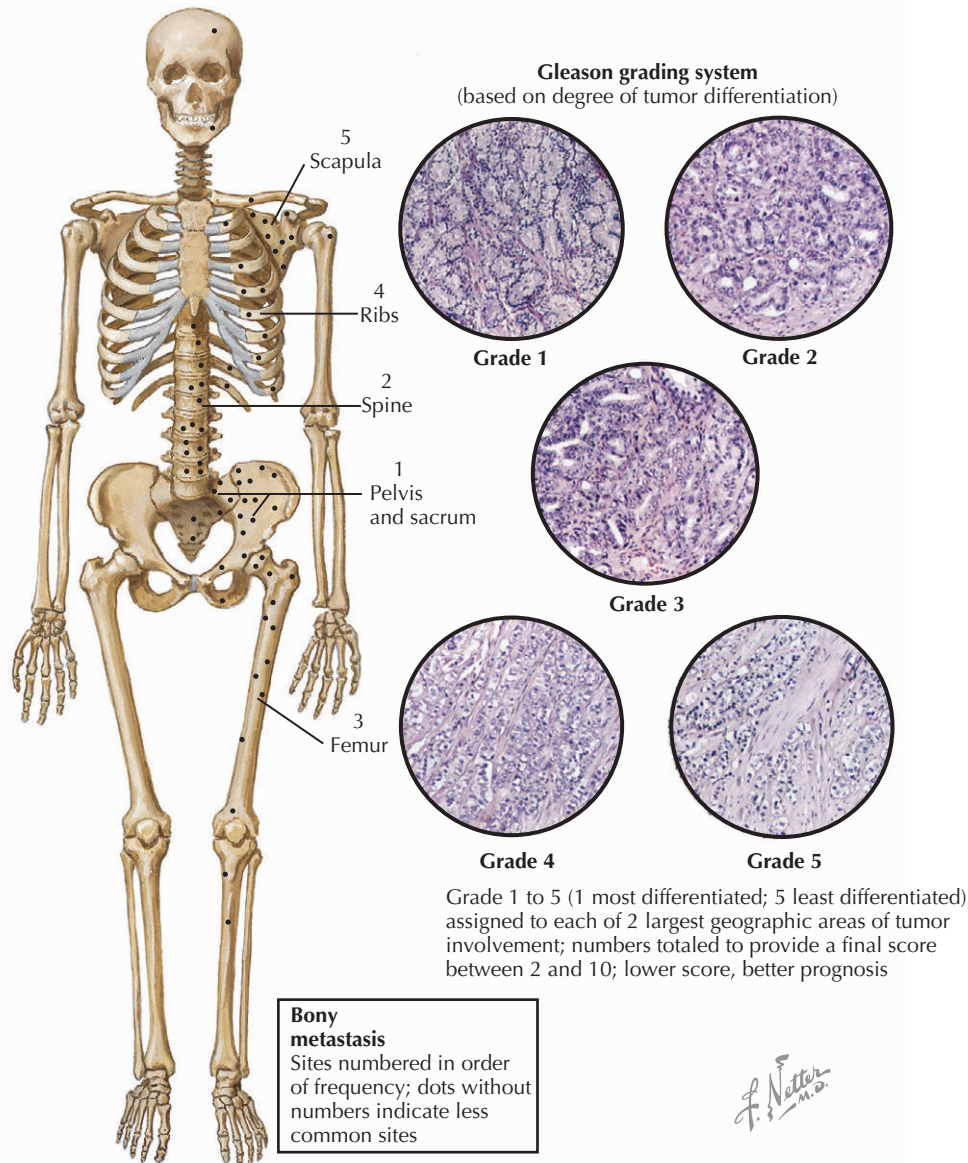

decrease the development of prostate cancer by 25% but may increase the risk for high-grade cancer and cause sexual side effects.

Clinical Presentation

Early-stage prostate cancer is usually asymptomatic. Symptoms referable to the prostate gland are often due to benign prostatic hyperplasia, which is not related to nor a risk factor for prostate cancer. Locally advanced prostate cancer may present with symptoms of bladder outlet obstruction or hematuria, and patients with metastatic disease may present with bone pain and, less commonly, spinal cord compression or obstructive uropathy (Fig. 81-1).

Differential Diagnosis

In addition to prostate cancer, prostatitis and benign prostatic hypertrophy are associated with an elevated serum PSA level. A course of antibiotics may lead to normalization of elevated PSA in patients with prostatitis. PSA levels in prostate cancer and benign prostatic hypertrophy overlap significantly, and currently a biopsy is the only test that can distinguish these two conditions.

Figure 81-1 Prostate Cancer.

Diagnostic Approach

Screening remains a controversial issue. The lack of consensus on PSA screening is reflected in the diversity of recommendations from public health and physician organizations. The American Cancer Society, the American Urological Association, and others recommend annual screening with PSA and digital rectal examination (DRE) starting at age 50 years. These same groups recommend initiating screening at age 45 years for high-risk patients—men of African-American descent or with a family history of prostate cancer, defined as a first-degree relative diagnosed before the age of 65 years. The National Cancer Institute, the U.S. Preventive Services Task Force, the

Canadian Task Force on the Periodic Health Exam, the Office of Technology Assessment, and the American College of Physicians have either not made a recommendation, recommended that screening be discussed with patients, or recommended explicitly against screening.

Of the screening tests for early prostate cancer, only the PSA assay stands out as both convenient to administer and potentially sensitive enough to detect cancer while it is localized to the prostate gland. DRE alone is not a reliable screening test, having failed to demonstrate effectiveness in preventing metastatic prostate cancer or death from prostate cancer in a case-control study and a quasi-cohort study. DRE, however, does detect some prostate cancers that are missed by PSA testing. Uncertainty about the

natural history of prostate cancer and the wisdom of detecting and treating asymptomatic patients is reflected in the extraordinarily high prevalence of prostate cancer detected at autopsy in men without a previous clinical diagnosis of prostate cancer. These studies from various countries consistently document that 20% to 30% of men die with unsuspected carcinoma of the prostate.

Pathology and Staging and Risk Stratification

Tissues obtained from transurethral resection of the prostate may be incidentally found to be involved with cancer. Patients with an elevated PSA level or a palpable nodule on DRE should undergo a needle biopsy of the prostate gland. Almost all prostate carcinomas are adenocarcinomas. In the Gleason grading system, the glandular differentiation patterns of the primary (largest) and secondary tumors are each scored from 1 (well differentiated) to 5 (poorly differentiated) and then added together to give a number from 2 to 10 (see Fig. 81-1).

Staging using the tumor-node-metastasis (TNM) system classifies T1 as not palpable and T2 as palpable tumors confined to the prostate gland. T1c describes nonpalpable tumors detected by random prostate biopsies performed because of an elevated PSA test. T3 tumors extend beyond the gland, and T4 tumors invade adjacent organs. N1 and M1 denote the presence of positive lymph nodes and metastatic disease, respectively.

