The oral cavity is defined as the region beginning at the vermilion border of the lip extending posteriorly to the end of the hard palate superiorly, the circumvallate papillae inferiorly, and the anterior tonsillar pillars laterally. Subsites of the oral cavity are the lips, buccal mucosa, gingiva and alveolar ridge, hard palate, floor of the mouth, retro-molar trigone, and anterior two thirds of the tongue. The oropharynx begins at the posterior border of the oral cavity and extends posteriorly to the posterior pharyngeal wall, inferiorly to the epiglottis, and superiorly to the soft palate. Subsites of the oropharynx are the base of the tongue (posterior one third), lateral and posterior pharyngeal walls, tonsillar area (including pharyngeal tonsils, tonsillar pillars, and tonsillar fossae), and soft palate. Together, the oral cavity and oropharynx have important roles in airway protection, deglutition, and communication. Loss or compromise of these functions increases with tumor extent, and preservation of these functions is an important principle in treatment.

Alcohol consumption and cigarette use are the primary risk factors in the development of SCC of the head and neck. In fact, 75% of oral cancers are associated with alcohol and tobacco use. Smoking confers a 1.9-fold risk to males and a 3.0-fold risk to females for developing head and neck cancer. The risk is proportional to pack-years and drinks per day. Other forms of tobacco use, including cigar smoking, pipe smoking, and smokeless tobacco, are also

associated with these lesions. Although alcohol consumption and tobacco use are accepted independent risk factors for SCC, their concurrent use results in a synergistic effect with an even greater propensity for malignancy. Induction of *p53* mutations in the oropharyngeal mucosa has been described in patients with an alcohol and tobacco history. Popular in India and Southeast Asia, the long-term use of betel nut quid, a mixture of cured tobacco and the product of *Areca catechu* tree, is also a known risk factor. Additionally, multiple studies have shown an association between human papillomavirus and a subset of SCC. Although it is included in discussion of oral cavity carcinoma, SCC of the lip differs from other oral cavity SCCs in that ultraviolet radiation exposure is the primary risk factor. Other associations include long-term immunosuppression and tertiary syphilis.

Clinical Presentation

SCC of the oral cavity and oropharynx can present in a variety of ways. The patient may experience seemingly innocuous persistent mouth or throat symptoms. Some patients may notice a new mouth or throat lesion. With clinical suspicion, careful attention is placed on the history. The presence of bleeding, halitosis, dysphagia, odynophagia, dysarthria, paresthesias, oral-dental pain, otalgia, poor fitting dentures, trismus, or weight loss is noted. A history of cigarette smoking or alcohol use should alert the clini-

cian that the patient is at high risk for SCC of the oral cavity and oropharynx.

Thorough physical examination should incorporate the use of a headlight and dental mirrors to facilitate examination of all mucosal surfaces in the oral cavity and oropharynx. Lesions of the retromolar trigone and anterior floor of mouth are missed most often during cursory examination because of their location behind the teeth. A tongue blade is instrumental in examining these “hidden” lesions. After examination of all mucosal surfaces, palpation of the floor of the mouth, tongue, base of the tongue, and tonsillar region should be performed. Palpable masses, areas of induration, ulceration, and tenderness should alert the clinician to the possibility of malignancy. Upon palpation, the extent of fixation to underlying periosteum should be noted, indicating mandibular or maxillary involvement. Cranial nerve function should be documented with particular attention to the hypoglossal nerve as well as the mandibular and lingual branches of the trigeminal nerve. Trismus may indicate invasion of the muscles of mastication. Examination of the neck for lymphadenopathy should always be performed.

Oral Cavity

Oral cavity SCC most commonly arises in the tongue (30% to 40%), lips (25% to 30%), and floor of mouth (15%). Within the oral cavity, SCC is likely to present as a non-healing ulcer, an exophytic lesion, or an indurated infiltrating mass. Of primary tongue lesions, posterolateral oral tongue (75%) and anterolateral tongue (20%) are most common (Fig. 84-1). These tumors are often asymptomatic until advanced stages, when they present with pain, bleeding, dysphagia, loose teeth, or difficulty with articulation.

SCC of the lip (see Fig. 84-1) presents as a nonhealing, crusting, ulcerative lesion or a scaly, hyperkeratotic lesion of the vermilion; about 90% occur on the lower lip as a result of increased sun exposure. The most common age range for patients with SCC of the lip is 50 to 70 years.

Primary malignancy of the maxillary and mandibular gingival ridges represents 10% of all oral cavity cancers, with a mean age of 66.7 years. Invasion of tumor into bone at presentation is not uncommon because the gingiva closely approximates it.

A palpable neck mass representative of metastasis to a cervical lymph node is present on initial evaluation in 15% to 30% of patients with oral cavity SCC (Fig. 84-2). However, neck metastases are less frequent (10%) with SCC of the lower lip. Submental and submandibular lymph nodes are the first-echelon drainage for most of the oral cavity, and these regions are most likely to be involved when metastasis is present. The upper deep jugular lymph nodes are also often involved. Because of the rich lymphatic drainage and near midline position of many oral cavity cancers, bilateral or contralateral cervical metastases are relatively common.

Oropharynx

Oropharyngeal tumors typically appear as ulcerative or infiltrating mucosal lesions. SCC of the base of the tongue (see Fig. 84-2) is often not visible during routine physical examination and is noticeable only on palpation. The most common sites for oropharyngeal SCC are the tonsil and the anterior tonsillar pillar. To a greater extent than its counterpart in the oral cavity, SCC of the oropharynx remains asymptomatic until the disease is advanced. The most common presenting symptoms are pain and dysphagia. In more advanced cases, these symptoms can be accompanied by dysarthria, referred otalgia, weight loss, hemoptysis, hoarseness, and stridor. Cervical metastases are identifiable upon presentation in up to 60% of patients and are most commonly seen in the deep jugular nodes.

Differential Diagnosis

Differential diagnosis includes inflammatory processes and benign lesions (see Chapter 11), salivary gland neoplasms (adenoid cystic carcinoma, mucoepidermoid carcinoma, and adenocarcinoma), lymphoma (primarily with tonsillar involvement), and sinonasal malignancies, which may erode into the oral cavity and oropharynx.

The concept of *field cancerization*, where widespread epithelial dysplasia occurs in high-risk individuals, applies to SCC of the upper aerodigestive tract. The incidence of synchronous primary SCC for the upper aerodigestive is reported between 3% and 15%.

Premalignant lesions should be recognized and followed closely because early identification of asymptomatic lesions is associated with much lower morbidity and mortality. Erythroplakia is the most important premalignant lesion of the oral cavity and oropharynx. Generally seen as a red, slightly raised lesion or a smooth, atrophic red lesion, erythroplakia is associated with a 90% chance of representing dysplasia, carcinoma in situ, or SCC at the time of presentation. Erythroplakia may also represent an inflammatory lesion of the mucosa, and management includes removal of irritating factors and treatment of infection, with follow-up in 10 to 14 days. If the lesion has not resolved, incisional biopsy of the periphery of the lesion is recommended to rule out carcinoma.

Leukoplakia (Fig. 84-3), defined as a white patch of mucosa not associated with any other disease, is associated with less than 5% malignant transformation. Management of leukoplakia involves serial examination by the clinician. Biopsy is necessary only for lesions that undergo rapid growth, become symptomatic, or are otherwise clinically suspicious. Lichen planus (LP) is associated with malignancy rarely (3% to 5%), and observation or symptomatic treatment is adequate for most cases. Erosive LP occasionally merits biopsy for diagnosis because this subtype is more likely to be associated with oral cancer. Like leukoplakia, all suspicious areas of LP should undergo biopsy.

Figure 84-1 Malignant Tumors of Oral Cavity.

Diagnostic Approach

A thorough history and physical examination is the most important step in diagnosis of lesions of the oral cavity and oropharynx. Early diagnosis is of paramount importance because small, asymptomatic lesions may be treated with a high rate of cure, with minimal morbidity. Once lesions become symptomatic, the cure rate drops, and the morbidity of treatment modalities increases dramatically.

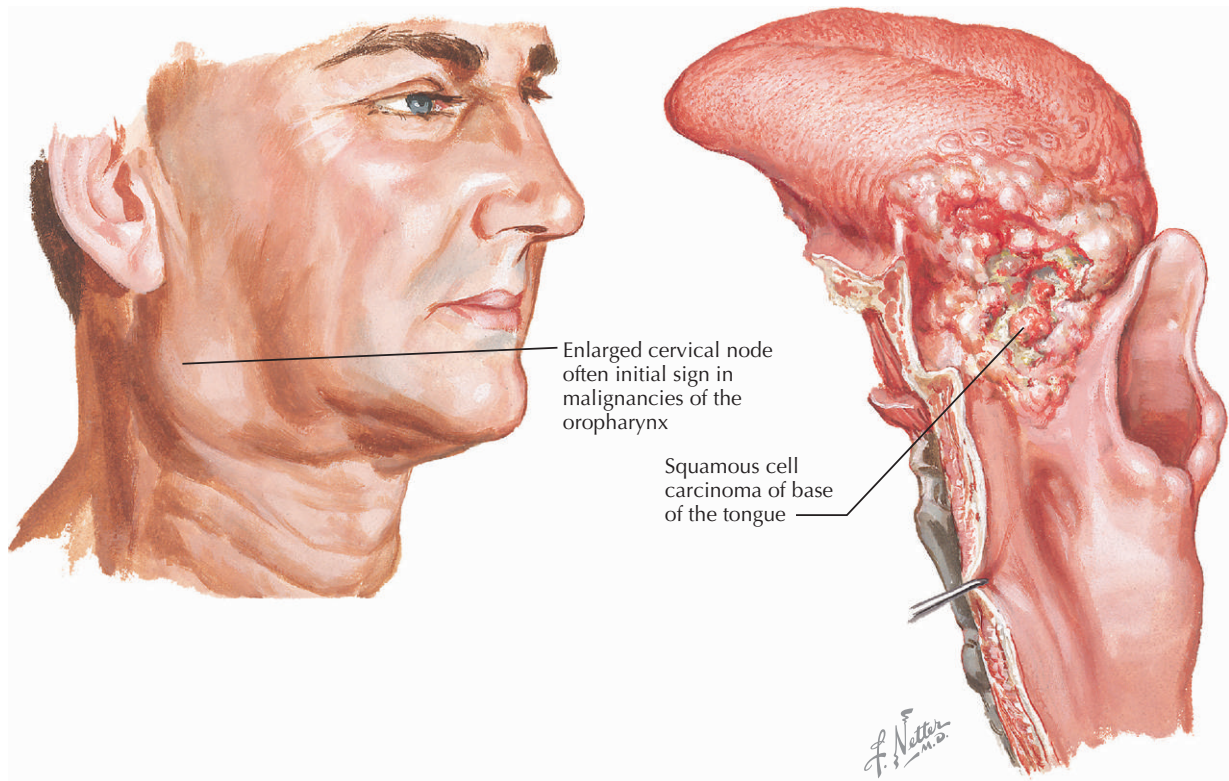

After treatment for 10 to 14 days and removal of irritants, the lesion should be reevaluated. If substantial improvement has not occurred, biopsy is indicated. Sore throat unresponsive to medical treatment, otalgia without evidence of ear disease, and unexplained dysphagia should receive further workup. Biopsy of suspicious lesions may be performed under local anesthesia if the lesion is easily accessible. Biopsy should not be excisional and should

include a section of the lesion as well as a small portion of adjacent normal-appearing mucosa. Biopsy of oropharyngeal lesions may be difficult to perform without general anesthesia.

Management and Therapy

Management

If the lesion is a superficial early SCC of the oral cavity, excision without extended workup may be appropriate. Otherwise, once the diagnosis is confirmed or strongly suspected, the patient should undergo panendoscopy (laryngoscopy, bronchoscopy, and esophagoscopy) to rule out a second primary SCC of the upper aerodigestive tract. A second primary will occur in as many as 15% of patients with SCC of the oral cavity or oropharynx. Preoperative

Figure 84-2 Malignant Tumors of Oropharynx.

studies include a chest radiograph and liver function tests to rule out distant metastasis or synchronous lung cancer. Radiographic evaluation of the mandible with a dental x-ray is indicated in some oral cavity cancers. Computed tomography (CT) or magnetic resonance imaging (MRI) may be indicated to better define the location and extent of the tumor and cervical metastases. Generally, contrast-enhanced CT of the neck (from skull base to clavicles) is most useful and expedient. Exceptions include cancer at the base of the tongue or suspicion of perineural invasion, when tissue planes are better imaged with MRI. On occasion, these imaging studies identify pathologic lymph nodes not palpable on physical examination.

Tumor staging is the most reliable predictor of prognosis. Staging using the tumor-node-metastasis (TNM) system is performed according to the guidelines of the American Joint Committee on Cancer (Table 84-1). T1 and early T2 lesions have an associated 60% to 95% 5-year survival rate when no cervical metastases are present. The presence of cervical metastasis results in a worse prognosis, with only 25% to 40% 5-year survival rate. More advanced disease (T3 and T4 lesions) carries 5-year survival rates of 11% to 40%. In general, oropharyngeal cancers have a worse prognosis than oral cavity tumors.

Other considerations in prognosis include tumor thickness and patient age. Tumor thickness has recently been shown to affect prognosis of oral cavity SCCs, with lesions more than 5 mm thick associated with significantly lower 5-year survival rates. Presence of SCC in young patients

(<35 years old) is generally a poor prognostic indicator, with most of these tumors representing aggressive disease.

Optimum Treatment

Precise staging is essential to developing an appropriate treatment plan. Treatment is comprised of surgical excision, radiation therapy, and combined modalities. Chemotherapy alone has not been shown to have curative potential in SCC of the head and neck but does have a role in palliation of advanced disease.

Early lesions (T1 and early T2) are generally amenable to single-modality treatment. Surgical resection with a wide margin (1 to 2 cm) of excision is the treatment of choice for most of these lesions. Radiation provides an alternative for patients in poor health or in whom surgical morbidity is deemed too great. Advanced lesions (infiltrative T2, and all T3 and T4) require combined modality treatment. In the oral cavity, resection is accompanied by postoperative radiation treatment. Advanced oropharyngeal SCC is treated with combined chemotherapy and radiation or resection and adjuvant radiation therapy. Tonsillar and base of tongue tumors appear to be particularly amenable to combined chemoradiation as the primary treatment.

Treatment depends on the size of the primary tumor and the presence of nodal disease. Patients with early lesions and no clinical evidence of lymphatic spread may be followed closely without specific therapy directed to the

Figure 84-3 Leukoplakia.

cervical lymph nodes. For more advanced disease, neck dissection with removal of lymph nodes at risk or radiation of the neck is required, even in the absence of clinically evident cervical metastasis. Presence of enlarged cervical lymph nodes requires neck dissection and adjuvant radiation treatment.

Treatment for advanced cancer of the oral cavity and oropharynx often results in functional loss. Primary radiation, or organ preservation therapy, followed by surgical excision of residual disease may result in decreased long-term morbidity. Despite continued improvement in treatment modalities and reconstructive techniques, dysphagia, dysarthria, and aspiration may occur after treatment. Patients often require tracheostomy and feeding tubes in the immediate postoperative period, and some require one or both for an extended period. Xerostomia, mucositis, fibrosis, lymphedema, and dysphagia are common side effects of radiation treatment.

Avoiding Treatment Errors

Early recognition of the signs and symptoms of oral cavity and oropharyngeal carcinoma is critical to optimum treatment. Referral to an otolaryngologist in a timely

manner will assist proper diagnosis and management. A neck mass should not be excised without a thorough head and neck exam to establish a primary site. A complete head and neck exam includes performing an office flexible fiberoptic laryngoscopy to assess extent of tumor and possible presence of second primary. Fine-needle aspirate of a neck mass with unknown primary will also aid in the diagnosis and management before surgical excision.

Future Directions

Several new chemotherapeutic agents such as epidermal growth factor receptor inhibitors show promise as adjuvant therapies for head and neck cancer. Other areas of promise include the use of intraoperative radiation. Gene microarray analysis has a promising role in identification of tissue biomarkers used to identify patients who are at risk for head and neck SCC or those who might benefit from certain treatment modalities. In the surgical realm, sentinel node biopsy is being evaluated as an alternative to neck dissection in patients with larger primary lesions and no evidence of nodal spread.

Although many new therapeutic options may soon be available, the role of tobacco and alcohol use in the devel-

Table 84-1 AJCC Staging of Oral Cavity and Oropharyngeal Cancer

Primary Tumor (T)	Oropharyngeal Cancer
TX: Primary tumor cannot be assessed T0: No evidence of primary tumor Tis: Carcinoma in situ T1: 2 cm or less T2: Tumor more than 2 cm but not more than 4 cm T3: More than 4 cm T4 (lip): Tumor invades adjacent structures (e.g., through cortical bone, inferior alveolar nerve, floor of mouth, skin of face) T4a (oral cavity): Tumor invades adjacent structures (e.g., through cortical bone, into deep (extrinsic) muscle of tongue, maxillary sinus, skin T4b (oral cavity): Tumor invades masticator space, pterygoid plates, or skull base or encases the internal carotid artery	T1: Tumor diameter <2 cm in greatest dimension T2: Tumor diameter >2 cm, but not >4 cm T3: Tumor diameter >4 cm T4a: Tumor invades the larynx, deep or extrinsic muscle of tongue, medial pterygoid, hard palate, or mandible T4b: Tumor invades lateral pterygoid muscle, pterygoid plates, lateral nasopharynx, or skull base or encases carotid artery
Regional Lymph Nodes (N)	Distant Metastases (M)
NX: Regional lymph nodes cannot be assessed N0: No regional lymph node metastasis N1: Metastasis in a single ipsilateral lymph node, <3 cm in greatest dimension N2: Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension; or in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension; or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension N2a: Metastasis in a single ipsilateral lymph node, >3 cm but not >6 cm in greatest dimension N2b: Metastasis in multiple ipsilateral lymph nodes, none >6 cm in greatest dimension N2c: Metastasis in bilateral or contralateral lymph nodes, none >6 cm in greatest dimension N3: Metastasis in a lymph node, >6 cm in greatest dimension	MX: Distant metastasis cannot be assessed M0: No distant metastases M1: Distant metastases present

opment of oral and oropharyngeal cancer cannot be over-emphasized. Avoidance of these risk factors is the most effective measure in reducing the incidence of head and neck cancer, and the clinician should take the responsibility of patient education as seriously as diagnosis and treatment.