Patients can be divided into well-defined prognostic groups based on the clinical characteristics of T stage on DRE, PSA level, and Gleason grade. Low-risk patients are defined as clinical stage T1c or T2a (tumor involving one half of one lobe), PSA <10, and Gleason score ≤6. Intermediate-risk patients have clinical stage T2b (tumor involving more than one half of one lobe but not both lobes), PSA of 10 to 20, or Gleason score of 7. High-risk patients have a clinical stage T2c (tumor involving both lobes) or higher, PSA >20, or a Gleason score of 8 or higher. Risk category is prognostic. After definitive local therapy, low-, intermediate-, and high-risk patients have been shown to have approximate likelihoods of 15%, 50%, and 70%, respectively, of having biochemical recurrence (detectable and rising PSA) at 5 years.

Management and Therapy

Localized Disease

Patients with clinically localized disease have several treatment options, including radical prostatectomy, external-beam radiation therapy, brachytherapy, and watchful waiting. Although radical prostatectomy has been shown to decrease disease-specific and overall mortality at 10 years when compared with watchful waiting, there are no randomized trials comparing surgery to radiation therapy.

Thus, treatment of localized prostate cancer remains controversial. Radical prostatectomy is the most frequently chosen treatment in patients younger than 70 years (Fig. 81-2). With a retropubic approach, the procedure is frequently preceded by a regional pelvic lymph node dissection. More than one third of patients with clinically localized disease are upstaged with capsular penetration, positive surgical margins, or involvement of the seminal vesicles or lymph nodes. The risk of finding positive lymph nodes increases with the T stage, Gleason grade, and PSA. A frozen section can be obtained intraoperatively and the prostatectomy aborted if the results are positive for metastatic nodal disease. The major side effects associated with radical prostatectomy include erectile dysfunction and urinary incontinence.

Radiation therapy can be delivered by external beam or by brachytherapy using iodine or palladium prostatic interstitial implants. External-beam radiation is given to a dose of about 70 to 78 Gy in daily fractions over 7 to 8 weeks. Seed implants permanently placed during an outpatient procedure may be used alone or in combination with external-beam radiation. Temporary high-dose-rate brachytherapy devices, inserted into the prostate gland for less than an hour and removed, remain investigational. Radiation therapy is associated with erectile dysfunction and rectal damage (radiation proctitis) and less commonly with urinary incontinence. Urinary retention secondary to prostate inflammation is a common but transient side effect of brachytherapy.

The third option is no treatment, also variously termed watchful waiting, expectant management, active surveillance, or observation. It involves deferring treatment until signs of progression or development of symptoms, but not initially attempting to eradicate the disease. The advantage is the lack of early complications associated with aggressive therapy but at the cost of potential late complications from locally advanced or metastatic prostate cancer, and death from prostate cancer, a possibility also faced by men who choose more aggressive treatment. Watchful waiting may be recommended to patients with low-grade disease, or a life expectancy of less than 10 years.

The treatment of locally advanced disease (T3 or T4) may consist of radiation and androgen deprivation. Addition of androgen deprivation therapy to radiation for patients with intermediate- or high-risk disease has been demonstrated to increase survival and should be strongly considered in these patients.

Relapsed Disease

Many men (up to 30% by some estimates) who were treated with curative intent for presumed organ-confined prostate cancer will have recurrence of their disease, first detected as a consistent rise in PSA level but without radiologic evidence of disease or symptoms. This scenario is termed *biochemical* or *PSA-only relapse*. Therapy for patients

Figure 81-2 Radical Prostatectomy.

with PSA-only relapse hinges on whether the relapse is thought to represent systemic disease or local recurrence of the tumor. Factors suggestive of systemic recurrence include both attributes of the original tumor (Gleason score 8 or greater, seminal vesicle invasion, or lymph node metastases) and characteristics at the time of recurrence (PSA recurrence-free survival <2 to 3 years and fast PSA doubling time, i.e., <9 months). Patients with presumed local recurrence of tumor can be offered treatment with salvage local therapy. Patients first treated with prostatec-

tomy can be administered salvage radiotherapy, whereas patients originally treated with radiation therapy can be salvaged with prostatectomy. Men with biochemical relapse thought to represent systemic disease often receive androgen deprivation therapy (ADT). However, when to institute ADT, immediately or delayed until clinical metastatic disease develops, remains controversial. Patients with biochemical recurrence have a varied prognosis, and many patients may develop clinical progression and death from prostate cancer over a period of 10 to 15 years, during

Figure 81-3 Androgen Deprivation in Metastatic Disease.

DHT, dihydrotestosterone; LH, luteinizing hormone; LHRH, luteinizing hormone–releasing hormone.

which time they are also at risk for dying from other conditions. Although there is some evidence that early ADT may delay disease progression and result in prolonged survival, the data are indirect and not consistent. Additionally, these studies do not take into account side effects of ADT, such as impotence, osteoporosis, and other quality-of-life parameters. Thus, the optimal timing of ADT for these patients is undefined and will need to be individualized.

Metastatic Disease

Metastatic prostate cancer is incurable. Patients are treated palliatively with ADT because prostate cancer cells initially require circulating testosterone for viability and prolifera-

tion (Fig. 81-3). Advantages of surgical castration with bilateral orchiectomy include immediate efficacy, compliance, and low cost. Medical castration using the long-acting preparations of a luteinizing hormone–releasing hormone (LHRH) agonist (leuprolide or goserelin) is used more commonly because of the psychological trauma associated with orchiectomy. LHRH is normally secreted from the hypothalamus in a pulsatile fashion; however, continuous stimulation of the LHRH receptor by the LHRH agonists leads to its down-regulation on the pituitary cells. LHRH agonists initially cause a transient surge in the testosterone level due to the stimulation of the pituitary LHRH receptor (flare phenomenon) and are therefore contraindicated in men with impending spinal cord com-

pression or urinary obstruction from prostate cancer. Short-term use of an antiandrogen agent such as flutamide or bicalutamide, which acts as a competitive inhibitor of the androgen receptor, is indicated for the first several weeks after administration of the LHRH agonist. The major common side effects of ADT (both surgical and medical) include loss of libido, erectile dysfunction, gynecomastia, hot flashes, loss of muscle mass, osteoporosis, anemia, and fatigue. Osteoporosis induced by ADT increases the rate of skeletal fractures; bisphosphonates prevent this treatment-related osteoporosis.

ADT is effective only temporarily because progressive disease will develop again after a median of 18 to 24 months. In this setting, second-line endocrine manipulations involving antiandrogens, low-dose steroids, or ketoconazole are often attempted. For patients who have been on long-term antiandrogen therapy, its discontinuation leads to reduction in PSA in 15% to 20% of cases; however, responses to second-line hormonal treatment tend to be infrequent and short lived.

The traditional view of prostate cancer as resistant to chemotherapy is changing. The combination of mitoxantrone and prednisone does not prolong the survival of hormone-refractory metastatic prostate cancer patients but does improve pain control and quality of life. Furthermore, docetaxel-based combination chemotherapy has been shown in randomized studies to impart a 2- to 3-month improvement in median survival over mitoxantrone and prednisone. Docetaxel represents the current standard of care for patients with metastatic hormone-refractory prostate cancer.

Zoledronic acid, a new potent bisphosphonate, decreases skeletal complications such as bone pain, fracture, and spinal cord compression in patients with hormone-refractory prostate cancer and bone metastases and is currently indicated as adjunct therapy. In addition to chemotherapy, palliation of pain associated with bone metastases may be achieved by external-beam radiation or systemic administration of bone-seeking radioactive isotopes (strontium-89 or samarium-153).

Medical Emergencies in Prostate Cancer Management

Prostate cancer frequently metastasizes to the bones and lymph nodes of the pelvis and retroperitoneum. It is one of the most common causes of spinal cord compression, an oncologic emergency that arises from epidural metastasis in the vertebral bodies and usually presents with midline accelerating back pain. Loss of ambulation due to weakness, and bowel and bladder incontinence are late symptoms that are usually irreversible despite treatment. The diagnosis can be made with computed tomography myelography or noninvasively with magnetic resonance imaging. Treatment consists of corticosteroids and radiation therapy or, in selected patients, surgical intervention. Initiation of

the LHRH agonist by itself in noncastrated patients is not recommended in this setting because of concerns about the flare phenomenon.

Obstructive uropathy may result from primary prostate cancer locally invading into the urethra and the bladder or extrinsic compressive obstruction of ureters by soft tissue nodal masses in the pelvis or retroperitoneum. It may progress to complete renal failure. Renal function can be preserved by relief of obstruction through percutaneous nephrostomy tube or internal stent placement.

Avoiding Treatment Errors

Optimal treatment of localized prostate cancer is currently undefined. Decisions should take into account the clinical risk factors for relapse, the life expectancy and comorbid illnesses of the patient, side-effect profile of the therapy, and patient preference. Primary care physicians should help patients understand the range of available options and the benefits and side effects of each option considered and avoid overly aggressive treatment in some cases. Recent surveys indicate that the use of androgen deprivation therapy as primary therapy for low-risk localized disease has been increasing in the United States recently, and this trend raises concerns about overtreatment of elderly patients with indolent disease.

Future Directions

Availability of the human genome sequence and advances in molecular profiling of tumors hold great promise for developing better prognostic and predictive markers and therapeutic agents specifically targeting cancer cells (e.g., drugs inhibiting kinases). Approaches to improve the treatment outcome of those patients unlikely to be cured by local treatment alone (e.g., high-risk group) will be explored. Treatment approaches to hormone-refractory prostate cancer will continue to be refined with available chemotherapeutic agents and novel molecularly targeted agents.

Additionally, technologic improvements in the treatment of early-stage prostate cancer are gaining popularity. The use of laparoscopic prostatectomy and, more recently, robotic prostatectomy is becoming more widespread because of their less invasive nature and faster patient recovery time. However, surgical and oncologic outcomes of these procedures will require additional long-term follow-up studies.

Upper Gastrointestinal Cancers

Introduction

Cancers of the upper gastrointestinal (GI) tract, including those of the pancreas, esophagus, stomach, liver, and biliary system, in order of U.S. prevalence, are together the most common cancer killers worldwide. Several of these tumors continue to have rising incidence in the United States, particularly esophageal cancer and hepatocellular (liver cell) carcinoma (HCC). Pancreatic cancer, despite being relatively uncommon, is the fourth leading cancer killer in the United States because of a nearly 1 : 1 ratio of cases and deaths. There has been a decline in proximal squamous cell carcinoma (SCC) of the esophagus and distal adenocarcinoma of the stomach, whereas the incidence of distal esophageal adenocarcinoma and proximal gastric carcinoma has increased. Upper GI cancers are 2 to 3 times more common in men than in women. SCC of the esophagus is 4 to 5 times more common in African Americans; adenocarcinoma is more prevalent in the white population. Cancer of the stomach is second only to lung carcinoma in incidence, with more than 750,000 new cases diagnosed worldwide each year. Incidence is highest in the Russian Federation and Japan. In the United States, there were an estimated 21,900 new cases and 13,500 deaths in 1999. This represents a dramatic decline in the past seven decades.

Pancreatic Cancer

Etiology and Pathogenesis

Tobacco use is the most well-established risk factor for pancreatic cancer, accounting for about 25% of cases. Known genetic syndromes and chronic pancreatitis account for only a small percentage of cases. At this point, most cases of pancreatic cancer are of unknown cause. Onset of diabetes has been shown to occur 1 to 3 years before diagnosis of pancreatic cancer in many cases.

Clinical Presentation

The most common presenting symptom of pancreatic cancer is abdominal pain, which is nonspecific in nature. Radiation of pain to the back is one distinguishing feature that also has ominous implications. Cancer of the head of the pancreas should always be considered in the differential diagnosis of painless jaundice. Venous thrombosis is exceedingly common in patients with pancreatic malignancies.

Differential Diagnosis

The differential diagnosis for a patient with epigastric pain and abnormalities of the pancreas on computed tomography (CT) includes pancreatitis (which can mimic tumors), cysts of the pancreas, cystadenocarcinomas (a relatively indolent form of tumor), and neuroendocrine tumors of the pancreas (Fig. 82-1).

Diagnostic Approach

Diagnosis of pancreatic cancer can occasionally be difficult because of the presence of significant amounts of scarring and inflammatory tissue in an apparent pancreatic mass. Not infrequently, patients with masses in the pancreatic head are taken to surgery without prior tissue confirmation of malignancy. CA19-9 is a carbohydrate antigen that can be a useful adjunct to diagnosis, but is not a specific marker. Staging of pancreatic cancer consists of imaging of the abdomen and chest, usually by CT. High-quality imaging is required to determine the relationship between the

Figure 82-1 Malignant Tumors—Cystadenocarcinoma, Islet Cell Carcinoma, and Chronic Relapsing Pancreatitis.

cancer and the local vasculature, which determines whether surgical resection is possible.

Management and Therapy

Optimum Treatment

LOCALIZED DISEASE. About 20% of patients present with disease that is amenable to surgical resection, a procedure that results in roughly a 20% chance of long-term survival. Pancreatic head tumors are treated surgically with a Whipple procedure, whereas more distal tumors are treated with partial pancreatectomy (Fig. 82-2). Adjuvant therapy is controversial; patients have been treated with a combination of 5-fluorouracil and radiation therapy based on a small randomized study, but subsequent data have not

confirmed this early result. Very recently, a German group showed that chemotherapy using gemcitabine can improve recurrence-free survival after surgery, a result that should prompt a study of chemotherapy alone versus chemoradiotherapy after surgical resection. Some centers routinely treat patients with chemoradiotherapy preoperatively, but to date, no randomized data support this practice. One advantage of preoperative therapy is that the patients with the worst prognosis often progress systemically during radiation and are thereby spared major surgery.

ADVANCED DISEASE. Advanced disease is generally palliated with either chemoradiotherapy in the case of non-metastatic but unresectable disease, or chemotherapy (again, gemcitabine based) in the case of metastatic disease. New therapies are desperately needed for patients with this disease.

Figure 82-2 Carcinoma of the Pancreas.

Avoiding Treatment Errors

Although a detailed discussion of treatment errors surrounding chemotherapy is beyond the scope of this book, it is important that patients with possible pancreatic tumors be managed by an experienced multidisciplinary team for optimal treatment planning before initiation of any treatment plan.