Cervical Neoplasia

Introduction

Since its adoption in the United States in the 1940s, universal screening using the Papanicolaou (Pap) test has decreased death from cervical cancer by more than 70%. Cervical cancer screening is the most successful cancer screening program in history.

Although the Pap smear has reduced cervical cancer deaths in the United States, many challenges remain. The most significant barrier is lack of compliance with screening recommendations, particularly in older women, the uninsured, ethnic minorities, and women in rural areas. In the United States, 50% to 70% of cervical cancer cases occur among women who have never been screened or who have not been screened within the past 5 years. Significant racial disparity exists in both incidence and death from cervical cancer, with the highest-risk ethnic group being Vietnamese women. Although cervical cancer accounts for only 2% of all cancer deaths in women, it ranks second among women aged 20 to 39 years.

Prevention of cervical cancer and cervical cancer mortality is feasible because (1) progression from early cellular abnormalities, termed low-grade dysplasia (LGSIL), through more severe dysplasia (high-grade dysplasia [HGSIL]), to carcinoma in situ (CIS) and invasive cancer is generally slow, allowing time for detection; (2) associated cellular abnormalities can be identified; and (3) effective treatment is available for premalignant lesions. Although screening has been successful in reducing squamous cancer incidence and mortality, the incidence of glandular or adenocarcinoma is increasing.

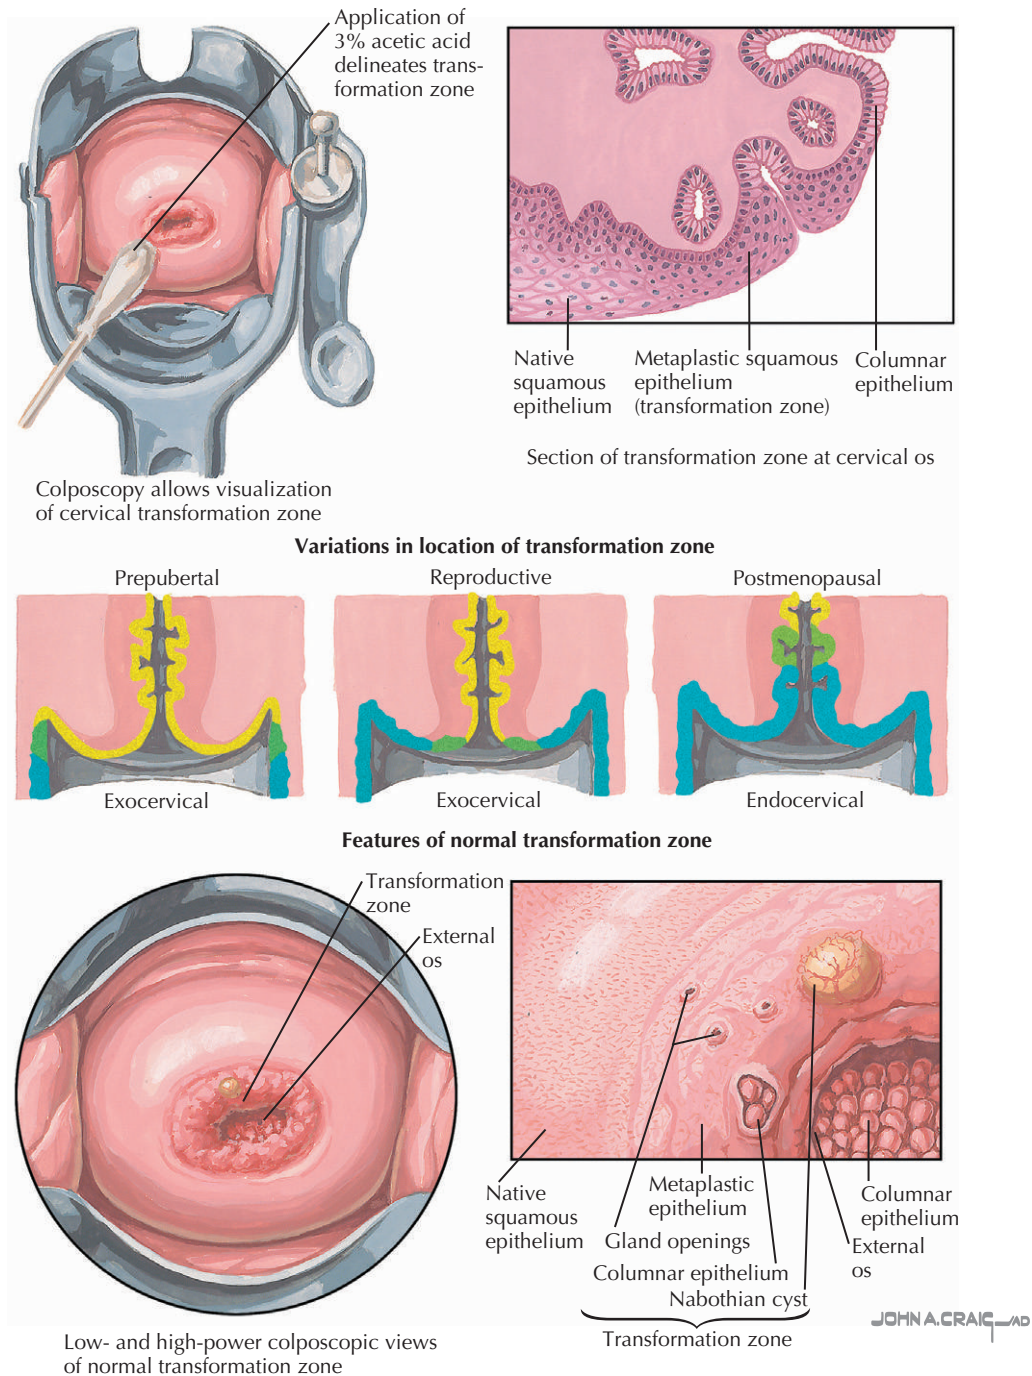

Etiology and Pathogenesis

Most cervical cancer develops within the cervical transformation zone, the region where the epithelial cells of the cervix and vagina undergo metaplastic transformation to the columnar epithelium that lines the endocervical glands. Figure 85-1 demonstrates the findings in this area, visualized during colposcopy. The susceptibility of women to squamous cancer is due to the fragility of this tissue in combination with its direct exposure to environmental carcinogens, the most important being the human papilloma virus (HPV).

HPV plays a central role in the development of cervical cancer. Ninety-five percent to 99% of squamous cell cervical cancers and 75% to 95% of high-grade CIN lesions have detectable HPV DNA. HPV is transmitted primarily by sexual intercourse and can persist in vulvar, vaginal, and cervical tissue throughout a woman's lifetime. As a group of more than 100 viral types, HPV viruses cause a diverse spectrum of diseases. HPV types 6 and 11 cause warts, and types 16 and 18 cause cancer. Among women without

cervical cytology abnormalities at baseline, those with high-risk HPV types have a relative risk for developing high-grade cervical lesions that is 58- to 71-fold higher than those without detectable HPV.

HPV DNA must integrate into the host genomic DNA to promote the changes that lead to cervical cancer. This event appears to be rare, but it is essential for cancer progression. In the absence of viral integration, the normal viral life cycle produces morphologic changes in the cervical epithelium characteristic of LGSIL. With viral integration, cellular changes characteristic of HGSIL and ultimately cancer are observed (Fig. 85-2). Interrelated host factors such as age, nutritional status, immune function, smoking, and possibly silent genetic polymorphisms modulate incorporation of viral DNA. It is estimated that nearly 100% of CIS and cancer lesions have integrated HPV DNA compared with a small minority of low-grade dysplastic lesions. The transition time from simple viral infection to integration of DNA and oncogenesis is unknown and may be influenced by the patient's risk profile. Natural history studies confirm that, in most cases,

Figure 85-1 Colposcopy.

the course of infection and cervical abnormalities progress in an orderly fashion from less to more severe lesions. Thus, the sequence of changes associated with HPV infection and the development of cervical cancer parallel the cytologic changes observed and are amenable to surveillance with Pap tests.

In the United States, peak incidence and prevalence of HPV infection occurs among women younger than 25 years; however, more than 30% of postmenopausal women have detectable HPV DNA using polymerase chain reac-

tion detection methods. Because most cervical cancers are associated with HPV infection, independent of age of cancer incidence, screening for epithelial changes caused by the virus is indicated in all age groups.

Clinical Presentation

Cervical cancer develops a clinically visible lesion when invasive, and, when deeply invasive, it spreads by local extension, through lymphatics or the bloodstream (Fig.

Figure 85-2 Cervical Cell Pathology in Squamous Tissue.

85-3). Preinvasive cervical neoplasias are rarely associated with symptoms. With progression to invasive cervical cancer, women are more likely to complain of abnormal vaginal discharge and intermenstrual bleeding, specifically after douching or coitus. Pain, loss of appetite, and weight loss are all late manifestations. Back pain may indicate ureteral obstruction related to pelvic sidewall involvement by tumor. Involvement of the bladder or rectum may present with bleeding as well as fistula formation.

Differential Diagnosis

Many cervical conditions, including genital tract infection, can influence Pap test interpretation and may result in false-positive findings. Certain benign conditions such as leiomyomas, primary herpes infection, endometriosis, and cervical polyps can cause a palpable or visible cervical mass. Uterine cancer can extend to the cervix and vagina and needs to be considered in the differential diagnosis.

Management and Therapy

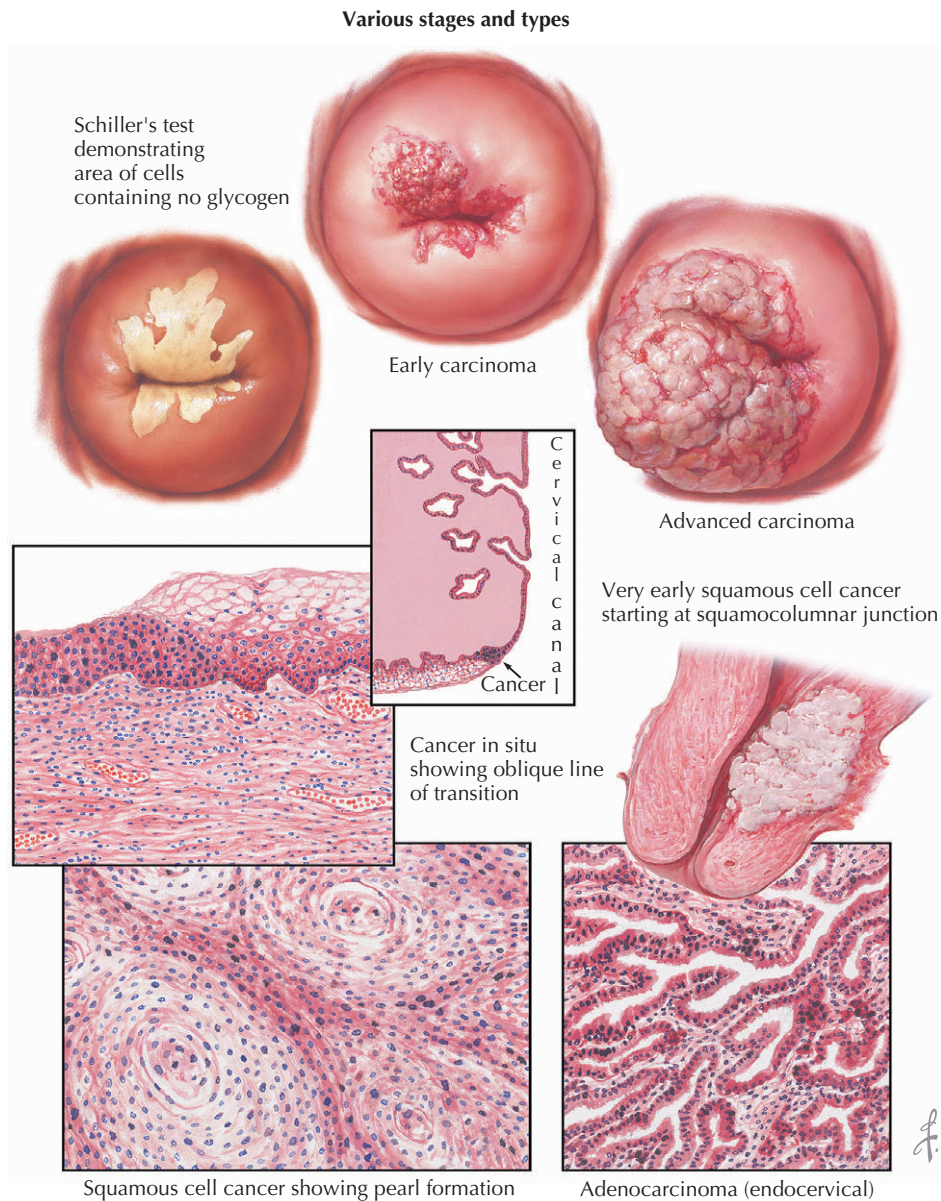

Screening

Pap test screening is recommended in women who are sexually active or age 18 or older. After three or more

consecutive annual examinations with normal findings, the Pap test may be performed less frequently at the discretion of the physician. In asymptomatic women who have undergone hysterectomy and who do not have a history of genital dysplasia or cancer, Pap tests are not necessary.

Conventional Triage of Abnormal Pap Tests

Treatment and management of screening cytologic abnormalities begins with referral to a specialist trained in colposcopy and therapy of preinvasive cervical dysplasia. Documented cases of invasive cervical cancer should be referred to a gynecologic oncologist. Understanding the triage of abnormal Pap tests requires an understanding of the current Bethesda classification of Pap test abnormalities (Box 85-1). Women with two atypical squamous cells of undetermined significance (ASCUS) or LGSIL Pap tests should undergo colposcopy and directed biopsy. A single HGSIL or cancer Pap test should prompt immediate referral for colposcopic evaluation. Whenever a clinically suspicious lesion or ulceration of the cervix is observed, referral for examination with colposcopy and biopsy should occur, irrespective of the Pap test result. Colposcopy includes magnified examination of the cervix

Figure 85-3 Cancer of Cervix.

after the application of dilute acetic acid, which accentuates dysplastic epithelium by turning it white. Directed punch biopsies of the cervix of all acetowhite lesions and any ulcerative areas showing atypical vascular patterns are performed to determine which patients require treatment and which require routine or close follow-up (Fig. 85-4).

Curettage of the endocervix is performed when the entire transformation zone cannot be visualized or when a visible lesion extends within the cervical canal. In most cases, histologically proven LGSIL is benign, and Pap test screening at frequent intervals is acceptable for compliant patients. HGSIL lesions are much more likely to develop into invasive cancer and therefore are treated. If the whole

lesion is visible on colposcopy, removal of all abnormal epithelium together with the whole transformation zone is performed by cryotherapy, laser ablation, or loop electrical excision. If the lesion is not totally visible or if it is large, cold knife conization is preferred.

Follow-up of patients with LGSIL lesions or who have undergone definitive treatment includes Pap test assessment every 3 to 6 months until three normal Pap tests are obtained. Yearly screening should be continued thereafter. Cytologic abnormalities detected on follow-up screening should be reevaluated with colposcopy.

Hysterectomy may be appropriate for certain women who have completed childbearing and desire definitive

Box 85-1 2001 Bethesda System (Abridged)**Specimen Adequacy**

treatment. Care must be taken to exclude invasive disease.

Optimum Treatment of Invasive Lesions

The current staging system of the International Federation of Gynecology and Obstetrics is presented in Box 85-2. Early-stage disease is amenable to both surgical and radiation therapy. The choice of method is based on many social and clinical factors. For tumors stage II and greater, radiation is the mainstay of therapy, with chemotherapy added to potentiate the efficacy of the radiation.

Radiation therapy can be used in all stages of disease, but surgery alone is limited to patients with stage I and IIa disease. The 5-year survival rate for stage I cancer of the cervix is about 85% with either radiation therapy or radical hysterectomy. The advantage of surgical management is evident in younger women in whom conservation of ovarian function is important.

The governing principle behind treating invasive cervical lesions surgically is based on the observation that cervical cancer typically spreads locally and to regional lymph nodes in a stepwise and predictable manner. En bloc resection of the primary tumor with margins requires radical dissection of both parametrial tissues and excision of a 2- to 3-cm vaginal margin. The degree of resection is tailored to the primary lesion size. If significant extracervical disease is demonstrated in the parametrial tissues or lymph nodes, hysterectomy is abandoned in favor of radiation therapy. Postoperative assessment of the hysterectomy specimen and lymph nodes for occult lymph node metastasis, parametrial involvement, or extensive lymphatic space invasion is critical in selecting which patients would benefit from adjuvant radiation therapy.

Radiation therapy can be administered by external beam to a total pelvic dose of 5000 cGy and as brachytherapy applied transvaginally to the cervix, and vaginal and parametrial tissues to boost the total dose to the tumor to 7500 cGy. In selected patients with large tumors or known pelvic lymph node involvement, the radiation fields are extended to include the para-aortic lymph nodes.

Recent reports of increasing the efficacy of radiation therapy with the infusion of low-dose platinum chemotherapy have led to this regimen becoming the standard of care for extracervical disease.