Stomach Cancer

Etiology and Pathogenesis

Environmental and genetic factors both play a role in development (Table 82-1). Migrants from high-risk areas who move to low-risk areas have an intermediate risk for development of cancer, as do their subsequent generations. *Helicobacter pylori* infection is associated with a threefold to sixfold increase in the risk for developing distal intestinal-type adenocarcinoma. The incidence of proximal gastric cancer has increased in parallel with distal esophageal cancer (see next section).

Clinical Presentation

Gastric carcinoma is asymptomatic in its early stages, or presents with vague abdominal symptoms (anorexia, abdominal discomfort, nausea and vomiting, melena, and

weakness) that are not clearly attributable to carcinoma; therefore, most gastric cancers are not diagnosed until the disease is advanced. Early satiety is a symptom associated with diffusely infiltrating carcinoma (Fig. 82-3). Weight loss, seen in more than 80% of patients, is associated with poorer survival. Symptoms attributable to metastatic disease include jaundice (from biliary obstruction), ascites, and abdominal pain.

Differential Diagnosis

Both the presentation and endoscopic appearance of gastric cancer can mimic benign gastric ulcers. Other malignancies that can mimic stomach cancer are GI stromal tumors (with a much better prognosis than adenocarcinomas), lymphomas, and other rare variants of carcinoma and sarcoma.

Diagnostic Approach

Many patients are diagnosed by endoscopy performed for symptomatic reasons or anemia. Upper endoscopy should always follow a negative colonoscopy in a patient with iron-deficiency anemia. Staging of gastric cancer is generally done by CT of the chest and abdomen. The main sites of spread of gastric cancer are liver, intra-abdominal lymph nodes, peritoneum, and lung. Peritoneal metastasis is often

Table 82-1 Risk Factors	
Gastric Cancer	Esophageal Cancer (Squamous Cell Carcinoma)
Nutritional Factors High salt consumption High nitrate consumption Low dietary vitamin A and C Lack of refrigeration	Alcohol
Exposure Rubber workers Coal workers <i>Helicobacter pylori</i> infection Epstein-Barr virus infection Radiation exposure Prior gastric surgery for benign disease	Smoking Lye ingestion Human papillomavirus infection
Genetic Factors Type A blood Pernicious anemia Hereditary nonpolyposis colon cancer Li-Fraumeni syndrome Autosomal dominant syndrome involving <i>p53</i> tumor suppressor gene mutation associated with soft tissue sarcoma, breast cancer, osteosarcoma, brain tumors, adrenal cortical tumors, acute leukemia Family history	Tylosis Autosomal dominant condition manifest by hyperkeratosis of palms and soles Plummer-Vinson syndrome Esophageal webs and iron-deficiency anemia
Preexisting Conditions Adenomatous gastric polyps Chronic atrophic gastritis Dysplasia Intestinal metaplasia Ménétrier's disease Poorly outlined disease, diagnosed in patients with giant gastric folds, dyspeptic symptoms, and hypoalbuminemia due to GI protein loss; the etiology is unknown Gastric ulcers	Achalasia Celiac sprue Other aerodigestive cancer Barrett's esophagus (adenocarcinoma)

Adapted from Karpeh M, Kelsen DP, Tepper JE: *Cancer of the stomach*. In DeVita VT, Hellman S, Rosenberg SA (eds): *Cancer Principles and Practice of Oncology*, 6th ed. Philadelphia, Lippincott, Williams & Wilkins, 2001, pp 1092-1126.

missed by conventional imaging studies, so laparoscopy is often performed before open surgery to avoid unnecessary laparotomy. Mediastinal lymph node spread is also common, and supraclavicular adenopathy (Sister Mary Joseph node) can also be found.

Prognosis

Depth of invasion and number of involved lymph nodes significantly alter prognosis. Additional adverse prognostic factors include advancing age, linitis plastica type, aneuploidy, and tumors of the gastric cardia or the gastroesophageal junction. The median survival time for metastatic cancer is less than 1 year even with therapy.

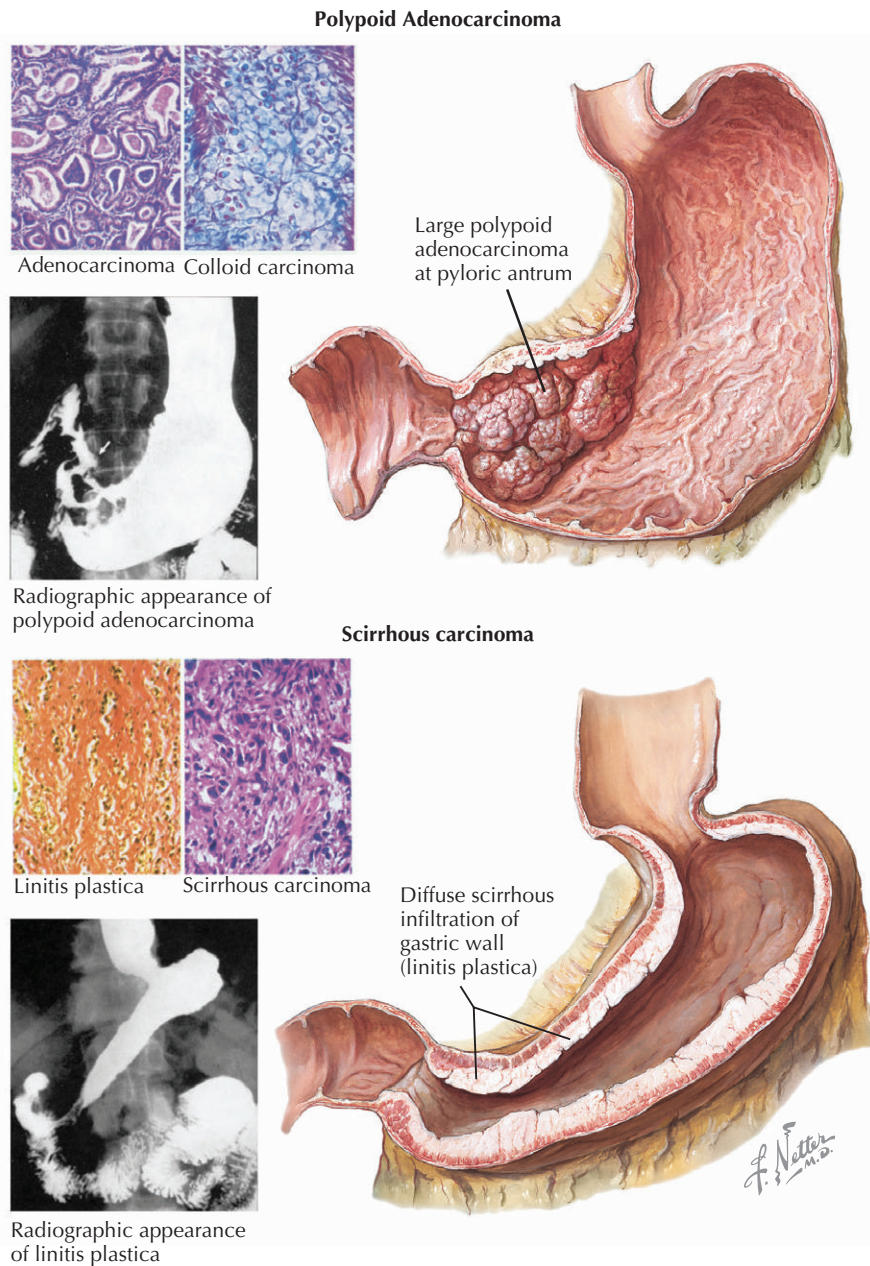

Management and Therapy

Optimum Treatment

LOCALIZED DISEASE. Localized gastric cancer is treated with partial or total gastrectomy depending on site, along with partial esophagectomy for gastroesophageal junction

tumors. There is controversy as to the extent of lymph node dissection required at the time of surgery. In Japan, a more extensive nodal dissection is performed, with reports of better overall survival rates. In the United States and Europe, a more limited dissection is performed because it is thought that more extensive operations only add to morbidity. Two randomized studies of Western versus Japanese lymph node dissection revealed no differences in outcome. The difference in outcomes has been attributed to more accurate staging (the so-called Will Rogers phenomenon) with the Japanese procedure. The operative mortality rate is about 5%, and long-term sequelae include dumping, heartburn, and reduced appetite. Gastric cancer can recur at the site of the initial tumor, local lymph nodes, in the peritoneal cavity, or distantly (usually the liver or lungs). Adjuvant therapy for stomach cancer currently includes concomitant chemotherapy and radiotherapy with further chemotherapy.

ADVANCED DISEASE. Advanced or metastatic stomach cancer may be treated with surgery for palliation, with

Figure 82-3 Carcinoma of the Stomach: Polypoid Adenocarcinoma and Scirrhus Carcinoma.

radiation often a reasonable alternative to palliate bleeding or symptoms related to eating. Chemotherapy can palliate symptoms, but effects are on average short-lived, and prolongation of survival by chemotherapy is on the order of 2 to 3 months.

Avoiding Treatment Errors

Although a detailed discussion of treatment errors surrounding surgery and chemotherapy is beyond the scope of this book, it is important that patients with stomach cancer be managed by an experienced multidisciplinary team for optimal treatment planning before initiation of any treatment plan.

Esophageal Cancer

Etiology and Pathogenesis

For squamous cell cancer of the esophagus, the most significant risk factors are alcohol consumption and tobacco use, which act both independently and synergistically. Patients with upper aerodigestive tract tumors have a 4% to 7% risk per year of esophageal cancer, suggesting a field effect of the aforementioned agents. The major known risk factor for adenocarcinoma is presence of Barrett's esophagus, which is associated with a 30- to 40-fold increase in risk (Fig. 82-4).

Figure 82-4 Malignant Tumors of Midportion and Distal Portion of Esophagus.

Clinical Presentation

Progressive dysphagia is present in 90% of patients. Dysphagia for solids precedes that for liquids. Typically, patients give a history of symptoms for 3 to 6 months before seeking medical attention. Weight loss is common, and symptoms can include cough or pneumonia from tracheoesophageal fistulas, chest pain from invasion of mediastinal structures, hoarseness from recurrent laryngeal nerve palsy, odynophagia, and hematemesis from tumor bleeding.

Differential Diagnosis

The differential diagnosis of esophageal dysphagia is given in Box 82-1.

Diagnostic Approach

The diagnosis of esophageal cancer is made endoscopically. Staging of the disease always involves CT scanning and often involves endoscopic ultrasound and positron emission tomography scanning (to look for occult meta-

Management and Therapy*Optimum Treatment*

SURGERY. Surgery should be considered in localized or loco-regional disease that has not invaded essential structures. Patients must be fit enough to withstand a thoracotomy. Even with lymphatic spread, prolonged local control and relief of symptoms are best achieved if surgery is included in the therapy. The decision on surgical approach is based on location of the tumor and the surgeon's preference. Right thoracoabdominal (Ivor-Lewis procedure), left thoracoabdominal, and transhiatal approaches are most common; morbidity and mortality rates are similar. Prognosis is related to tumor stage, not type of procedure performed. The long-term survival rate after surgical resection ranges from 10% to 30% in most series. Most recurrences are at the site of the initial tumor, but metastatic recurrence is seen most commonly in the liver and lungs.

RADIATION THERAPY AND CHEMOTHERAPY. As primary therapy, chemoradiation is approximately equivalent to

surgical resection in terms of rate of cure, but is inferior in local disease control. Chemotherapy and radiation therapy given before (neoadjuvant) surgery is considered standard at many centers based on weight of phase II data but is still somewhat controversial.

Recent consideration has been given for treating carcinomas of the cardia of the stomach as well as tumors of the gastroesophageal junction similarly to adenocarcinoma of the esophagus. The rationale is the similarity in epidemiology, genetic abnormalities, prognosis of these malignancies, and the frequency at which gastric carcinoma invades submucosally into the distal esophagus.

Avoiding Treatment Errors

As in the case of other cancers discussed in this chapter, the importance of a multidisciplinary team in initial patient evaluation and therapeutic decision making cannot be stressed enough. The key is to involve multiple specialty perspectives.