Local-regional cervical cancer recurrences can often be salvaged, with some long-term survivors. After primary surgical management, pelvic recurrences can be treated with radiation therapy with curative intent if no distant metastatic disease is present. Isolated lung metastasis can be treated with surgical excision with good results in patients without other sites of recurrence. Chemotherapy for advanced or recurrent disease yields short-lived responses of 30%.

Figure 85-4 Colposcopic Views of Abnormal Cervical Changes.

Avoiding Treatment Errors

Although screening algorithms for preventing cervical cancer have been successful, errors occur and represent one of the most common reasons for litigation. Most errors occur for two reasons: failure of the cytopathologist to detect an abnormality due to human error or limitations in sensitivity of the Pap test, or inadequate triage and follow-up Pap abnormalities. Many technologic innovations, such as liquid-based cytology and computer-assisted

screening, have improved incrementally the sensitivity of the Pap test for detecting high-grade lesions. In addition, incorporating HPV testing can improve sensitivity of testing at the expense of specificity.

All clinical offices that perform Pap smear screening need to have well-documented processes in place for following patients and communicating all abnormal results to them. Documentation of such communication is critical to ensure compliance. Several computer software systems are available to automate communication and provide prompts

Box 85-2 Staging of Cervical Cancer**Stage I**

The carcinoma is strictly confined to the cervix (extension to the corpus should be disregarded).

Stage IA: Invasive cancer identified only microscopically.

All gross lesions even with superficial invasion are stage IB cancers. Invasion is limited to measured stromal invasion with maximum depth of 5.0 mm and no wider than 7.0 mm.

Stage IA1: Measured invasion of stroma no greater than 3.0 mm in depth and no wider than 7.0 mm

Stage IA2: Measured invasion of stroma greater than 3.0 mm and no greater than 5.0 mm and no wider than 7.0 mm. The depth of invasion should not be more than 5.0 mm taken from the base of the epithelium, either surface or glandular, from which it originates. Preformed space involvement (vascular or lymphatic) should not alter the staging but should be specifically recorded so as to determine whether it should affect treatment decisions in the future.

Stage IB: Clinical lesions confined to the cervix or preclinical lesions greater than IA

Stage IB1: Clinical lesions no greater than 4.0 cm in size

Stage IB2: Clinical lesions greater than 4.0 cm in size

Stage II

The carcinoma extends beyond the cervix but has not extended to the pelvic wall. The carcinoma involves the vagina but not as far as the lower third.

Stage IIA: No obvious parametrial involvement

Stage IIB: Obvious parametrial involvement

Stage III

The carcinoma has extended to the pelvic wall. On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. The tumor involves the lower third of the vagina. All cases with a hydronephrosis or nonfunctioning kidney are included unless they are known to be due to other causes.

Stage IIIA: No extension to the pelvic wall

Stage IIIB: Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney

Stage IV

The carcinoma has extended beyond the true pelvis or has clinically involved the mucosa of the bladder or rectum. A bullous edema as such does not permit a case to be allotted to stage IV.

Stage IVA: Spread of the growth to adjacent organs

Stage IVB: Spread to distant organs

Adapted from Modifications in the staging for stage I vulvar and stage I cervical cancer. Report of the FIGO Committee on Gynecologic Oncology. International Federation of Gynecology and Obstetrics. Int J Gynaecol Obstet 50(2):215-216, 1995.

for unresolved abnormal testing and may be helpful at reducing such errors.

Future Directions

Given the pathogenetic role of HPV in cervical cancer and the virus prevalence among sexually active women, much research has focused on the development of an HPV

vaccine. Two prophylactic HPV vaccines have emerged, Gardasil (Merck & Co.) and Cervarix (Glaxo-Smith-Kline). Both are composed of noninfectious, recombinant HPV viral-like particles from HPV 16 and 18, which account for about 70% of all cervical cancers. Gardasil also offers protection from HPV 6 and 11, associated with genital warts. The results from large-scale randomized phase II and III clinical trials of these vaccines have been impressive, demonstrating almost 100% short-term protection from cervical dysplasia. Persistent protective effects have been seen beyond 2 years for each of these vaccines.

The quadrivalent Gardasil vaccine is approved by the U.S. Food and Drug Administration for use in women and adolescents aged 9 to 26 years. In June 2006, the Federal Advisory Committee on Immunization Practices (ACIP) recommended routine vaccination of females 11 to 12 years of age with three doses of this vaccine. This vaccination series can be started as early as 9 years of age. The ACIP also endorsed vaccination for all females 13 to 26 years of age, regardless of prior sexual activity.

Although these highly effective and well-tolerated vaccines have great potential in the reduction of cervical dysplasia and cervical cancer, many questions remain both in the implementation of routine vaccination and the durability of immunity. It is also unclear whether these vaccines may offer cross-protection against other HPV types or if these vaccines may also be efficacious in men. Challenges also exist in the future for the much needed distribution of these vaccines to economically disadvantaged women worldwide in the hope of reducing the global burden of cervical disease.

Although HPV vaccination and newer screening technologies offer great promise, the major failure in preventing cervical cancer death in the United States remains lack of compliance with screening. Studies show that the strongest influence on compliance is whether physicians emphasize the importance of screening. Racial disparity still exists in outcomes of treatment. Finally, the National Cancer Institute (NCI) has recognized that the identification of biomarkers, which might better identify those cytologic abnormalities that are clinically significant, would dramatically improve the cost-effectiveness of current screening algorithms. A consequence of the improved sensitivity of current screening methods is a loss of specificity. The number of women with an abnormal Pap test has increased significantly since the Bethesda system was adopted in 1988. Screening techniques, like liquid-based cytology and computer-assisted analysis, have greater sensitivity, but their cost is prohibitive for many patients.

Based on a recent study of minimally abnormal Pap tests, the NCI has concluded that women with ASCUS tests who do not have high-risk HPV may be screened yearly. The results of this study are significant given that ASCUS is the most common Pap test abnormality but correlates with biopsy-proven dysplasia in fewer than half of women with the finding.

Cervical cancer prevention will require a look forward to new technology while continuing to look back and fully implement what has been to date the most successful cancer prevention strategy adopted.

Testicular Cancer

Introduction

Testicular cancer is the leading cancer among men ages 15 to 35 years, although it is responsible for less than 1% of all human tumors. Up to 95% of tumors presenting in the testes in this age group are germ cell tumors, with the remainder primarily accounted for by lymphomas and some gonadal stromal tumors. Testicular germ cell tumors are primarily of pure seminoma or nonseminoma (embryonal, yolk sac, teratoma, choriocarcinoma) histology.

In 2006, about 8250 new cases of testicular germ cell tumor were diagnosed in the United States. With the implementation of effective chemotherapeutic strategies, fewer than 5% of affected patients will succumb to the illness. The incidence of testicular cancer has continued to rise over the past several decades. Although the cause of this trend remains unknown, the disease is much more prevalent in white males when compared with their African American counterparts, and the rising incidence appears to be limited to whites. The incidence of testicular cancer in African American males is about one fourth of that observed for white males.

Etiology and Pathogenesis

Several risk factors are associated with the development of this cancer; however, most patients will not display any of the known risk factors. The increased risk associated with cryptorchidism is especially notable, and patients with an undescended testicle that is not repaired by age 5 years pose a particularly high risk for the development of carcinoma in *either* testicle. About 10% of testicular tumors are associated with cryptorchidism; 25% of these tumors occur in the contralateral, normally descended testicle. The reported rate of malignant transformation of the cryptorchid testis varies from 3- to 14-fold that of a normal testis. Other risk factors include infertility or subfertility, HIV infection, and family history of testicular cancer.

Clinical Presentation

Testicular germ cell tumors most commonly present as a painless nodule on the testis, although about 30% of patients report dull pain in the testicle. Roughly 10% of patients present with acute testicular pain, and another 10% have symptoms or signs of metastatic disease (Fig. 86-1). Any concerning lesion or symptom requires expeditious evaluation with a testicular ultrasound, a highly sensi-

tive test in the diagnosis of testicular cancer. The general ultrasound appearance of testicular germ cell tumors is that of parenchymal irregularities in an otherwise smooth and homogeneous-appearing testis (Fig. 86-2).

Germ cell tumors sometimes arise outside of the testicle, generally along the midline of the body in developmental rest areas of germinal tissue. Another presentation is that of metastatic disease without evidence of a primary testicular tumor. In this case, the primary lesion has “burned out.” These clinical scenarios require a high index of suspicion in the absence of a testicular mass when there is midline lymphadenopathy and other signs compatible with underlying testicular cancer. Finally, paraneoplastic phenomena such as gynecomastia or other signs or symptoms of widespread disease can add to the diagnostic challenge.

Differential Diagnosis

The differential diagnosis of testicular cancer includes alternate causes of testicular nodularity, pain, or swelling. Testicular torsion, epididymitis, and hydrocele lead the differential diagnostic list. Additional diagnoses to consider include orchitis, trauma or hematoma, hernia, and gumma associated with syphilis.

Figure 86-1 Scrotum and Contents.

Diagnostic Approach

Biology of Testicular Neoplasm

Tumors of the testis often secrete biologic markers that are detectable in the peripheral blood. The availability of reliable serum tumor markers has greatly improved the screening and identification of tumors of germ cell origin. Alpha fetoprotein (AFP), human chorionic gonadotropin (β -HCG), and lactate dehydrogenase (LDH) provide rapid and quantitative measures of testicular germ cell tumor activity in many cases. Additional utilization of tumor markers in staging, surveillance, and prognosis is discussed

later in this chapter. These markers should be obtained as a priority in the evaluation of a testicular nodule.

AFP is commonly secreted by embryonal cells of nonseminomatous germ cell tumors. This protein is not produced by pure seminoma cells and always marks the presence of nonseminomatous germ cells either in the primary tumor or in a metastatic site, even when the tumor histology favors a pure seminoma diagnosis. The 6-day serum half-life of AFP may lead to confusion in the interpretation of samples drawn soon after orchiectomy.

β -HCG is secreted by syncytiotrophoblast giant cells, which may be a component of choriocarcinoma, embryo-

Figure 86-2 Ultrasound Findings in the Testicle.

A, Side by side vascular flow evaluations of the normal testicle (left) and diseased testicle (right). **B**, Standard ultrasound findings in the testicle, with hypoechoic lesions in a homogeneous background. **C**, Homogeneous bland appearance on ultrasound of a normal testis.

nal carcinoma, and pure seminoma. As a functional hormone, β -HCG may induce paraneoplastic phenomena such as gynecomastia by enhancing secretion of estrogen by the testis.

Several cytogenetic markers are associated with testicular germ cell tumors. In particular, isochromosome 12p (i12p) is a frequent cytogenetic abnormality that can be identified with each of the germ cell tumor histologies. It is associated with a poorer prognosis.

Pathologic Classification

The classification of testicular germ cell neoplasms includes two main subdivisions: seminoma and nonseminomatous

germ cell tumor (NSGCT). The incidence of each of these two histologic types is roughly equivalent. Key elements of the tumor histology are uniquely important in determining a treatment plan. In particular, the presence of tumor cells in the spermatic cord or lymphovascular invasion portends a higher risk for disease spread to the abdomen.

Nonseminomatous Germ Cell Tumor

Because testicular cancer is derived from cells with pluripotency, the NSGCT is generally composed of a mixed histology, although one or more tumor types may be predominant among the others. Cells that resemble yolk sac, embryonal, or teratoma tissue may be present mixed with cells derived from seminoma. These tumors can produce all or some of the classic tumor markers and classically produce both AFP and β -HCG (Fig. 86-3).

Seminoma

Testicular seminoma is a unique subtype of the testicular neoplasms. Although the pattern of spread for both types of testicular neoplasm is identical, the susceptibility to chemotherapy, and in particular radiation, of the pure seminoma makes this distinction critical to treatment, follow-up, and prognosis. The diagnosis of seminoma requires not only the presence of abundant seminoma within the tumor, but also the *exclusion* of other malignant cellular features. The presence of even a small contribution by an alternate cell type is sufficient for diagnosis of mixed NSGCT. Typically, seminoma does not secrete any measurable tumor markers, but this tumor can occasionally result in positive β -HCG tests. In contrast, the presence of measurable serum levels of AFP or LDH should alert the physician to the presence of unsampled NSGCT.

Gonadal Stromal Tumors

Tumors arising from the gonadal stroma, although uncommon, constitute a distinct subset of tumors. These neoplasms are classified as Leydig, Sertoli, or gonadoblastoma tumors and together account for less than 5% of all tumors of testicular origin.

Staging

The staging of testicular germ cell neoplasms is dependent on the following: tumor invasiveness within the contents of the scrotal sac, the presence of retroperitoneal lymphadenopathy, tumor marker level, and the presence of metastatic disease (excluding pulmonary metastatic disease). When evaluating a patient with a testicular nodule, the clinician should keep in mind that the primary lymphatic drainage of the testis follows the pattern of embryonic descent of the testicle from the ipsilateral region of the renal hilum (Fig. 86-4). Once staged using the conventional TNM staging algorithm, patients are assigned to one of three risk group categories: good risk, intermediate

Figure 86-3 Testicular Tumors I: Seminoma, Embryonal Carcinoma.

risk, and poor risk. The central purpose is to predict long-term disease-free survival and cure. Risk stratification is also a critical determinant in the choice of chemotherapy. Tables for TNM staging and inclusion criteria for risk categories stratification are provided (Tables 86-1, 86-2, 86-3, and 86-4).

Management and Therapy

Optimum Treatment of Seminoma

Stage I

The treatment of stage I seminoma remains an area of active controversy because 15% to 20% of patients who

undergo surveillance will relapse in the retroperitoneum. Seminomas are radiosensitive neoplasms, and radiation to the infradiaphragmatic region including para-aortic lymph nodes with 20 to 30 Gy has become the standard of care for most individuals. The emerging use of adjuvant single-agent cisplatin or carboplatin for one or two cycles has been increasingly considered an appropriate alternative to radiation therapy. However, 85% or more of stage I patients will achieve a long-term disease-free outcome with no further therapy after orchiectomy. Therefore, for selected patients who are committed to a strict regimen of surveillance (Table 86-5), or for whom a relative contraindication to radiation therapy or chemotherapy exists, orchiectomy alone is a reasonable option. With radiation

Figure 86-4 Testis Descent through the Deep Body Wall.

or chemotherapy, the rate of recurrence in these individuals following adjuvant treatment is less than 5%.

Stage II

Stage II seminoma is treated as stage II nonseminomatous germ cell tumor with conventional chemotherapy [see Principles of Chemotherapy].

Treatment of Nonseminoma

Principles of Chemotherapy

Cisplatin is the single most effective chemotherapeutic agent in the management of testicular germ cell tumors; carboplatin is not an alternative except in the case of adju-

vant therapy for pure seminoma. Since the advent of cisplatin-containing multidrug combinations, testicular germ cell tumors have become highly curable cancers, even in advanced stages. The focus of recent advances in the treatment of testicular germ cell tumors has been to limit the intensity of therapy with the goal of reducing the severity of both short-term and long-term sequelae of chemotherapy treatment without compromising efficacy. The standard three-drug regimen for testicular germ cell tumor is BEP, comprising bleomycin, etoposide, and cisplatin given in 3-week cycles. Long-term side effects associated with chemotherapy include premature ischemic heart disease, kidney disease, and hypertension. Another late effect that must be considered in patients who receive chemotherapy is the potential negative impact on fertility.

Table 86-1 Risk Stratification of Seminoma and Nonseminoma

Risk	Seminoma	Nonseminoma
Good	Any primary, any markers, no nonpulmonary visceral mets	Testicle or retroperitoneum primary, <i>and</i> No nonpulmonary visceral mets, <i>and</i> Good markers (all): AFP <1000; β -HCG <5000; LDH <1.5 \times ULN
Intermediate	Any primary, any markers, nonpulmonary visceral mets	Testicle or retroperitoneum primary, <i>and</i> No nonpulmonary visceral mets, <i>and</i> Int. markers (any): AFP, 1000-10,000; β -HCG, 5000-50,000, LDH 1.5 \times to 10 \times ULN
Poor		Mediastinum primary tumor, <i>or</i> Nonpulmonary visceral mets, <i>or</i> Poor markers (any): AFP >10,000; β -HCG >50,000; LDH >10 \times ULN

AFP, alpha fetoprotein; β -HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; ULN, upper limit of normal.

Table 86-2 TNM and Serum Marker Stages

T Stage	Tumor Status	M Stage	Metastatic Involvement
pTx	Primary tumor cannot be assessed	Mx	Distant metastasis cannot be assessed
pT0	No evidence of primary tumor	M0	No metastatic disease
pTis	Intratubular germ cell neoplasia	M1	Distant metastasis
pT1	Limited to the testis and epididymis, no lymphatic/vascular invasion; tumor may invade into the tunica albuginea but not the tunica vaginalis	M1a	Nonregional nodal or pulmonary metastasis
pT2	Tumor limited to the testis and epididymis with vascular/lymphatic invasion, or tumor extending through the tunica albuginea with involvement of the tunica vaginalis	M1b	Distant metastasis other than to nonregional lymph nodes and lungs
pT3	Invades the spermatic cord	S Stage	Serum Markers
pT4	Invades the scrotum	Sx	Marker studies not available or not performed
N Stage	Nodal Status	S0	All marker studies within normal limits
Nx	Regional lymph nodes cannot be assessed	S1	LDH, <1.5 \times ULN; AFP <1000; β -HCG <5000
N0	No involved regional lymph nodes	S2	LDH, 1.5 \times to 10 \times ULN; AFP, 1000-10,000; β -HCG, 5000-50,000
N1	Total lymph node mass \leq 2 cm	S3	LDH >10 \times ULN; AFP >10,000; β -HCG >50,000
N2	Total lymph node mass 2-5 cm		
N3	Total lymph node mass >5 cm		

AFP, alpha fetoprotein; β -HCG, human chorionic gonadotropin; LDH, lactate dehydrogenase; ULN, upper limit of normal.