Hepatocellular Carcinoma**Etiology and Pathogenesis**

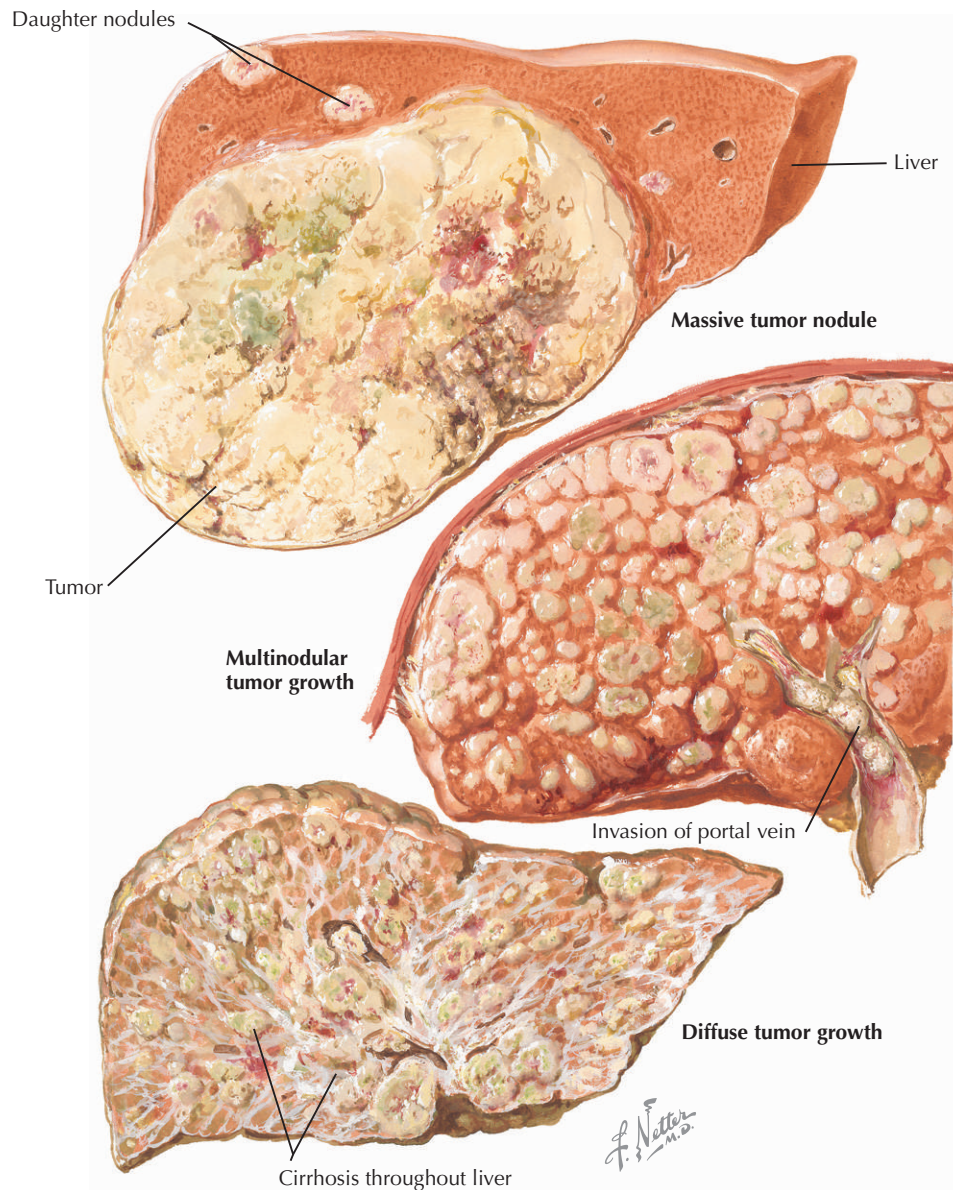

Most HCCs arise in a background of chronic liver disease (Fig. 82-5). Worldwide, the most common cause is hepatitis B infection, which can lead to HCC before the development of cirrhosis. In the Western world and Japan, hepatitis C virus infection has become the most common cause of HCC. In this setting, significant cirrhosis is usually (>70% of cases) present at the time of cancer diagnosis. Alcohol use can be a major contributor to the development of HCC in patients with chronic hepatitis, but alcoholic cirrhosis alone induces cancer development with far lower frequency. Other less common causes of chronic liver disease, such as hemochromatosis, Wilson's disease, and α_1 -antitrypsin deficiency, can also predispose to HCC.

Clinical Presentation

Tumors in the liver are largely asymptomatic. Occasionally, HCCs can present with pain, but other symptoms are nonspecific and include anorexia, weight loss, worsening ascites, and encephalopathy. Occasionally HCC can present dramatically with peritoneal hemorrhage or with the signs and symptoms of metastatic disease. Screening is recommended for patients with known chronic hepatitis or end-stage liver disease, generally with serum alpha fetoprotein (AFP) measurements and ultrasound or magnetic resonance imaging (MRI) depending on the patient's risk.

Differential Diagnosis

The signs and symptoms of developing HCC overlap with those of progressive end-stage liver disease, thus worsening liver function in such a patient should warrant consideration of imaging studies and measurement of serum

Figure 82-5 Primary Hepatic Carcinoma.

AFP. The pathologic differential diagnosis of HCC includes metastatic tumors from other sites and intrahepatic bile duct tumors (cholangiocarcinomas). Most metastatic cancers in the liver are adenocarcinomas and are generally distinguishable from HCC morphologically or by immunohistochemistry.

Diagnostic Approach

Imaging of HCC is difficult because of the background of chronic liver disease. CT scans have a propensity to underestimate disease, whereas MRI often shows lesions that are difficult to interpret as cancer or noncancerous processes such as inflammation or liver regeneration. Because HCC remains confined to the liver in most cases, extensive extra-

hepatic imaging is not necessary except in the case of symptoms that require investigation. Prognosis and treatment options are strongly influenced by the presence of portal vein thrombosis, so attention should be paid to this on imaging studies.

Management and Therapy

Optimum Treatment

When possible, transplantation or resection is the treatment of choice. Unfortunately, a minority of patients are eligible for these therapies. Small tumors detected by screening can be effectively managed by radiofrequency ablation. Because the criteria for listing of patients for liver transplantation is often in flux, patients with end-stage

liver disease should be managed by a multidisciplinary team of gastroenterologists, surgeons, radiologists, and medical oncologists. HCC that is not amenable to surgery or ablation is very difficult to manage; the disease is resistant to most chemotherapy agents, and the liver is intolerant of external-beam radiotherapy. One potentially palliative therapy with controversial efficacy is embolization (or chemoembolization) through the hepatic artery using particulate matter such as Gelfoam or beads composed of various soluble polymers.

Avoiding Treatment Errors

Patients with hepatobiliary cancers are complicated, particularly given the possibility of transplantation as a treatment, and should for the most part be managed at a tertiary care center by an experienced multidisciplinary team.

Future Directions

Despite improvements in survival during the past few decades, the prognosis of upper GI tract malignancies remains poor. Because of the relative rarity of most of these conditions in Western countries, research progress has been slow. Pancreatic cancer remains perhaps the most difficult of all cancers, with rapid progression and few effective therapies. Recently erlotinib, an agent targeting the epidermal growth factor receptor, has shown promise in a well-conducted randomized trial; but gains in survival were on the order of only weeks. In the coming years, newer agents studied in more common conditions such as lung cancer and colon cancer will be studied in the upper GI cancers, with hope that improvements in prognosis will follow. For the moment, advances in predictive capabilities, particularly for patients known to be at risk for esophageal cancer (Barrett's esophagus patients) and HCC, will be important in discovering these diseases at curable stages.

Skin Cancer

Introduction

Skin cancer is a major health problem in the United States with 1.3 million new nonmelanoma skin cancers and 51,000 new melanomas diagnosed annually. Nonmelanoma and melanoma skin cancers together account for 40% of all malignancies. The annual cost to treat nonmelanoma skin cancers in the United States approaches \$650 million. The incidence of both nonmelanoma and melanoma skin cancers has been steadily increasing. This increase is most likely due to increased sunlight exposure, increased longevity of the population, and increased surveillance. Early detection and treatment can have a significant impact on morbidity and mortality.

BASAL CELL CARCINOMA

Etiology and Pathogenesis

Basal cell carcinoma (BCC) is the most common skin cancer, accounting for more than 75% of all nonmelanoma skin cancers. There are 750,000 to 900,000 new cases in the United States each year. The ultraviolet radiation of sunlight is the most important causative factor, with both sunburns and cumulative dose over years being important. Thus, most of these cancers are located on sun-exposed areas, 85% of them on the head and neck. Incidence increases with age; it is uncommon in those younger than 50 years and rare in young adults. Persons with light skin, blue eyes, and blonde hair are at greater risk because of their relative lack of natural photoprotection with melanin pigment.

Clinical Presentation

The patient is often unaware of these painless tumors because of their very slow growth rate. Frequently slight bleeding after minor trauma (e.g., face washing) brings the patient to the physician. The most common clinical appearance of a BCC is a discrete, smooth, pink papule or nodule with a translucent or pearly sheen, telangiectasias, and a rolled border. A central erosion or ulceration is often evident; however, the appearance may vary considerably. Superficial BCC may present as a thin, scaly, red plaque easily confused with eczema or tinea. Morpheaform BCC

may appear similar to a yellow-white scar. Pigmented BCCs most often have a blue-black stippling or may have sufficient melanin to appear as a black nodule.