Although these individuals often have primary sperm defects in count or viability on analysis, every patient considering chemotherapy should receive counseling about the likelihood of infertility and be given the option of expeditious sperm banking.

Stage I Optimum Treatment

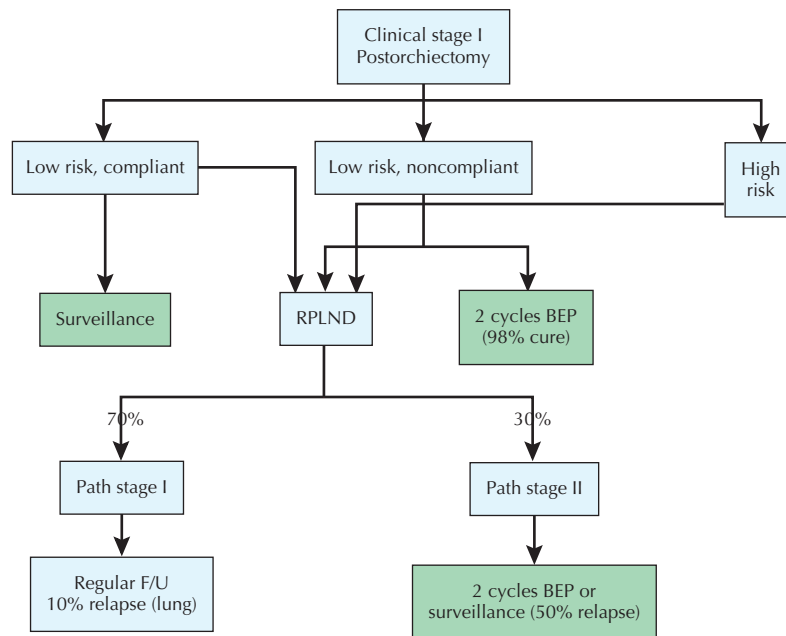

Nonseminomatous germ cell tumors are less radiosensitive than pure seminomas, and therefore adjuvant therapy with radiation is not considered a part of the algorithm for stage

I disease (Fig. 86-5). These patients also have a risk for relapse between 25% and 35%, but with a rate of cure that approaches 95% after salvage therapy. Three appropriate management options are available: (1) surgical retroperitoneal lymph node dissection, (2) adjuvant chemotherapy, or (3) surveillance (see Table 86-5).

Surgical management of these tumors requires the involvement of a skilled urologic surgeon. Although laparoscopic approaches are an exciting and potentially highly valuable addition to management, an open ipsilateral tem-

Figure 86-5 Treatment Algorithm: Stage 1 Nonseminoma.

BEP, bleomycin, etoposide, and cisplatin; F/U, follow-up; RPLND, retroperitoneal lymph node dissection.

**Table 86-3** Definition of Stages

Stage	Definition
I	Limited to the testis
Ia	T1, N0, M0, S0
Ib	T2-T4, N0, M0, S0
Is	Any T, N0, M0, S1-3
II	Spread to regional nodes
IIa	Any T, N1, M0, S0-1
IIb	Any T, N2, M0, S0-1
IIc	Any T, N3, M0, S0-1
III	Metastatic disease
IIIa	Any T, any N, M1a, S0-1
IIIb	Any T, N1-3, M0, S2
	Any T, any N, M1a, S2
IIIc	Any T, N1-3, M0, S3
	Any T, any N, M1a, S3
	Any T, any N, M1b, any S

Table 86-4 Five-Year Disease-Free Survival Estimates for Each Stage of Testicular Cancer

Stage	Seminoma	Nonseminoma	Overall

3-5	Every 3 mo	Every 3 mo	Every 6 mo
>5	Annually	As needed	As needed

plate retroperitoneal lymph node dissection (RPLND) remains the standard of care. The advantage of surgical management is that it provides both diagnostic material and local control. When the RPLND specimen is pathologically negative, the risk for development of recurrence in the abdomen is essentially nil. These patients, however, maintain an overall risk for recurrence of about 10% with the primary site of relapse in the lung. They should undergo routine annual follow-up for disease recurrence. When the RPLND specimen reveals viable germ cell tumor, the risk for recurrence in the abdomen is significantly lessened. However, the possibility of recurrence inside or outside the abdomen is still significant, about 50%. These indi-

viduals must continue to undergo intensive surveillance, including imaging and tumor marker studies, for at least 5 years, or they should consider adjuvant chemotherapy. The potential late effects of RPLND include retrograde ejaculation as a result of nerve damage along the node template. Because of this risk, an experienced urologic surgeon should have specific training in nerve-sparing approaches. With these newer approaches, the risk for retrograde ejaculation is less than 5% to 10%; however, the risk for both minor and major complications of RPLND is greater when performed after chemotherapy.

Adjuvant chemotherapy (conventionally two cycles of BEP) will reduce the risk for recurrence to less than 5%.

Finally, compliant patients who are good candidates for close follow-up due to lower risk features of their primary tumor can consider surveillance as a reasonable alternative to both RPLND and adjuvant chemotherapy.

Stage II Optimum Treatment

Surgery and chemotherapy are the mainstays of treatment in stage II patients. RPLND is considered a standard of care when markers are negative after orchiectomy. Additional chemotherapy is considered based on the identification of viable tumor and the extent of involvement. Chemotherapy for good-risk disease consists of either four cycles of EP or three cycles of BEP. Both regimens are equivalent based on randomized clinical trials. Alternatively, the use of primary chemotherapy is an appropriate course of action. Residual masses in the retroperitoneum should be resected to prevent the malignant degeneration of what may represent mature teratoma. Observation only is also acceptable if indicated by the clinical situation. Patients who meet criteria for intermediate or poor-risk disease despite of the apparent staging should be treated with additional chemotherapy or early consideration for enrollment in a clinical trial.

Clinicians must recognize the not uncommon development of retroperitoneal or other masses during the course of chemotherapy. This occurrence may herald primary refractory disease but more commonly represents the growth of a teratoma component of these masses despite chemotherapeutic efficacy for the remaining germ cell tissue.

Stage III Optimum Treatment

The management of stage III disease virtually parallels that of stage II disease. Standard chemotherapy followed by resection of residual masses in the absence of persistent marker elevation is appropriate for good-risk disease. In intermediate- or poor-risk disease, the more intensive four cycles of BEP or consideration of clinical trial therapy remains the mainstay of treatment decision making.

Management of Relapsed or Refractory Disease

Numerous regimens have been developed as salvage treatment for those situations in which primary chemotherapy is ineffective. Most still depend on the use of cisplatin as the single most active chemotherapeutic drug. Multiagent chemotherapy regimens incorporate ifosfamide and vinblastine or paclitaxel, with cisplatin, and have reasonable rates of response and even benefits to survival. Additionally, the use of ablative chemotherapy followed by autologous stem cell transplant has been used successfully in specialty centers. In patients with a long time to disease recurrence, reexposure to EP or BEP may be feasible and effective.

Avoiding Treatment Errors

The most significant treatment errors in testicular cancer involve dosing errors of the chemotherapeutic agents that comprise the BEP regimen. Severe pulmonary toxicity, fever and neutropenia, and renal failure may develop in these cases. Standardized, and preferably computerized, chemotherapy order sheets and a redundant system of checking chemotherapy dose calculations can help minimize the possibility of medication errors.

Future Directions

When treating a generally young population with curative intent, the importance of considering the long-lasting effects of therapeutic interventions requires special emphasis. Although the high cure rate of testicular cancer is a therapeutic triumph, new research efforts must now focus on identifying the late effects of treatment, including premature coronary artery disease, neuropathy, and renal impairment, as patients treated in their late teens and early 20s reach retirement age and beyond. Finally, the importance of educating patients about the problems to anticipate in the months and years following treatment warrants special emphasis. This will require the development of an effective system of care that provides long-term support and follow-up.

This seminal manuscript established BEP chemotherapy as the standard of care for treatment of testicular cancer.

Thyroid Cancer

Introduction

Thyroid cancer is a relatively rare malignancy. It is estimated that in the United States in 2006 there will be about 30,000 new cases and 1500 deaths related to thyroid cancer. A frequent presentation of thyroid cancer is as a thyroid nodule, and the prevalence of thyroid nodules is high. It is estimated that in the United States about 275,000 new thyroid nodules will be detected each year and about 5% of all adults have a palpable thyroid nodule. However, only 5% of palpable nodules are malignant. Thus, despite the relative rarity of thyroid cancer, many patients will undergo an evaluation for thyroid cancer.

Clinical Presentation

The clinical history may provide insight into the diagnosis. A very rapid enlargement over hours suggests hemorrhage into an existing thyroid nodule. Most hemorrhagic nodules are benign; however, up to 10% may be malignant. A rapid growth over weeks is suggestive of malignancy. Thyroid nodules that are larger (>3 cm) and develop in a short period of time (<2 months) are concerning for anaplastic thyroid cancer, lymphoma, or metastasis to the thyroid. However, the absolute size of the thyroid nodule is not predictive of malignancy. A change in size of an existing nodule or rapid growth during thyroid replacement therapy is suggestive of malignancy.

The patient's gender, age, environmental exposure, and family history may provide additional value information and help estimate the risk for malignancy. The risk of a thyroid nodule being malignant is twice as high in men as in women. The risk for malignancy increases with younger age, and about 20% of solitary nodules in patients younger than 20 years are malignant. A history of radiation exposure to the neck increases the risk for developing benign and malignant thyroid masses. Therapeutic radiation to the neck for skin infections, enlarged tonsils, adenoids, and thymus was common practice in the 1950s and 1960s. The Chernobyl nuclear accident spread radiation throughout Europe, with short-lived iodine isotopes being deposited in Russia, Ukraine, and Belarus. Thyroid cancer incidence in these regions has increased 12- to 34-fold, especially among children who were exposed. A careful history of

radiation exposure is particularly important for immigrants from these regions.

A prior history of malignancy, the presence of tumor syndrome, and other clinical syndromes should raise clinical suspicion of thyroid cancer as well. The syndrome of multiple endocrine neoplasia (MEN) types IIA and IIB raises the suspicion for medullary thyroid cancer (MTC). MEN IIA consists of MTC cancer (all cases), pheochromocytoma, and hyperparathyroidism, whereas MEN IIB consists of MTC, mucosal neuromas, and pheochromocytomas, and patients tend to have a marfanoid body habitus. A family history of non-MTC is important as well because about 5% to 10% of patients with papillary thyroid cancer may have a family history of thyroid cancer. Gardner's syndrome and Cowden's disease (multiple hamartomas) are associated with well-differentiated thyroid cancer.

Differential Diagnosis and Diagnostic Approach

The differential diagnosis of thyroid nodule is extensive (Box 87-1). A thorough physical examination of the head and neck should be the initial step in the evaluation. The size, number, and consistency of any nodules should be noted. The thyroid gland and thyroid nodules will move with swallowing, whereas mass external to thyroid will not. A careful palpation of the neck for any lymphadenopathy should be performed. Large, multiple, or fixed lymph nodes are suggestive of malignant involvement. The next

step in the evaluation is a fine-needle aspiration (FNA). This test is accurate and has limited morbidity, and the results are generally available in several days. The sensitivity and specificity are about 90% and 70%, respectively. The results of an FNA are generally reported as benign, malignant, suspicious, and nondiagnostic. A nondiagnostic biopsy, generally as a result of insufficient cells for evaluation, should not be considered evidence of a benign process. The level of clinical suspicion is used in guiding the workup when a definitive diagnosis cannot be made cytologically. The negative predictive value has been reported to be 97%; however, a biopsy negative for malignancy when there is a high clinical suspicion for malignancy should be further evaluated with a surgical or ultrasound-guided biopsy. If the fine-needle biopsy is suggestive of lymphoma, an excisional biopsy should be pursued.

Several laboratory tests are frequently included in the initial evaluation. A thyroid-stimulating hormone (TSH) level may be useful in determining whether the patient is euthyroid, hypothyroid, or hyperthyroid, and is helpful if a benign disorder such as Hashimoto's thyroiditis is being considered in the differential diagnosis. Patients with an elevated TSH should have a complete thyroid function panel performed. If a patient has a personal or family history of MTC or if the FNA is suggestive of MTC, a serum calcitonin and a screening for the *RET* proto-oncogene should be included in the initial evaluation. The disease phenotype is correlated with the position and type of *RET* proto-oncogene mutation. Thyroglobulin levels are useful for monitoring for recurrence of well-differentiated thyroid cancer after complete thyroidectomy; however, they should not be part of the initial evaluation. The use of radioactive iodine or technetium-99m to evaluate the thyroid nodule is of limited utility and does not help to discriminate between benign and malignant nodules. The initial imaging modality of choice is a thyroid ultrasound. This can be used to detect nonpalpable nodules,

evaluate neck lymph nodes for malignant involvement, and serially follow nodules. Certain characteristics seen on ultrasound are suggestive of malignancy; however, ultrasound characteristics cannot accurately distinguish between malignant and benign lesions. Ultrasound-guided FNA may increase the sensitivity of the biopsy by reducing the chances of missing the nodule in question.

Management and Therapy

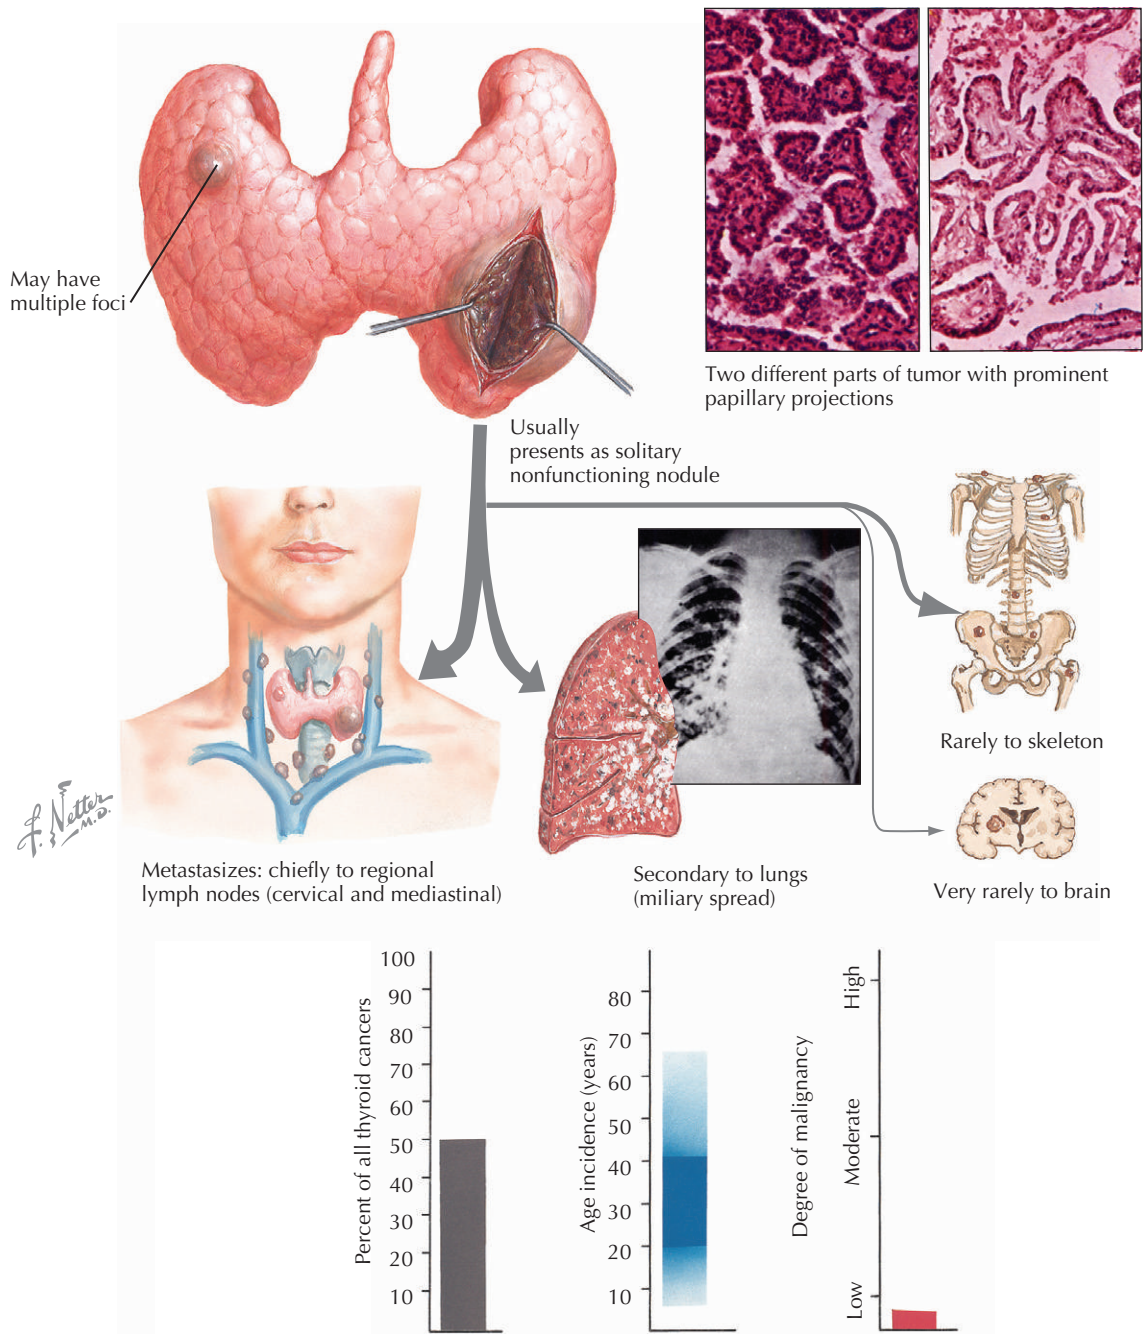

Surgical Management

Thyroid cancer is frequently divided into three general categories: well differentiated, poorly differentiated, and medullary, and the histology directly affects the surgical management. The primary management of thyroid cancer is surgical resection. A fiberoptic evaluation of the larynx to assess for vocal cord paralysis should be performed on all patients undergoing thyroid surgery. This is required because assessment for vocal cord paralysis based on symptoms and clinical history is insensitive, and vocal paralysis may indicate invasion of the recurrent laryngeal nerve or the airway. The use of computed tomography (CT) scans results in a delay radioactive iodine scanning and treatment of about 6 to 8 weeks. Thus, the use of CT scanning should be limited to select patients whose surgical resection may be improved with the additional information obtained by the CT scan. Patients with lymphadenopathy on physical exam or ultrasound and patients with diagnosis of papillary thyroid cancer, which has a higher rate of nodal involvement, should undergo preoperative CT scanning. A thorough assessment of the nodal involvement preoperatively will facilitate a more complete and directed nodal dissection at the time of surgery. In this situation improvement in surgical resection is probably of greater benefit than earlier postoperative treatment with radioiodine.

Well-Differentiated Thyroid Cancers

The well-differentiated category generally consists of papillary thyroid cancer, follicular thyroid cancer, and Hürthle cell carcinoma. Papillary thyroid cancer is associated with the microscopic feature of psammoma bodies that can be calcified and can appear as microcalcifications on ultrasound (Fig. 87-1). One feature of papillary thyroid cancer is its tendency for being multifocal, and about one third of patients will have lymph node involvement at the time of diagnosis. Of the well-differentiated thyroid cancers, papillary thyroid cancer has the lowest rate of distant metastases. Follicular thyroid cancer is pathologically characterized by capsular or vascular invasion. Follicular thyroid cancer tends to present as solitary tumors and has a more aggressive clinical course and a higher rate of distant metastases than papillary thyroid cancer. At the time of diagnosis, about 10% to 15% of patients will have metastatic disease. Hürthle cell carcinoma is characterized

Figure 87-1 Papillary Carcinoma of the Thyroid.
Clinical characteristics of papillary carcinoma of the thyroid.

by the presence of oncocytes rich in mitochondria (Hürthle cells), and vascular and capsular invasion. The diagnosis of Hürthle cell cancer and follicular thyroid cancer can only be made on a surgical specimen because evidence of capsular or vascular invasion is required for the diagnosis.

The primary principle of the surgical management of well-differentiated thyroid cancer is that there should be complete resection of all gross disease in the thyroid and involved lymph nodes. The extent of surgery, partial thy-

roidectomy versus total thyroidectomy, is a debated issue. Most of the studies are retrospective and do not definitively support one procedure over the other. There are several risk stratification systems to better estimate the chances of recurrence, and many physicians select the surgical procedure on the potential for recurrence. However, many of these risk stratification systems use factors that are not known preoperatively, which limits the application of these systems in selecting the surgical procedure. Patients

without evidence of nodules in the contralateral lobe, no evidence of lymph node involvement, and thought to be at low risk for recurrence can probably be treated effectively with resection of the involved lobe and the isthmus. It is recommended that patients who are thought to be at high risk for recurrence undergo total thyroidectomy. Most surgeons in the United States perform a total thyroidectomy. Potential advantages of performing a total thyroidectomy are the removal of occult microscopic disease in the contralateral lobe, allowing the monitoring for disease recurrence with serial thyroglobulin levels, and allowing the use of radioiodine to ablate any remaining thyroid tissue. Patients with no clinical evidence of lymph node involvement do not require an elective neck dissection, and patients with clinically evident disease preoperatively should have the involved lymph nodes removed, but do not require a formal neck dissection.

Poorly Differentiated Thyroid Cancers

Anaplastic thyroid cancer and the rare types of thyroid cancer, insular and large cell, are often included in the category of poorly differentiated thyroid cancers. Anaplastic thyroid cancer represents the most aggressive form and accounts for about 1% to 2% of all thyroid cancers. This is a very aggressive malignancy with a median survival in most studies of 3 to 6 months. Most patients present with locally advanced disease with symptoms consisting of stridor, dysphagia, dyspnea, neck pain, and tenderness. Regional lymph node metastases, vocal cord paralysis, and direct invasion into the surrounding tissues are common. Many patients will have metastatic disease at presentation, with the most frequent sites of metastases being the bone, lung, and brain. Pathologically, anaplastic thyroid cancer can be confused with lymphoma and MTC; however, MTCs stain positive for calcitonin, and lymphoma cells are positive for leukocyte common antigen. Frequently, securing a safe airway to prevent death from asphyxiation can be a critical component of palliating patients. If the patient develops an emergent airway obstruction, securing the airway requires a tracheostomy. In nonemergent circumstances, an elective tracheostomy and radiotherapy are treatment options. Radiotherapy can achieve local control in about 80% of the cases, but does not provide long-term control of this disease.

Medullary Thyroid Cancer

The surgical management of MTC differs. The current guidelines recommend that surgical treatment should include a total thyroidectomy and a modified radical neck dissection. The chances of biochemical cure, defined as normalization of basal and stimulated calcitonin levels, is dependent on the presence or absence of lymph node involvement.

Patients should have calcitonin levels checked before surgery. If the calcitonin level remains elevated postoperatively, residual disease in the neck is unlikely, and serum

calcitonin scan of the chest and abdomen or MRI is indicated to detect distant metastases. In persistent or recurrent MTC, the chance of biochemical cure with surgical resection is about 20% at experienced centers. Patients who are determined to have a MEN syndrome who have a high risk for developing thyroid cancer may undergo a prophylactic thyroidectomy.

Postoperative Management

The three components of the postoperative care consist of thyroid ablation with radioiodine, TSH suppression, and surveillance for recurrence. There is significant variability and debate about which groups of patients should receive radioiodine thyroid ablation. It is generally not offered to patients with tumors smaller than 1 cm because the risk for recurrence of these cancers is thought to be low. Some clinicians offer radioiodine to patients with tumors larger than 1.5 or 2.0 cm regardless of risk factors, whereas other physicians use it only in patients with tumors larger than 2.0 cm or those with other risks factors. Treatment with radioiodine in high-risk tumors has been shown to reduce the rate of recurrence and cancer-specific mortality.

A common method of delivering radioiodine is for patients to withdraw thyroid hormone until the TSH is elevated to 30 μ IU/mL. This can take about 4 to 6 weeks. Two weeks before therapy, the patient is placed on a low iodine diet and then undergoes a low-dose radioiodine whole-body scan, which can assist in choosing the appropriate treatment dose of radioiodine. Radioiodine ablation is usually performed after the whole-body scan, and a post-treatment whole-body scan is performed. Patients who have had an iodinated contrast CT scan in the previous 6 to 9 months should have a low 24-hour urinary iodine clearance measured. The urinary iodine clearance should be less than 200 μ g/d per gram of creatinine before radioiodine ablation. The administration of radioactive iodine should be delayed until this level is reached.

Thyroid hormone is initiated after radioiodine treatment, and the dose is titrated to suppress TSH. Some studies indicate a lower rate of tumor recurrences with lifelong TSH suppression, and the optimal level of TSH suppression may vary with the risk for recurrence. The surveillance for recurrence should consist of periodic physical exams, TSH, and thyroglobulin levels, and antithyroglobulin antibodies every 6 to 12 months. Antithyroglobulin antibodies should be checked with thyroglobulin because antibodies make thyroglobulin measurements unreliable. Because of problems of laboratory variability, the thyroglobulin levels should ideally be performed at the same laboratory. Patients with distant metastases or soft tissue invasion on initial staging or a detectable thyroglobulin level should undergo periodic neck scans and diagnostic radioiodine scans every 12 months. A recombinant TSH-stimulated thyroglobulin test is appropriate in low-risk patients. Thyroglobulin and diagnostic radioiodine tests cannot be used in patients who underwent a subtotal thy-

roidectomy. When patients have elevated thyroglobulin levels, a workup for metastatic disease should be initiated. The initial workup frequently includes an ultrasound to evaluate for a local recurrence and radioiodine scans. If the tumor produces thyroglobulin, but is not radioiodine-avid, an 18-fluorodeoxyglucose positron emission tomography scan may provide valuable information. CT scans and bone scans are also frequently used.

Recurrent or Metastatic Disease

About one third of patients will experience a tumor recurrence, and most will recur within the first 10 years after diagnosis. The rate of metastases varies with histology, and about 10% of patients with papillary thyroid cancer, 25% with follicular thyroid cancer, and 35% with Hürthle cell cancer will develop distant metastases. The prognosis is better for patients with radioiodine-avid lung metastases, and worse for skeletal and non-radioiodine-avid metastases. If a patient is suspected of having a local recurrence, the diagnosis should be confirmed on FNA biopsy given the risks of additional surgery in the neck. Surgical resection of the local recurrence is the preferred treatment, and it is generally followed by radioiodine ablation. External-beam radiotherapy may be used for recurrent cancers that are not amenable to surgical resection and not responsive to radioiodine. The fibrosis that develops after external-beam radiotherapy complicates or prevents any further surgical interventions; therefore, this treatment should only be used after consultation with surgical colleagues.

When patients have nonresectable metastases or distant metastatic disease, the primary treatment is radioiodine. This can be a very effective therapy. However, about one third of patients will undergo dedifferentiation, which consists of the loss of the ability to produce thyroglobulin and the ability to concentrate radioiodine. This creates difficulty in monitoring the disease burden and renders radioiodine ineffective. Chemotherapy is generally the standard therapy for metastatic malignancies. In metastatic thyroid cancer, several chemotherapeutic agents have been explored; however, there is no established chemotherapy for well-differentiated thyroid cancer. For anaplastic thyroid cancer, agents such as doxorubicin and paclitaxel have demonstrated activity with a response rate of about 20%. The treatment of metastatic MTC is surgical resection if recurrence is localized. If the recurrence is diffuse, chemotherapy has a limited role in the treatment of metastatic disease. Given the lack of proven effective therapies for metastatic thyroid cancer of all subtypes, the enrollment of patients in clinical trials is critical to develop new therapeutic options.

Avoiding Treatment Errors

One potential clinical decision-making error is interpreting a nondiagnostic or suspicious biopsy result as negative

for malignancy. If the clinical suspicion for malignancy is high, nondiagnostic results should lead to an ultrasound-guided FNA or surgical biopsy. In the preoperative workup, one potential error is the indiscriminate use of CT scanning, which can also limit the ability of the patient to receive radioactive iodine after the surgical resection. Only carefully selected patients should undergo preoperative CT scans. In the postoperative surveillance period, two potential errors are inadequate thyroid suppression and biochemical monitoring for recurrence. Anaplastic thyroid cancer is a rare and very aggressive malignancy, and a delay in a referral for airway management can result in airway compromise and the need for emergent tracheostomy.

Future Directions

Given the modest activity of current agents in the treatment of recurrent and metastatic disease, there is increasing interest in the development of novel therapeutic agents. During the past several years, there has been greater understanding of the proto-oncogenes and pathways responsible for the development of malignancy, and agents that specifically target these pathways are entering clinical trials. The *RET* oncogene and RAF kinases are frequently mutated in papillary thyroid cancer, and there is interest in exploring the multitargeted tyrosine kinase inhibitors, ZD6474 and AZD6244, which target this pathway. These agents are currently entering phase II trials. Other targeted therapies are currently in development and will soon enter clinical trials.

Palliative Care for Patients with Advanced Cancer

Introduction

Palliative care refers to care at the end of life. Palliative medicine is now increasingly recognized as a distinct area of medicine, and the principles of symptom management are being incorporated into surgery, pediatrics, family medicine, and internal medicine. The goals of the interventions are to relieve symptoms and suffering in individuals with advanced disease. Although these goals are often addressed in patients with cancer, similar goals are now acknowledged as important in end-stage heart and lung disease and in neurodegenerative conditions such as Alzheimer's disease and amyotrophic lateral sclerosis. Although simple medical management of a symptom such as pain does not require this type of specialized approach, the broader context within which the symptom of pain may be seen often benefits from psychological counseling and from addressing social, existential, spiritual, and other dimensions of the symptom. It is the use of a multidisciplinary approach that recognizes and utilizes the numerous facets of care at end of life that distinguishes palliative care from other disciplines.

Approach to the Patient

The approach to a cancer patient at the end of life must address the futility of additional active, disease-oriented treatments. In the United States, this has been particularly difficult because of the environment in which cancer is treated. This environment has led to a continued reduction in the number of days that the patient is on hospice in the United States (a surrogate marker for stopping active treatment).

A recent review by Okon and Gomez describes an approach that acknowledges the multidimensional nature of end-of-life care. Pain should be addressed in the context of the totality of depression, impact on function, and social support. Several tools and approaches are discussed by the authors to evaluate the role of autonomy, communication, closure of life affairs, economic burden, and transcendental and existential issues on symptoms at the end of life.

Pain

Pain that is seen at the end of life in cancer patients is often a combination of disease and treatment effects. Surveys of this population throughout the world have shown that 70% to 80% of patients with cancer will have pain and that in at least one third of those patients, the pain will interfere with function. Points that are important in the history are location, character, and severity. The role of movement (incidental pain) is also important. The perception of pain is commonly altered by other symptoms (e.g., fatigue, weakness, nausea, constipation, dyspnea, coughing); or psychological factors (e.g., depression, anxiety, and feelings of hopelessness or anger). The impact that the pain has on a patient's daily activities and psychosocial functioning varies greatly. Pain and the context within which it is viewed may change frequently, and reassessments should be done at intervals that account for the rate of change.

Pathophysiology of Pain

The afferent pathways for pain in the nervous system begin with nociceptors, specialized receptors that respond to noxious physical or chemical stimuli widely distributed throughout the body except in the brain. Pain afferent fibers enter the spinal cord through the dorsal root and synapse in the dorsal horn and then ascend through the spinothalamic and spinoreticular paths to the thalamus and the reticular system, respectively. The efferent pathways, which modulate nociceptive transmission, originate in the central nervous system and travel down the lateral posterior column into the peripheral nerves. The efferent pathways are activated by endogenous endorphins and can be activated centrally by opioids that mimic the activity of endogenous endorphins. The neurotransmitter serotonin is also believed to be important in some of these descending pathways, and this may account for the action of antidepressants in the treatment of pain.

Classification of Pain

Nociceptive pain arises from direct stimulation of the nociceptors by physical or chemical stimulation of the nerve endings due to tissue damage; it is often divided into somatic and visceral pain. Somatic pain is described as aching pain that is often well localized. Visceral pain is poorly localized and described as squeezing or a pressure sensation; it may be referred to distant cutaneous sites. It is caused by infiltration, compression, or distention of thoracic or abdominal viscera that are innervated by the sympathetic nervous system. Neuropathic pain is burning or tingling with intermittent lancinating pain that results from tumor infiltration or compression of a peripheral nerve or the spinal cord. This type of pain is also seen in diabetic neuropathy or postherpetic neuralgia.

Optimum Treatment of Pain

If the disease is responsive, treatment of the underlying condition can provide significant pain relief. However, for most patients during their disease course, symptom management will also be needed. The management of cancer pain has employed the World Health Organization (WHO) Analgesic Ladder that was developed 20 years ago. A review of the history of this three-step ladder by Foley emphasizes the multidimensional nature of pain that is addressed in this document. For many patients with cancer, treatment begins with the strong opioids described in WHO step 3. Most of these patients' pain will not be controlled with drugs that are used at steps 1 and 2. The step 3 drugs include morphine, hydromorphone, and methadone. Analgesia may have been used at the beginning of the illness, but with progression of the disease or inability to relieve the pain with disease-focused therapy, symptom management with stronger opioids and other measures become more important. Radiation of a painful

bone lesion may still play a role in this population, and many of the short-course schedules used outside of the United States are now being used in this country with excellent results. Stabilization of the spine by external bracing may diminish incident pain. Use of bisphosphonates for selected tumors—breast and prostate cancer and myeloma—may relieve the pain of bony metastases. Although the WHO Analgesic Ladder is not ideal, it remains the best known effort to adopt principles of cancer pain management throughout the world. There are now more than 30 guidelines from more than 12 countries. Worldwide, access to pain medications remains a major issue.

Avoiding Treatment Errors

An extensive review is beyond the scope of this chapter; several topics are briefly discussed. Balancing the need to relieve pain with the side effects of the analgesics used occurs with the management of almost all patients. Several of these agents have unique issues associated with them. For example, the use of drugs such as fentanyl, given in micrograms, with a patient-controlled analgesia pump requires attention to the programming of the pump. Drugs that have a long half-life in the body, such as methadone, have the potential for cumulative effects that may not be immediately seen. Recently, the U.S. Food and Drug Administration has published a warning for this drug and the potential for cardiac arrhythmias. Many of the opioids are cleared by drug-metabolizing enzymes in the liver (the cytochrome P-450 system), and there is the potential for clinically apparent drug interactions, such as phenocopying, that could occur with codeine and other drugs that affect the CYP 2D6 isozyme.

Conversions of all the opioids, especially methadone, need to take into account the issue of incomplete cross-tolerance for the new drug leading to overdosing if a reduction in starting dose is not done.

Anorexia and Cachexia

Cancer cachexia refers to the weight loss and particularly loss of muscle mass and adipose tissue commonly associated with advanced cancer. The syndrome of loss of appetite and weight loss is as common in the advanced cancer patient as that of pain. Although other conditions such as AIDS have similar loss of weight, the alteration of metabolism is more profound in cancer. In contrast to starvation, there is an increase in energy expenditure and much greater proteolysis. Although originally thought to be a form of starvation of the host as a result of the consumption of calories by a highly metabolic tumor creating a calorie deficit for the body, recent work has shown a more complex picture. Substances produced by the tumor such as proteolysis-inducing factor promote breakdown of protein. In response to the tumor, the patient (host) may make such

factors as tumor necrosis factor (TNF), interleukin-6, and interleukin-1. These host-derived cytokines further accelerate the loss of weight. There may be derangements in the autonomic nervous system such as decreased emptying of the stomach or slowing of transit time in bowel emptying.