Differential Diagnosis

The common, nodular type of BCC has a distinctive appearance that is seldom missed because of its pearly sheen and central dell or ulceration (Fig. 83-1). At times, nodular BCC may resemble sebaceous adenoma or other appendage tumors. Superficial BCC is often mistaken for actinic keratosis, tinea, or eczema. Morpheaform BCC may resemble scar tissue, morphea, or chronic radiodermatitis. Pigmented BCC is infrequently confused with melanoma.

Diagnostic Approach

The diagnosis is not difficult to make clinically, but the skin biopsy provides confirmation.

Management and Therapy

Optimum Treatment

Basal cell carcinomas are slow-growing tumors, and treatment is usually not urgent. Metastasis is rare, but the tumor is capable of unrestricted growth causing local destruction; hence, complete ablation of the tumor is indicated. BCCs with morpheaform, infiltrating, or

Figure 83-1 Nodular Basal Cell Carcinoma.

micronodular histopathologic patterns are more difficult to cure. Tumors in certain facial sites are more resistant to ablation regardless of the method used. High-risk areas include the medial canthus, nasolabial fold, alar crease, postauricular sulcus, and concha. The selection of the type of treatment requires consideration of several factors: the size and location of the tumor, its histologic subtype, ready access to and cost of the treatment, time frame available for treatment, skill of the physician, patient age, and intervening medical conditions. Guidelines for use of different modalities are as follows:

Curettage and electrofulguration: small tumors (<1 cm), sites not prone to high recurrence rates, nonaggressive histologic patterns, speed and ease of treatment, when secondary intention healing is adequate, to minimize cost

Cryosurgery: indications similar to those for curettage and electrofulguration

Radiation therapy: larger tumors, older patients, tissue conservation, to avoid disfiguring scars

Topical chemotherapy (5-fluorouracil): for superficial tumors only (in the epidermis and at the dermal-epidermal junction), to avoid or minimize scarring

Surgical excision: any size tumor, any location or histopathologic pattern, rapid healing, planned scar placement

Mohs chemosurgery (micrographic surgery): any size tumor, aggressive histopathologic patterns, sites prone to high recurrence rates, recurrent tumors, tissue conservation relative to traditional surgical excision

The prognosis for BCC is excellent. Overall, the 5-year cure rate for small, primary (i.e., previously untreated) BCCs is about 95%, regardless of the treatment used. Larger tumors, tumors in select sites, and tumors with certain histopathologic patterns will not have as high a cure rate.

Avoiding Treatment Errors

The simple expedient of performing a biopsy before definitive treatment will prevent most cases of undertreatment and overtreatment. The pathology report should comment on whether or not the tumor has a histopathologic pattern that warrants a particular treatment. For example, by obtaining a biopsy report that confirms an infiltrating pattern in the BCC, the physician will know to use a more aggressive treatment, such as scalpel excision or Mohs chemosurgery, and to avoid undertreatment with curettage and electrofulguration.

Another avoidable treatment error is selecting an appropriate treatment based on the location and size of the malignancy.

Future Directions

Newer treatment modalities for BCC include topical imiquimod, photodynamic therapy, and systemic retinoids. A greater impact will be felt from prevention programs: public education to limit sun exposure, use of topical sunscreens and protective clothing, increased skin cancer screening by physicians, patient awareness and self-screening, and cessation of tanning bed use.

SQUAMOUS CELL CARCINOMA

Etiology and Pathogenesis

Squamous cell carcinoma (SCC) is the second most common cutaneous malignancy with an incidence of 7 to 12 per 100,000 in the white population of the United States. It is a sun-associated tumor; acute sunburns and cumulative dose are both important in causation. Hence, these cancers are more likely to develop in those with blue eyes, blonde hair, and fair skin. Persons with outdoor occupations, those with heavy recreational sun exposure, and those living in semitropical or tropical regions are at greatest risk. Most SCCs probably arise from an antecedent lesion, the actinic keratosis, a premalignant focus of intraepidermal dysplasia brought about by chronic sun exposure. It is an erythematous, scaly lesion from a few millimeters to several centimeters in size. The scale may be so thick as to form a cutaneous horn. SCC in situ is referred to as Bowen's disease (Fig. 83-2).

Factors other than sunlight that can play a significant role in the pathogenesis include certain strains of human papillomavirus, especially in the periungual and genital regions, topical agents (tar, creosote, nitrogen mustard), and some ingested chemicals (arsenic). Any chronic inflammatory focus on the skin can lead to SCC, but usually the inflammation is present for years before the cancer forms; chronic discoid lupus erythematosus lesions and vascular ulcers are examples of cancer-inciting lesions. Old thermal burn scars and sites of therapeutic x-ray exposure are well

Figure 83-2 Bowen's Disease.

known to cause SCC decades after the initial injury or treatment.

Clinical Presentation

SCC presents as papules, nodules, or plaques, which are erythematous and hyperkeratotic (Fig. 83-3). Bowen's disease is a thin, pink, scaly plaque, which may mimic a superficial fungal infection or dermatitis; the scale may be thin or compact, yellow, and thick. Although the tumor begins in the epidermis and may remain superficial for a long time, ultimately it invades into the dermis, and even subcutaneous tissues, forming a deep nodular mass. Erosion of the epidermis or deeper ulceration may occur early or late. The growth rate is variable. It may grow slowly or may double in size in a matter of weeks. In an early, superficial phase, it may be indistinguishable from an actinic keratosis or eczema. Later, its malignant nature is more obvious when a deeper, ulcerated nodule develops. The clinical appearance of even the advanced SCC may not be sufficiently distinct from other, less common cutaneous malignancies; however, its localization in an area of sun-damaged skin or in an area of old burn injury or radiation dermatitis leads one to suspect the diagnosis.

Differential Diagnosis

SCC that is in situ can resemble actinic keratosis, eczema, dermatophytosis, or in the perineum, extramammary Paget's disease. Invasive SCC must be differentiated from actinic keratosis, keratoacanthoma, granulomas, and a wide variety of benign and malignant, primary and metastatic, cutaneous tumors.

Diagnostic Approach

A definitive diagnosis can seldom be made on the basis of clinical examination alone. Skin biopsy should always be done.

Figure 83-3 Squamous Cell Carcinoma.

Management and Therapy

Optimum Treatment

The modalities and the criteria for selection used in the treatment of BCC are also used for SCC. The prognosis for SCC of the skin is good. Five-year cures are greater than 90% overall, although rates for larger and more deeply invasive tumors are lower. Metastases are not rare, approaching 3% to 4%. Tumors on the ears and lips and those that develop in thermal burn or radiation treatment sites are particularly likely to metastasize.

Avoiding Treatment Errors

Obtaining a definitive biopsy diagnosis is important before undertaking tumor ablation. The physician must also recognize that the treatment technique needs to be customized for the size and location of the carcinoma.

Future Directions

As in the case of BCC, prevention programs will have the greatest impact on this disease. Pathogenesis-based therapies under investigation include cyclooxygenase inhibitors,

topical immunomodulators, and inhibitors of hedgehog signaling.