Anorexia is defined as the decline in food intake to the point that caloric intake does not provide enough energy for the amount of caloric expenditure. In advanced cancer, this symptom is due to several causes. These include alteration in taste thresholds to bitter and sweet; changes in the oropharyngeal environment due to treatment with damage to the mucosa, and loss of salivary function. The degree of symptoms may vary by the type of tumor and its treatment. The two syndromes often occur simultaneously, and symptoms can be very disturbing to the patient's family or caretakers; however, they do not always cause the patient discomfort. Patient and family education is very important.

Optimum Treatment

The initial treatment involves encouraging increased oral intake or the use of high calorie nutritional supplements; however, as the patient becomes more ill, these measures may not be sufficient. The use of total parenteral nutrition has not been shown to be beneficial in affecting survival in a variety of cancers, both adult and pediatric. Treating symptoms that may be contributing to the syndrome is an important aspect of managing anorexia and cachexia.

Pharmacologic approaches may result in an increased appetite or sense of well-being; less frequently, they result in improvement in objective parameters such as weight gain or lean muscle mass. Potential adverse effects must be balanced against the relatively modest benefits. Often, decisions are made based on the patient's and the family's preferences and the level of anxiety and discomfort created by the anorexia and cachexia.

Corticosteroids, usually dexamethasone or methylprednisolone, are used most often. Trials have shown an improvement in appetite and performance status, but they have been associated with adverse events such as gastrointestinal hemorrhage, cushingoid body features, and myopathy. These relatively inexpensive medications are also beneficial in the treatment of chronic nausea and pain and may be beneficial in the treatment of cancer-associated fatigue. The proper dose and duration of treatment have not yet been definitively determined.

The progestational agent, megestrol acetate, is often used in this situation. Several studies have documented its effectiveness in increasing appetite and food intake in a significant percentage of patients. The dose used has varied from 480 to 1600 mg daily. Side effects include fluid retention, edema, and erectile dysfunction in men. There is some concern about a possible increased risk for deep venous thrombosis. The high cost of megestrol acetate,

especially in comparison to corticosteroids, must be considered with the use of this agent.

Emerging Therapies

Dronabinol, a derivative of marijuana, has shown some activity as an appetite stimulant and in the treatment of chronic nausea, benefits that have increased interest in its use in the treatment of cancer cachexia and anorexia. As expected, there are associated mood effects, somnolence, and confusion. Thalidomide is believed to alter levels of TNF, a cytokine that may be responsible for anorexia and cachexia. A preliminary study revealed some therapeutic efficacy. Thalidomide may be of benefit in the treatment of coexisting insomnia also. It is a teratogen and has been associated with adverse events such as dry mouth, somnolence, and peripheral neuropathy. Melatonin is believed to alter TNF levels and is relatively well tolerated. A preliminary study revealed some efficacy in preventing weight loss in patients with metastatic cancer. Anabolic steroids have been considered as a possible treatment for these symptoms, although a recent randomized controlled trial showed that they were inferior to dexamethasone or megestrol acetate. Recently, attention has focused on the use of ghrelin, a peptide that stimulates food intake.

Hydration

Often patients with advanced cancer have a decline in their oral intake due to cancer fatigue, persistent nausea and vomiting, and cancer anorexia and cachexia. Family members and members of the medical staff will often raise the issue of the palliative benefits of intravenous hydration. Many family members have concerns that if intravenous fluids (IVF) are not initiated, the patient will "die of thirst," and this fear is often compounded if the patient has dry mucous membranes or the appearance of dehydration. The family may perceive the decision to discontinue intravenous hydration as letting him or her die, and they must be educated before any discussion or decision to forego or discontinue hydration.

The risks and benefits of IVF are debated in the palliative care community because many studies evaluating its use have been done in very heterogeneous patient populations. The symptoms, clinical outcomes evaluated, and evaluation methods used have varied among studies, making direct comparison difficult. The argument in favor of the use of IVF is that the patient may have less delirium related to dehydration and a lower frequency of adverse events from altered drug metabolism due to renal insufficiency. There is no evidence that the use of IVF in this setting prolongs life to any significant degree. Arguments against the use of IVF focus on the risk for fluid overload and possible benefits such as decreased pulmonary and gastrointestinal secretions with less nausea and vomiting; decreased urine production with fewer episodes of incontinence; and diminished need for use of urinary catheters.

Many patients complain of thirst or dry mouth while in the terminal phases of their illness, and this can cause significant discomfort for the patient and the patient's family. A study by McCann and colleagues found that 66% of patients admitted to a palliative care unit complained of thirst or dry mouth on admission, but with the use of small amounts of oral fluids, ice chips, and routine mouth care, these symptoms were relieved for several hours in most patients. This study supports the use of these simple measures initially to address a patient's complaint of thirst or dry mouth before considering the initiation of IVF.

Avoiding Treatment Errors

Given the relative paucity of data on the risks and benefits of intravenous hydration and the relative risks and benefits of fluid deficiency in the palliative setting, it is impossible to give definitive recommendations on this subject. Often the decision will have to be made based on the condition and wishes of the individual patient and his or her family and on the opinion of the physician and medical staff caring for the patient. Careful attention to the volume of fluid may avoid the possibility of rapidly worsening renal function and the potential for opioid-induced neurotoxicity, but at the same time not overhydrate the individual to cause a worsening of dyspnea.

Future Directions

Worldwide, there are increasing numbers of palliative care specialists both in developed and developing countries. In the United States, the development of a separate boarded specialty is underway. The development of such programs in the United States requires resolution of reimbursement issues; however, demand for such services continues to increase.

Fever of Unknown Origin

Introduction

Fever is common with many acute illnesses. The fever usually resolves spontaneously. However, certain patients develop prolonged fever without clear cause, posing a diagnostic challenge for their physicians.

Petersdorf and Beeson established the classic definition of fever of unknown origin (FUO) in 1961. They defined FUO as (1) illness of more than 3 weeks' duration, (2) temperature of 38.3°C (101°F) on several occasions, and (3) uncertain diagnosis after 1 week of study in hospital. Although this definition of FUO has been very useful, changes in the practice of medicine have significantly altered the approach to patients with persistent fever. In 1991, Durack and Street proposed revisions to the definition, including the substitution of three outpatient visits or 3 hospital days for the third criterion. Alternatively, the third criterion can be replaced with uncertain diagnosis after 1 week of evaluation. In addition, Durack and Street proposed distinguishing classic FUO from nosocomial, neutropenic, or HIV-associated FUO, given differences in etiologies and underlying conditions.

Etiology and Pathogenesis

More than 200 diseases have been linked to FUO. The five primary categories of FUO are infection, malignancy, noninfectious inflammatory diseases, miscellaneous, and undiagnosed (Fig. 89-1). Infections represent about 30% to 50% of cases; malignancies, 20% to 30%; noninfectious inflammatory diseases, 10% to 30%; miscellaneous, 15% to 25%; and undiagnosed, 5% to 15%. Most case series on FUO report infections as the most common diagnosis; however, some studies have shown an increase in cases due to noninfectious inflammatory diseases. The prevalence of febrile illnesses varies geographically, with infections being more common in developing countries and tropical regions. Causes also vary according to host factors such as underlying immunosuppression and hospital and health service exposures.

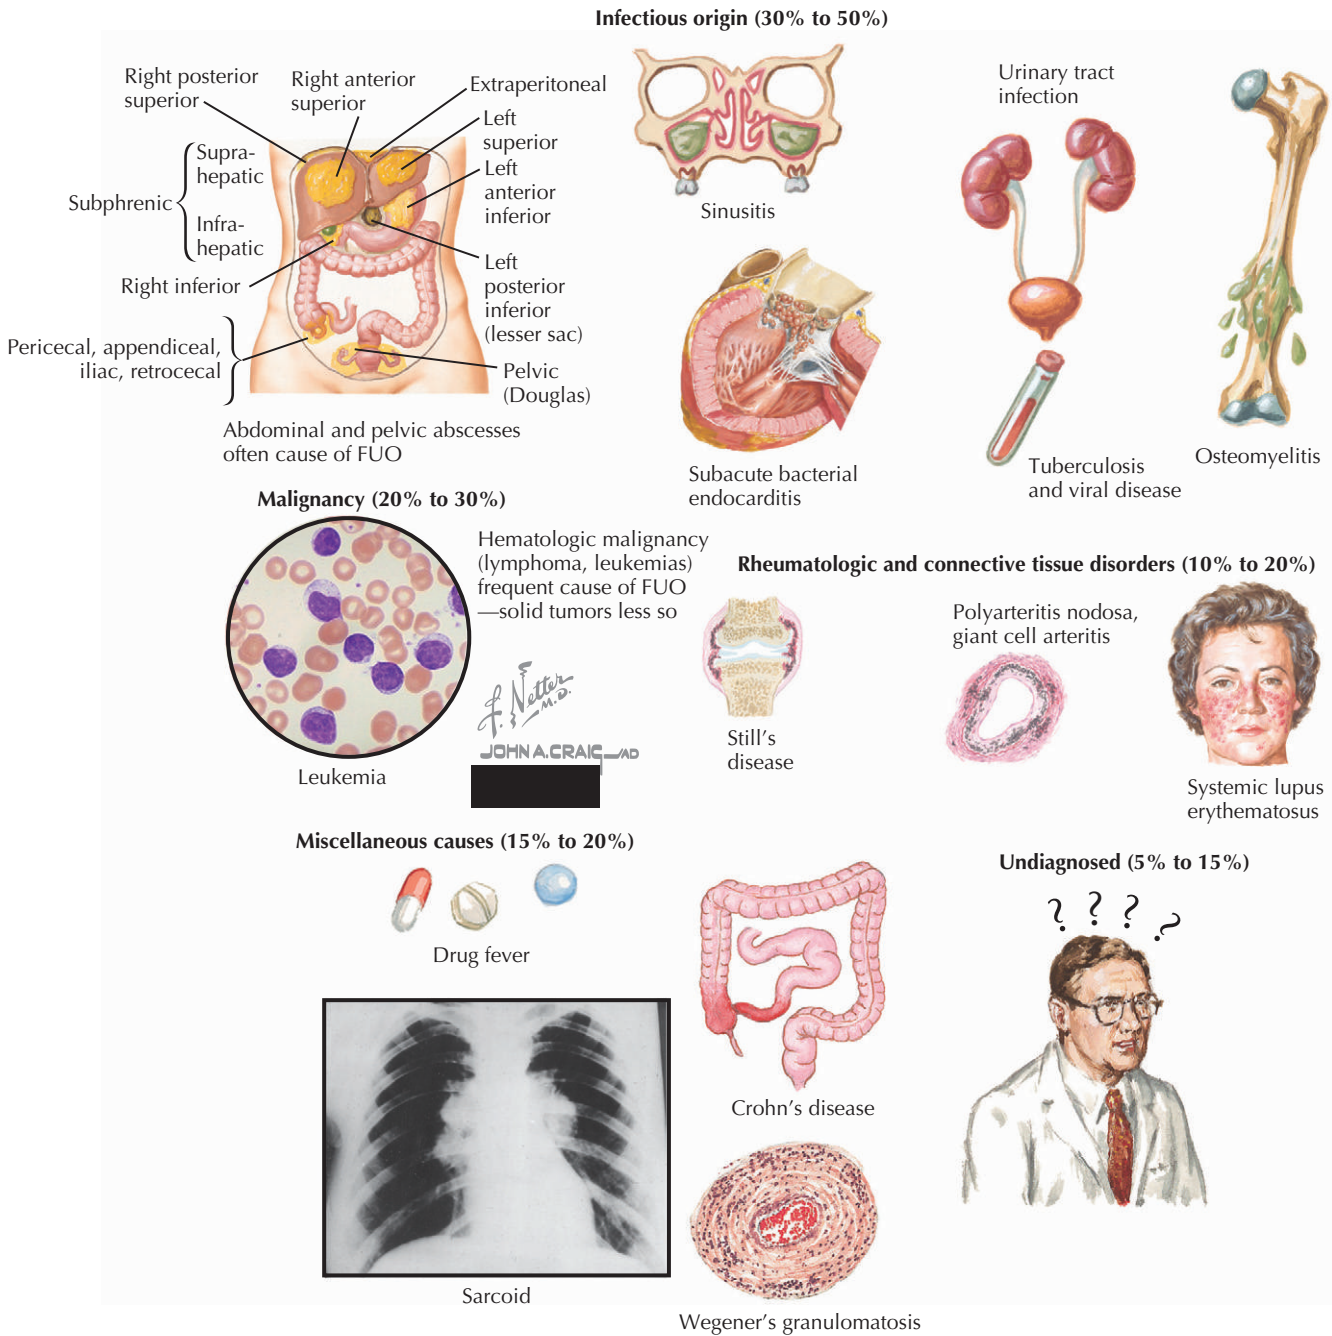

The most commonly identified infections are abscesses, tuberculosis, and viral infections. Abscesses, predominantly intra-abdominal, have remained a leading cause of FUO over the past three decades. Hepatic, subhepatic, and subdiaphragmatic abscesses are common. Other locations include the retroperitoneal, splenic, appendiceal, pericolonc, perinephric, and pelvic areas. Underlying conditions such as diabetes mellitus, immunosuppressive medications,

prior surgery, and cirrhosis have been associated with the development of occult abscesses.

Tuberculosis is the most common source of FUO in most case series and often presents with miliary or extrapulmonary involvement. Viral infections have been increasingly recognized because of the availability of tests for cytomegalovirus (CMV) and Epstein-Barr virus (EBV). HIV infection, either with acute or previously undiagnosed established infection with concurrent opportunistic infection, also may cause FUO. Acute HIV infection as a cause of fever is frequently not considered but should be included in the differential diagnosis of individuals presenting with a mononucleosis-like illness, particularly with high-risk sexual or injection drug use exposure. Acute HIV infection is also among the most common causes of FUO among returned travelers in addition to malaria and typhoid fever. Many other infections have been associated with FUO, including cat-scratch disease (*Bartonella* species infection), brucellosis, histoplasmosis, leishmaniasis, malaria, psittacosis, relapsing fever, and leptospirosis.

Subacute bacterial endocarditis (SBE), osteomyelitis, sinusitis, and urinary tract infections also cause FUO. SBE is a less common cause than in the past because of improvements in blood culture methods and echocardiography. However, true culture-negative cases (without antibiotic

Figure 89-1 Potential Causes of Fever of Unknown Origin.

administration before obtaining blood culture specimens) still constitute 3% to 5% of large series. Culture-negative endocarditis is more common with infections due to *Coxiella burnetii* (Q fever); *Tropheryma whippelii*; *Brucella*, *Mycoplasma*, *Chlamydia*, *Histoplasma*, *Legionella*, and *Bartonella* species infection; and the HACEK group, including *Haemophilus*, *Actinobacillus*, *Cardiobacterium*, *Eikenella*, and *Kingella* species. Fastidious organisms may be missed in routine culture.

Several neoplastic diseases may cause fever and may present as FUO. Hematologic malignancies are most common, including Hodgkin's and non-Hodgkin's lymphoma. Leukemia also may cause FUO, but less commonly. Solid tumors cause FUO less commonly than lymphomas and leukemias. Renal cell carcinoma may cause fever and FUO, although only 2.5% of cases present with FUO. Carcinoma of the colon may cause persistent fever. Other solid tumors occasionally associated

with FUO include hepatocellular carcinoma, gastric carcinoma, pancreatic carcinoma, mesothelioma and leiomyosarcoma.

The two most common rheumatologic diseases associated with FUO are Still's disease (juvenile rheumatoid arthritis) and giant cell arteritis. Still's disease occurs in young adults and is associated with episodic fever, arthralgias, arthritis, and commonly, a rash. Fever may precede the onset of joint symptoms, but the diagnosis cannot be made until arthritis develops. Giant cell arteritis is an important cause of FUO in patients older than 50 years with a high erythrocyte sedimentation rate (ESR). FUO in elderly patients is more frequently due to noninfectious inflammatory diseases and, in developed countries, exceeds infection as the most common cause. Polyarteritis nodosa is a rare but important cause of FUO. Other rheumatologic diseases causing FUO include systemic lupus erythematosus (SLE), polymyositis, rheumatoid arthritis, Takayasu's arteritis, and mixed cryoglobulinemia.

Many other disorders fall under the miscellaneous category. Drug fever is another common cause. Drug fever may be caused by allergic reactions, idiosyncratic reactions, or altered thermoregulation. Drug fever is more common in hospitalized patients and in patients with AIDS. Drug fever can occur without other symptoms or signs but is suggested by simultaneous rash or peripheral eosinophilia.

Factitious fever, which is most often identified in young people who are associated in some way with the medical profession, is surprisingly common. Several granulomatous diseases are associated with FUO, including Crohn's disease, Wegener's granulomatosis, sarcoidosis, and granulomatous hepatitis. Alcoholic hepatitis can be associated with persistent fever and appears to be common in the community setting. Other conditions associated with FUO include recurrent pulmonary emboli, thyroid disease, hematoma, atrial myxoma, and familial Mediterranean fever. Fever can also result from hypothalamic dysfunction related to massive strokes and anoxic brain injury.

Despite adequate diagnostic evaluation, a significant proportion of patients with FUO will remain without a confirmed diagnosis. Many of these patients will recover spontaneously without sequelae. Other patients will develop manifestations of their underlying illness over time, eventually leading to a definitive diagnosis.

Clinical Presentation

By definition, the clinical presentation of FUO includes fever. The fever may be high or low and relatively constant or intermittent. Generally, the more prolonged the fever, the less likely that an infection is the cause. Other symptoms and signs may or may not be present. If present, these can provide crucial clues to the diagnosis. Relatively minor findings should not be overlooked or dismissed.

Differential Diagnosis

As discussed, a wide variety of diseases can cause FUO. In approaching the patient meeting criteria for FUO, one should first consider if they have classic, nosocomial, neutropenic, or HIV-associated FUO. Classic FUO occurs in immunocompetent hosts, with onset as an outpatient and fever documented on at least three outpatient visits or persistent for at least 3 weeks. Nosocomial FUO represents all patients with fever onset after admission to the hospital, and persisting for at least 3 days with no diagnosis after initial workup. Differential diagnosis of nosocomial FUO includes drug-resistant bacteria, drug fever, deep venous thrombosis secondary to immobility, *Clostridium difficile* colitis, noninfectious postoperative fever due to inflammatory responses, and increased risk for infections secondary to surgical procedures, urinary and respiratory instrumentation, and intravascular devices. In addition, endotracheal intubation and gastric and enteral feeding tubes increase the risk for nosocomial sinusitis, which can present as FUO in intensive care units.

Immunosuppressed patients have the highest incidence of FUO among all patient groups and frequently do not manifest signs or symptoms of inflammation. FUO in either the neutropenic or HIV-infected patient significantly alters and broadens the differential diagnosis. Diagnostic workup for neutropenic or immune-suppressed patients should consider reactivation of latent viral infections such as herpesviruses, fungal infections including *Candida* and *Aspergillus* species, drug fever, and graft-versus-host disease. The differential diagnosis for infectious etiologies in HIV-infected patients broadens to include opportunistic infections such as toxoplasmosis, disseminated *Mycobacterium avium* complex infection, *Pneumocystis jiroveci* pneumonia, and CMV, and can be guided by CD4 cell count.

Because infections are the most common etiology of fever, travel history is crucial to assess the risks for tropical illness from travel abroad and infections associated with particular geographic areas, such as Rocky Mountain spotted fever in the southeast and midwestern United States and malaria and leishmaniasis in endemic regions. A history of animal and insect exposure should be obtained to assess the risk for infections related to arthropods, particularly during seasons when mosquitoes and ticks are most active.

Evidence of particular organ system involvement should lead to a narrowing of the differential diagnosis. For example, lymph node involvement may suggest lymphoma, CMV, EBV, tuberculosis, toxoplasmosis, or *Bartonella* species infection (cat-scratch disease), among others.

Diagnostic Approach

A critical step in the evaluation of FUO, although commonly overlooked, is the documentation of fever. If fever

Figure 89-2 Diagnostic Considerations in Fever of Unknown Origin.

TB, tuberculosis; ETOH, alcohol; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

>38° C (101° F) on several occasions

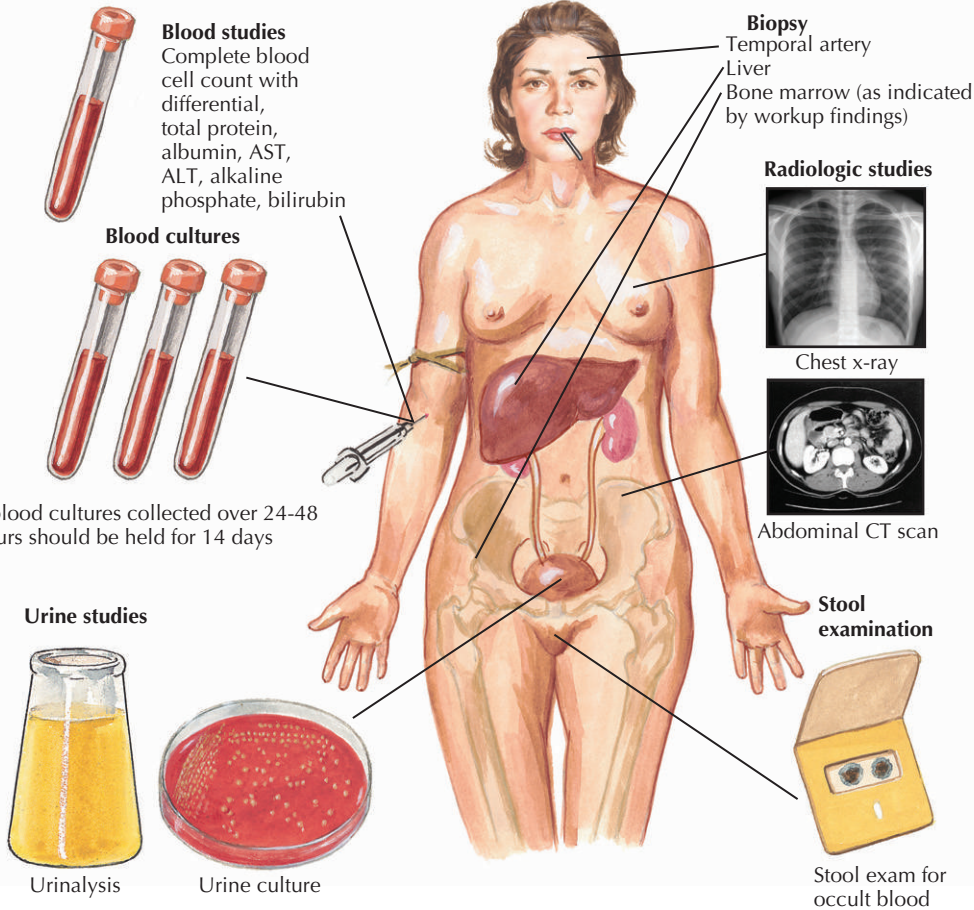

Fever should be documented

Detailed history with emphasis on medications, previous medical and surgical illness, TB exposure, ETOH and drug abuse, travel, animal and occupational exposures and hobbies

Comprehensive physical exam with emphasis on skin, temples, eyes, oral cavity, lymph nodes, thyroid, and genitalia (including prostate)

Laboratory studies
(many have been completed to establish criteria for FUO)

F. Netter M.D.
JOHN A. CRAIG, MD
D. Mascaro

is not demonstrated during the evaluation, the patient should document the fever with a reliable thermometer. Documentation and evaluation of fever patterns, however, rarely lead to the diagnosis.

An extremely thorough history and physical examination is essential (Fig. 89-2). Frequently, the clues to appropriate next steps in the evaluation are found within the history and physical examination. The history should include detailed questions about medications, previous medical illnesses, previous surgical illnesses, tuberculosis exposure, prior evaluations with purified protein derivative

(PPD), alcohol and illicit drug use, domestic and foreign travel, animal exposures, occupational exposures, sexual history, sick contacts, and hobbies. Careful questioning about all body systems is essential to detect relatively minor symptoms that might provide important clues to the diagnosis. The presence of immunosuppression expands the breadth of initial laboratory and radiographic studies and the pace of diagnostic pursuit given the potential for rapid deterioration.

Special attention should be given to examination of the skin, temples, eyes, oral cavity, lymph nodes, thyroid, and

genitalia as part of a comprehensive examination. In men, the prostate should be examined and a careful pelvic examination is essential in women to evaluate for pelvic inflammatory disease. Positive physical findings should lead to a targeted investigation and early diagnosis. However, subtle physical findings may be overlooked, especially in older patients. Findings may also change over time, necessitating repeated, careful examinations.

Many common laboratory tests are likely to have been completed before a patient satisfies the criteria for FUO. Initial laboratory studies should include routine studies, such as complete blood count with differential, total protein, albumin, aspartate aminotransferase, alanine aminotransferase, alkaline phosphatase, and bilirubin. Urinalysis and urine culture should be performed. A pregnancy test should be obtained to rule out the possibility of ectopic pregnancy as the cause of fever, particularly in the presence of abdominal discomfort in women.

Typically, three blood cultures spaced over a 24- to 48-hour period are sufficient. False-negative blood cultures can occur in the face of antibiotic therapy, which may necessitate repeat cultures if empirical therapy was initiated before collection of the cultures. With the satisfaction of FUO criteria, blood cultures for rare pathogens should be performed. Blood cultures should be held for up to 14 days. A culture using alternative techniques, such as lysis centrifugation procedure, should be considered to enhance detection of fastidious organisms. Direct communication with the microbiology laboratory is encouraged to identify preferred procedures for isolating rare or fastidious organisms in a given laboratory.

A chest x-ray should be obtained. A tuberculin skin test should be placed early in the evaluation, but a negative PPD alone does not rule out tuberculosis. The sensitivity of PPD in extrapulmonary tuberculosis is often relatively low, and immunosuppressed patients may be anergic. Biopsy of involved lymph nodes, bone marrow, or the liver is often required because the yield of sputum acid-fast bacillus stain and culture is decreased for miliary tuberculosis. Stool should be examined for occult blood at least three times to provide clues to underlying gastrointestinal diseases, such as Crohn's disease or carcinoma of the colon.

An antibody test for HIV should be performed to rule out chronic HIV infection, or a viral detection assay should be used if acute HIV infection is suspected. The erythrocyte sedimentation rate (ESR) may provide useful information. In most cases, an ESR greater than 100 mL/hour suggests the presence of a major systemic disease, such as giant cell arteritis or tuberculosis. Unfortunately, slightly or moderately elevated ESR (20 to 40 mm/hr) is common in FUO and can be difficult to interpret, especially in elderly patients. A normal ESR argues against connective tissue diseases.

CT scan of the abdomen and pelvis should be obtained early in the evaluation. Occult abscesses, which can often be readily identified by CT, are one of the most common

causes of FUO. Detection of an abnormality by CT may be followed by a CT-guided biopsy to establish the definitive diagnosis. CT of the chest occasionally provides evidence of lung disease not readily apparent by chest radiography. MRI or angiogram should be obtained if vasculitis is suspected.

Several radionuclide scanning techniques have been used in the evaluation of FUO. The most commonly used tests are gallium-67 scans and indium-labeled leukocyte scans. Bone scans are sometimes useful in the diagnosis of occult osteomyelitis or metastatic neoplastic disease. Positron emission tomography with ^{18}F -fluorodeoxyglucose has also been used. Generally, these tests do not provide a specific diagnosis, but on occasion, they may yield a focus for further evaluation. Nuclear medicine tests should generally be used as second-line imaging tests in the absence of clinical diagnostic clues or when clinical clues are confusing. Physicians should not rely heavily on these tests and should interpret results cautiously.

In younger patients, serologic studies can play a role in the diagnostic evaluation. Generally, serum samples should be obtained and frozen for later testing during the initial evaluation of the patient with persistent fever. Generally, indiscriminate use of serologic studies is not cost effective. Given the low prevalence of many of the diseases that cause FUO, the pretest probability of serologic tests is low, and they may lead to false-positive results. A classic example is serologic tests for Lyme disease, which is not associated with FUO but may have false-positive serology. Serologic tests should generally be selected only in response to diagnostic clues in the history, physical examination, and routine laboratory tests. However, routine serology for certain pathogens may be warranted in endemic areas, such as for *Brucella* and *Leishmania* species and Q fever in Mediterranean countries and the Middle East. Another important exception is serologic tests for SLE, for which antinuclear antibody and anti-double-stranded DNA should be performed in most younger patients with persistent fever.

Patients with lymphadenopathy and persistent fever may be evaluated with serologic titers for CMV, EBV, and HIV. Antibody titers for CMV and EBV must be interpreted cautiously. Serologic tests for HIV should be repeated after 2 to 3 months to identify seroconversion. Polymerase chain reaction (PCR) testing allows more rapid diagnosis of several infections and is available for EBV, CMV, tuberculosis, HIV, and human herpesvirus 6 and 7.

Biopsy procedures, particularly of the bone marrow and liver, can be important diagnostic tools in the evaluation of FUO. Bone marrow biopsy may be helpful in identifying hematologic malignancies and miliary tuberculosis. Cultures for mycobacteria, as well as bacteria and fungi, should be performed on all biopsy specimens. Bone marrow aspiration alone is probably not adequate in the evaluation of FUO. Liver biopsy can yield the diagnosis, but only if

abnormalities are detected on routine studies of liver function.

Temporal artery biopsy is indicated early in the evaluation of the elderly patient with FUO and elevated ESR. Signs and symptoms of giant cell arteritis may be minimal or limited to persistent fever alone. A generous length (2 to 3 cm) of temporal artery should be obtained at biopsy. Bilateral specimens may be necessary.

In older patients, colonoscopy to search for colon carcinoma is reasonable. Echocardiography, both transthoracic and transesophageal, may also be considered to look for valvular lesions consistent with endocarditis, especially if blood cultures may have been obscured by prior antibiotic therapy.

Laparoscopy is occasionally necessary when other evaluations have failed to yield a diagnosis. Most intra-abdominal processes can be identified with CT, and biopsies can be performed percutaneously with CT guidance. Generally, if the imaging studies are negative, invasive exploration of the abdomen is not indicated.

Many patients with FUO will have no diagnosis at the end of an intensive evaluation. If no diagnosis has been established after a thorough investigation and the patient is stable, a period of observation is indicated if the patient's general condition is not compromised. The period of observation may lead to new findings that lead to the diagnosis or the symptoms may resolve spontaneously.

Management and Therapy

The appropriate management of FUO depends primarily on the identification of the underlying etiology. However, certain general rules of management should be considered.

Early in the evaluation of FUO, especially in older patients, all nonessential medications should be discontinued, including medications that have been used for a lengthy period of time. Drug fevers can be caused by long-standing medications. A costly investigation may be avoided if fever resolves after discontinuation of medications.

Empirical therapeutic trials should be avoided whenever possible, particularly in the setting of immunocompetent hosts with classic FUO. Given the frequent spontaneous resolution of the FUO, cure cannot be ascribed to the treatment with certainty. Furthermore, use of therapeutic agents, especially antibiotics, can obscure findings or tests that might lead to a definitive diagnosis.

In contrast, prompt empirical antibiotics, and sometimes antifungals, are the cornerstone of management for patients with neutropenic FUO. These patients are routinely taking antibiotics and antifungals as prophylaxis before the onset of fever and necessitate consideration of broader antimicrobial coverage while the diagnostic workup is underway. Fever often resolves following the recovery of neutrophil counts, with no clear diagnosis. Empirical antibiotics also may be warranted in the case of

nosocomial or HIV-associated FUO, depending on clinical severity and likely infectious causes.

Optimum Therapy

The treatment of FUO is specific to the cause of fever, and prognosis is determined by both the cause and the presence of underlying immunosuppression or comorbidities.

Avoiding Treatment Errors

Failure to obtain a thorough medical history and to perform a comprehensive physical examination is likely the most critical error in identifying possible causes of FUO. Empirical therapeutic trials should be avoided except for cases in which all diagnostic approaches have failed and the clinical condition of the patient does not allow for careful observation. If empirical antimicrobial therapy is initiated, cultures should be obtained before administration if possible, to allow subsequent targeted and optimized therapy to cultured pathogens.

Future Directions

FUO will remain an important diagnostic challenge despite advances in imaging and diagnostic tests allowing rapid diagnoses of many causes of persistent fever. The availability and the number of pathogens detectable by rapid antigen and PCR testing will likely continue to expand in the next decade. New molecular genetic tools are being investigated for difficult-to-diagnose disorders such as familial Mediterranean fever and Muckle-Wells syndrome, and such genetic analysis may prove useful in the future for selective diseases. Those cases that remain undiagnosed present a substantial challenge to the physician.

The authors present a comprehensive review of FUO with specific attention given to classic FUO, nosocomial FUO, immune-deficient FUO, and HIV-related FUO, in addition to FUO in return travelers. They present a thorough differential diagnosis for each category and provide historical, diagnostic, and imaging recommendations for the evaluation of FUO.
6. Petersdorf RG, Beeson PB: Fever of unexplained origin: Report of 100 cases. *Medicine* 40:1-30, 1961.
In this landmark paper, Petersdorf and Beeson developed criteria for the definition of FUO that remained the medically accepted definition in the clinical evaluation and studies of FUO until changes to the original definition were proposed in 1991.
7. Vanderschueren S, Knockaert D, Adriaenssens T, et al: From prolonged febrile illness to fever of unknown origin. *Arch Intern Med* 163(9):1033-1041, 2003.
A prospective study of FUO among only immunocompetent patients between 1900 and 1999 reported on the time period until diagnosis, the final diagnoses, and the percentage of cases that remained undiagnosed.

Septicemia

Introduction

The clinical condition characterized by fever, tachycardia, hypotension, and metabolic acidosis in the presence of demonstrated or suspected infection has been labeled with various terms such as septicemia, sepsis, sepsis syndrome, and septic shock. These terms are used interchangeably by some clinicians, but experts have developed more precise definitions to provide clinicians and clinical research scientists with a common basis for their observations and treatments. However, there is clinical evidence and utility in the recognition that patients may progress along a continuum from sepsis to septic shock.

Sepsis is defined as a systemic response to presumed or confirmed infection (organisms in a normally sterile site) with clinical evidence of abnormal body temperature ($>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$); tachycardia; metabolic acidosis, usually accompanied by compensatory respiratory alkalosis and tachypnea; and an elevated or depressed white blood cell count. Severe sepsis implies evidence of organ hypoperfusion such as decreased renal function, hypoxemia, or altered mental status. Septic shock applies to the presence of hypotension and organ hypoperfusion despite adequate fluid resuscitation (Table 90-1).

Sepsis and septic shock are common clinical conditions that are extremely challenging to manage successfully. Often, the microbiologic diagnosis is obscured because of antimicrobial therapy given before the patients arrive at the treating facility or during acute resuscitation before diagnostic cultures are obtained. Frequently, patients have underlying severe illness such as immune suppression, hematologic or other malignancies, or disruption of host defenses such as severe burns. Patients may present with altered mental status so that medical history is unobtainable or unreliable. The rapid progression to multiorgan failure may make identification of the initial pathogenic process (e.g., pneumonia, pyelonephritis, or intra-abdominal infection) difficult.