MELANOMAS

Etiology and Pathogenesis

Melanomas develop in fair-skinned people most frequently; they are unusual in dark-skinned people. In 1% to 6% of cases, there is a familial history. Patients with large numbers of nevocellular nevi may have an increased risk, especially if some of those nevi are dysplastic. Melanomas develop in normal-appearing skin most often but may evolve from a preexisting nevus of either the congenital or acquired type. History of perceptible change in any pigmented lesion is of paramount importance. Although there is an association between melanomas and sun exposure, it is quite common for melanomas to develop on relatively sun-protected sites; head and neck, torso, and upper and lower extremities are all common sites. Usually, they first appear as nonpalpable, pigmented lesions. Their innocuous appearance and small size cause them to be overlooked or thought of as a “mole” or “age spot.” They expand laterally at the dermal-epidermal junction, and increasing diameter or perimeter irregularities prompt the patient or the physician to be suspicious. Eventually they change from macular, nonpalpable, lesions to nodular lesions.

The rate of melanoma diagnosis has doubled since 1986. Yet there is no change in the melanoma death rate, nor is there a change in the incidence of advanced disease. Some authors contend that there is not an epidemic of melanomas but an epidemic of biopsies and diagnoses.

Clinical Presentation

On examination, one usually sees a pigmented lesion with color that may vary from light brown to black, but areas of red or white are not rare (Fig. 83-4). The size of the lesion can vary from a few millimeters to several centime-

ters, and borders are usually irregular and indistinct. Ulceration is a late change. The natural variation in the appearance of benign, nevocellular nevi makes the diagnosis difficult.

Differential Diagnosis

Melanoma most often must be differentiated from benign, congenital, or dysplastic nevi; seborrheic keratosis; tattoo; foreign body; or in the case of amelanotic melanoma, pyogenic granuloma.

Diagnostic Approach

Several tools have been developed recently to more precisely define melanomas. Epiluminescence is the use of an illuminated magnifying lens to examine lesions for subtle variations in pigment pattern, which might indicate malignancy. Digital epiluminescence microscopy is available to store and compare images of suspicious lesions. Ultimately, the diagnosis is made histopathologically after a biopsy specimen is taken. Incisional biopsy of a portion of a melanoma does not predispose to metastasis or worsen prognosis; however, it is important to get a representative specimen to make a diagnosis and aid in prognosis. A shave biopsy should not be done because it may not provide the opportunity to assess the depth of invasion of the melanoma. The dermatopathologist will make the diagnosis of melanoma and assess a level of invasion. A number of subclassifications exist, with corresponding histopathologic and clinical features: lentigo maligna melanoma, nodular melanoma, superficial spreading melanoma, acral lentiginous melanoma, and desmoplastic melanoma. These classifications are less important than the level of invasion in planning treatment and assessing prognosis.

Management and Therapy

Optimal Treatment

The treatment of melanomas is surgical. The extent of surgery depends on the location, size, and depth of invasion of the melanoma. A microstaging is done at biopsy to determine the histopathologic level of invasion, measured in millimeters (Breslow levels). The Breslow level is the single most important predictor of survival for patients with melanoma. Patients with tumors less than 0.76 mm thick have a 96% 5-year survival rate, whereas patients with tumors greater than 4 mm have a 47% chance of 5-year survival. Larger melanomas, deeper melanomas, and melanomas on the head, neck, hands, and feet require wider margins of excision. The Breslow level determines the margin of excision: in general, in situ melanomas are excised with 0.5- to 1.0-cm margins, tumors with levels less than 1 mm are excised with 1.0-cm margins of clinically normal skin; tumors with levels of 1 to 2 mm are

Figure 83-4 Melanoma.

excised with 1- to 2-cm margins, and tumors with levels greater than 2 mm get 2- to 2.5-cm margins.

Additional Treatment

Elective lymph node dissection for patients with melanoma confined to the skin has not been shown to improve survival. It may improve survival if there are clinically involved regional lymph nodes. Sentinel lymph node biopsy uses lymphoscintigraphy to determine the first (“sentinel”) node in a regional basin with subsequent biopsy of that node to search for metastatic foci. This is a useful staging procedure but imparts no survival benefit for the patient and is not the standard of care. Interferon- α_{2b} for patients with metastatic disease has been approved by the U.S. Food and Drug Administration, although no statistically significant benefit has been demonstrated in prospective trials. Numerous tumor vaccine therapy trials are ongoing, but no systemic adjuvant therapy provides survival benefit yet.

Avoiding Treatment Errors

The most common error in the treatment of pigmented lesions is failure to accurately diagnose the lesion. Melanomas can clinically mimic several different benign pigmented lesions, and vice versa. Skin biopsy is essential before treatment. Further error can be avoided if the biopsy removes the entire lesion, thereby eliminating the chance of sampling error wherein a nonrepresentative portion of the lesion only is examined.

Follow-Up Care

Patients who have had a BCC or a SCC should be observed for 5 years with routine skin examinations and palpation for lymph nodes to check for recurrence of the tumors as well as surveillance for the development of new, primary cutaneous malignancies. About 30% to 50% of patients with skin cancer experience another, separate skin cancer within a few years. The frequency of the follow-up examinations varies depending on the character of the initial tumor, the level of sun damage, and precancerous change.

Patients who have had a melanoma should undergo lifelong follow-up to check for recurrence or the development of second primary melanomas, which may occur in as many as 8% of patients. Initially, check-up visits should be no longer than every 6 months, extending to 12 months in later postoperative years. Patients with a family history of melanoma and dysplastic nevi should be observed more closely. Screening for occult metastases from early melanomas is generally not warranted, although chest x-rays are often obtained in patients with thicker melanomas.

All patients should be educated about the risks of sun exposure and need to use sunscreens that have sun protec-

tion factor of 15 or higher and provide ultraviolet A and B protection. Instruction in self-examination should also be a routine part of follow-up care.

FUTURE DIRECTIONS

Although the principal treatment for all skin cancers remains surgical ablation, several new treatment modalities are under investigation. Photodynamic therapy uses a systemic or topical application of a photosensitizing chemical followed by intense or laser light to the area to bring about a more or less selective destruction of the tumor tissue with relative sparing of adjacent tissue. Immunomodulators are currently under investigation. Imiquimod, a heterocyclic amine, has shown potent antiviral and antitumor action both experimentally and in recent clinical trials. The role of radiation therapy is being revisited because some melanomas have been shown to be radiosensitive.

These authors suggest that high-dose interferon can give a reduction in 2-year mortality but stop short of claiming any benefit in sentinel lymph node-positive patients.

Cancer of the Oral Cavity and Oropharynx

Introduction

The oral cavity and oropharynx are among the most common sites of head and neck cancer. In the United States, there are 30,000 new cases of cancer arising in these sites, accounting for 8000 deaths per year. In developing nations, these numbers are much higher, with oral cavity cancer being the third most common malignancy after cervical and gastric cancers. Squamous cell carcinoma (SCC) accounts for greater than 90% of oral cavity and oropharyngeal malignancies followed by minor salivary gland malignancies in the oral cavity and lymphoma in the oropharynx. Discussion in this chapter is limited to SCC of the oral cavity and oropharynx.

Etiology and Pathogenesis