Sepsis is the 10th leading cause of death in the United States and the leading cause of death in critically ill patients. However, sepsis may be the immediate cause of death in other common, independently categorized causes of mortality such as cancer and pneumonia. About 80% of severe sepsis cases in intensive care units in the United States and Europe during the 1990s occurred after admissions for unrelated causes. The incidence of sepsis increased almost fourfold from 1979 to 2000, to an estimated 660,000 cases (240 cases per 100,000 population) of sepsis or septic shock per year in the United States. Mortality due to sepsis remains high despite recent trends showing a decline in some settings.

Etiology and Pathogenesis

For consistency in this chapter, sepsis and septic shock will be considered to be caused by a microbiologic organism with or without documented bloodstream infection. Other conditions can cause clinical syndromes indistinguishable from sepsis-related infection, although the exact mechanisms leading to the clinical presentation in those conditions are less clearly defined.

In the past, gram-negative bacilli were most commonly associated with bacteremia and sepsis in the United States.

During the past 15 to 20 years, gram-positive cocci such as *Staphylococcus aureus*, coagulase-negative staphylococci, and enterococci have become more common, especially as causes of nosocomial bloodstream infections. Recent trends also show an increase in cases of severe sepsis caused by fungi, in particular *Candida* species. However, almost any overwhelming microbiologic infection can lead to sepsis syndrome and septic shock. Possible etiologic agents include rickettsia and rickettsia-like organisms; fungi, such as *Candida*, *Aspergillus*, and *Cryptococcus* species; parasites such as those that cause malaria; acute toxoplasmosis in the

Table 90-1 Diagnostic Criteria for Sepsis

Syndrome	Criteria	Comment
Sepsis	Confirmed or suspected infection in normally sterile site Temperature >38° C or <36° C Heart rate >90 beats/minute Respiratory rate >20 breaths/minute or PaCO ₂ <32 mm Hg WBC >12,000 cells/mm ³ or <4000 cells/mm ³ , or >10% immature forms Systolic blood pressure of <90 mm Hg, MAP <70 mm Hg, or a reduction of >40 mm Hg from baseline	Sepsis-related hypotension must have no other cause.
Severe sepsis	Lactic acidosis Oliguria Altered mental status Acute lung injury	Implies sepsis-associated organ dysfunction distant from the site of infection. Hypotension can be reversed by fluid resuscitation.
Septic shock	Requires administration of pressor therapy to maintain blood pressure	Hypotension persists despite adequate fluid resuscitation.

MAP, mean arterial pressure; PaCO₂, arterial carbon dioxide partial pressure, WBC, white blood cell.

immunocompromised host; and even some viral infections. The lung, abdomen, and urinary tract are the most common sites of infection, but the source of infection remains unidentified in up to one third of cases. Blood culture specimen results are positive in only about 30% of cases. Culture of other sites such as sputum, urine, cerebrospinal fluid, or pleural fluid may reveal a specific etiology, but areas of localized infection that trigger the process may not be accessible to culture.

Infectious agents activate both proinflammatory and anti-inflammatory responses, which are mediated, in part, by monocytes, macrophages, and neutrophils. These activated cells interact with endothelial receptors leading to the release of cytokines such as tumor necrosis factor (TNF), interleukin (IL), proteases, leukotrienes, reactive oxygen species, nitric oxide, arachidonic acid, and platelet-activating factor. Microvascular injury, thrombosis, and capillary leak result from the multiple interactions at the vascular endothelium and are further affected by dysregulation of the coagulation and complement cascades. Diffuse endothelial disruption leads to tissue hypoxia and associated organ dysfunction.

The exact pathogenesis underlying the development of severe sepsis and septic shock remains elusive, likely related to the heterogeneity of patients, infectious agents, and events that initiate inflammatory mechanisms. The previous prevailing theory that septic shock represents an exaggerated, uncontrolled inflammatory response to bacteremia, endotoxemia, fungemia, or more localized severe infection (Fig. 90-1) was based primarily on animal studies in which high levels of circulating cytokines such as TNF- α were found. However, the levels of TNF- α and IL-1, which are the major proinflammatory cytokines, were exponentially higher in these animals than in septic patients. Notably, high levels of TNF- α have been associated with sepsis due to meningococemia in humans, and

are correlated with mortality. However, additional research in humans revealed that the presence of an exaggerated systemic inflammatory response, as measured by levels of TNF, TNF- α , or IL-1 β , was much less frequent than expected.

The precise role of TNF- α and IL-1 in the pathophysiology of sepsis remains to be determined. These cytokines produce leukocyte-endothelial adhesion followed by the release of platelet-activating factor, IL-8, arachidonic acid metabolites, and clotting factors, all of which contribute to the generation of fever, tachycardia, tachypnea, ventilation-perfusion abnormalities, lactic acidosis, and disseminated intravascular coagulation. However, more recent work has revealed that septic patients demonstrate features of immunosuppression, including increased susceptibility to nosocomial infections, loss of delayed hypersensitivity, and failure to clear pathogens. A newer theory proposes that early sepsis may involve increases in inflammatory mediators, but then progresses toward an immunosuppressive state in which anti-inflammatory responses predominate.

Clinical Presentation

The initial presentation of sepsis may be subtle, but the rapid progression of this syndrome usually makes the general diagnosis obvious, although the specific infectious agent may remain obscure. Minor mental status changes or confusion may be very early signs of sepsis. Hyperventilation has been noted as an early sign in closely monitored patients who are found subsequently to be septic. Most patients are either hyperthermic or hypothermic and complain of chills or have rigors. Some debilitated and elderly patients may have minimal symptoms other than confusion, and negligible signs other than orthostasis or

Figure 90-1 Septicemia.

PAI-1, plasminogen activator inhibitor-1; TAFI, thrombin activatable fibrinolysis inhibitor.

frank hypotension. Neutrophil counts may be high, but neutropenia is also a common manifestation.

Although the line between primary clinical manifestations and subsequent complications is arbitrary, the complications of sepsis, including organ hypoperfusion, coagulopathy, and endothelial damage, represent a continuum from sepsis syndrome to septic shock. Patients frequently present with evidence of organ hypoperfusion such as hypotension, oliguria, hypoxemia, acidosis, and liver function abnormalities. Patients may also have signs of a consumptive coagulopathy with thrombocytopenia and bleeding, and depressed myocardial function with elevated heart rate and cardiac output. Adult respiratory distress syndrome (ARDS) or diffuse pulmonary capillary leak syndrome may be a somewhat later finding. Because of the very rapid progression of sepsis, some patients may present with evidence of ARDS.

Differential Diagnosis

Other processes or stimuli may cause systemic inflammatory responses resulting in a clinical syndrome that is indistinguishable from sepsis. Burns and pancreatitis are the

most common noninfectious causes, as well as adrenal insufficiency, pulmonary embolism, myocardial infarction, cardiac tamponade, dissecting or ruptured aortic aneurysm, occult hemorrhage, and drug overdose. Other causes of severe tissue injury such as trauma may also result in a sepsis-like appearance.

Diagnostic Approach

Diagnostic signs of septic shock syndrome may be subtle during the very early manifestations, but they are usually obvious once the process has evolved. Determining the source of the infection and the specific microbial agent is the main issue in diagnosis. Medical history, including predisposing disorders, recent antimicrobial therapy, diet, travel, and exposure information is important. If possible, one should obtain a history of symptoms from the patient to help localize the source of infection. Cultures of blood, urine, and sputum (cerebrospinal fluid, wounds, and peritoneal fluid when indicated) are essential. If possible, the appropriate diagnostic studies should be obtained before antibiotic administration to increase the diagnostic yield. Most retrospective studies evaluating the effect of antibi-

Table 90-2 Evidence-Based Recommendations for Treatment of Sepsis

Treatment Modality	Recommendation	Grade of Evidence
Antimicrobials	Intravenous antibiotics should be initiated within one hour of suspected sepsis	E
Bicarbonate	Not indicated for lactic acidosis with pH ≥ 7.15 due to hypoperfusion	C
Cultures	Cultures from appropriate sites should be obtained before antimicrobial administration	D
Deep venous thrombosis prophylaxis	Low-dose unfractionated heparin or low-molecular-weight with heparin or mechanical device if heparin use is contraindicated	A
Fluid resuscitation	Natural or artificial colloids or crystalloids are appropriate because data do not support superiority of either type	C
Glucose control	Maintenance of blood glucose < 150 mg/dL (8.3 mmol/L)	D
Initial resuscitation within first 6 hours	Continuous insulin and glucose infusion with glucose monitoring every 30-60 minutes to achieve above Resuscitation goals in first 6 hours: <ul style="list-style-type: none"> ▪ Central venous pressure: 8-12 mm Hg ▪ Mean arterial pressure ≥ 65 mm Hg ▪ Urine output ≥ 0.5 mL/kg/hr ▪ Central venous or mixed venous oxygen saturation $\geq 70\%$ 	B
Mechanical ventilation	Low tidal volumes of 6 mL/kg of predicted body weight while maintaining end-inspiratory plateau pressures < 30 cm H ₂ O for ALI/ARDS	B
Recombinant human activated protein C	Indicated for APACHE II ≥ 25 , multiple organ failure, or ARDS due to sepsis, septic shock, and no absolute contraindication related to bleeding risk or relative contraindication for which risk exceeds benefit	B
Blood transfusion	Red blood cell transfusion if central venous or mixed venous oxygen of 70% not achieved after first 6 hours Red blood cell transfusion only for hemoglobin < 7.0 g/dL (< 70 g/L) after hypoperfusion resolved, in the absence of coronary artery disease or lactic acidosis during initial resuscitation	B
Steroids	IV corticosteroids (hydrocortisone 200-300 mg/day, for 7 days in 3-4 divided doses or by continuous infusion) with septic shock unresponsive to fluid replacement	C
	Corticosteroid doses of > 300 mg of hydrocortisone daily should not be used as treatment for severe sepsis or septic shock	A
Stress ulcer prophylaxis	H ₂ receptor inhibitors for all patients with severe sepsis	A

ALI, acute lung injury; APACHE, Acute Physiology and Chronic Health Evaluation; ARDS, adult respiratory distress syndrome. Grade of recommendations: A, supported by at least two level I investigations; B, supported by one level I investigation; C, supported by level II investigations only; D, supported by at least one level III investigation; E, supported by level IV or V evidence.

Grade of evidence: I, large, randomized trials with clear-cut results; II, small, randomized trials with uncertain results; III, nonrandomized, contemporaneous controls; IV, nonrandomized, historical controls and expert opinion; V, case series, uncontrolled studies, and expert opinion. Adapted from Dellinger RP, Carlet JM, Masur H, et al: *Surviving Sepsis Campaign guidelines for management of severe sepsis and septic shock*. *Crit Care Med* 32(3):858-873, 2004.

otic initiation in bacteremic patients found a decrease in mortality when “appropriate” empirical antimicrobials were started within 48 hours of collecting blood cultures. Stool culture and screening for *Clostridium difficile* toxin are sometimes overlooked.

Management and Therapy

Therapy is divided into several categories including hemodynamic support, antimicrobials, tissue oxygenation goal-directed therapy, and specific interruption of the inflammatory cascade. Despite advances in antimicrobial therapy during the past half century, dramatic improvements in mortality from severe sepsis syndrome have not

occurred. Imbalance between oxygen demand and supply results in total tissue and organ hypoxia due to the physiologic hallmarks of sepsis and septic shock, including peripheral vasodilation, decreased cardiac function, intravascular volume loss due to endothelial dysfunction, and increased metabolic demand. Recent therapeutic advances for sepsis include recombinant human activated protein C for severe sepsis, corticosteroids in septic shock, prompt goal-directed therapy to improve tissue hypoperfusion, and intensive insulin therapy (see later). In 2003, an expert panel reconvened to update key recommendations for the management of severe sepsis and septic shock based on available data (Table 90-2), and key recommendations are discussed next.

Table 90-3 Empiric Antibiotic Therapy

Clinical Setting	Possible Therapies
Outpatient admission	Third-generation cephalosporin (e.g., ceftriaxone, cefotaxime) or piperacillin/tazobactam, or imipenem (or meropenem or ertapenem) each with an aminoglycoside; plus vancomycin
Intra-abdominal	Piperacillin/tazobactam or imipenem (or meropenem or ertapenem), each with an aminoglycoside; tigecycline is an alternative when <i>Pseudomonas</i> coverage is not thought to be indicated; plus vancomycin
Hospitalized patient*	Imipenem (or meropenem or ertapenem) or piperacillin/tazobactam (at doses to cover <i>Pseudomonas aeruginosa</i>) plus aminoglycoside; ceftazidime, cefepime, and ciprofloxacin are alternatives; plus vancomycin
Neutropenic patient	Imipenem (or meropenem or ertapenem), cefepime, ceftazidime alone or with an aminoglycoside; piperacillin/tazobactam (at doses to cover <i>Pseudomonas aeruginosa</i>) is an alternative; plus vancomycin plus fluconazole (caspofungin is an alternative)
Possible methicillin-resistant <i>Staphylococcus aureus</i>	Linezolid and daptomycin are possible alternatives to vancomycin depending on the site of infection. (Daptomycin should not be used in the case of pneumonia, and there is limited experience with linezolid for certain syndromes such as endocarditis and meningitis)
Possible tick exposure	Add doxycycline

* Local epidemiology of nosocomial infection and antibiotic resistance patterns should be used to guide therapy.

Optimum Treatment

Diagnostic cultures should be obtained before antibiotic administration, and antibiotic therapy should ideally be directed at specific pathogens. However, early in the course of septic shock, the precise pathogen is usually not known and may remain obscure after extensive investigation. In general, the severity of the illness dictates broad antimicrobial coverage unless there is a high degree of certainty as to the likely pathogen, and should be initiated within 1 hour of the suspicion or recognition of severe sepsis. Table 90-3 presents suggested empiric antibiotic therapy for patients with sepsis or septic shock in a variety of settings.

Early goal-oriented therapy focuses on optimization of tissue oxygen delivery as measured by mixed venous oxygen saturation, pH, or arterial lactate levels. This approach has demonstrated improved survival compared with standard fluid resuscitation and maintenance of blood pressure. Physiologic goals during the first 6 hours of resuscitation include the following: (1) central venous pressure 8 to 12 mm Hg, (2) mean arterial pressure ≥ 65 mm Hg, (3) central venous oxygen saturation $\geq 70\%$, and (4) urine output ≥ 0.5 mL/kg/hr (using transfusion, inotropic agents, and supplemental oxygen with or without mechanical ventilation).

Recombinant human activated protein C (drotrecogin alfa), which promotes fibrinolysis and inhibits thrombosis and inflammation, reduced mortality in patients with severe sepsis from 30.8% to 24.7% in a randomized, controlled trial. Not surprisingly, the drug was associated with

a small but statistically significant increase in the incidence of severe bleeding, including intracranial hemorrhage. A second trial was conducted to evaluate the benefit of drotrecogin alfa in adults with severe sepsis and a low risk for death, defined as an Acute Physiology and Chronic Health Evaluation (APACHE) II score of less than 25 and no more than single organ failure. The study revealed no beneficial treatment effects for this patient group, but an increased incidence of serious bleeding complications. Drotrecogin alfa (activated) is currently approved by the U.S. Food and Drug Administration only for the treatment of severe sepsis in patients with more than one organ dysfunction or an APACHE II score of greater than 25.

During the past decade, multiple trials of mediator-based therapy designed to disrupt the inflammatory cascade involved in the pathogenesis of sepsis have been disappointing. Agents including antiendotoxin antibodies, TNF antagonists, IL receptor antagonists, and other agents have not demonstrated significant benefit. However, several randomized, controlled trials of glucocorticoid therapy for septic shock demonstrated a significant benefit in shock reversal. Current guidelines recommend intravenous corticosteroids (hydrocortisone, 200 to 300 mg/day in 3 or 4 divided doses for 7 days) for septic shock unresponsive to fluid resuscitation.

Intensive glycemic control emerged as an important management strategy following a large trial that demonstrated decreased mortality in patients with severe sepsis and blood glucose kept between 80 and 110 mg/dL (4.4 to 6.1 mmol/L) on continuous insulin and glucose infusion. Intensive insulin therapy for bacteremic patients was asso-

ciated with a lower mortality rate than conventional therapy (12.5% vs. 29.5%) and reduced the frequency of sepsis episodes by 46%. The beneficial effect of intensive insulin therapy on mortality persisted regardless of a prior history of diabetes. Current guidelines suggest keeping blood glucose less than 150 mg/dL (8.3 mmol/L) or between 100 and 140 mg/dL. Frequent monitoring is critical to avoid hypoglycemic brain injury.

Although catheter-related infections (CRIs) have decreased with improved sterilization techniques and equipment, they remain the leading cause of bloodstream infections. Several randomized controlled trials evaluating the prevention of CRI through the use of catheters coated with heparin, chlorhexidine-sulfadiazine, and antibiotics showed a reduction in catheter colonization but not in bloodstream infections.

Avoiding Treatment Errors

The most serious errors associated with sepsis syndrome are likely to be diagnostic rather than therapeutic. Noninfectious causes of systemic inflammatory response syndrome (e.g., pancreatitis) should always be considered, as should mimics of the sepsis syndrome such as large pulmonary emboli and adrenal insufficiency. More unusual pathogens that may not yield positive blood cultures, such as malaria, tuberculosis, or histoplasmosis, should also be considered.

Future Directions

Sepsis is an increasingly common clinical syndrome with a high mortality rate despite modern interventions. The failure of anti-inflammatory agents to improve the outcome of sepsis has prompted investigators to rethink the pathophysiology underlying sepsis and septic shock, and to consider whether sepsis syndrome results from both proinflammatory and immune suppressive responses. In the past decade, new treatment strategies for sepsis have emerged, including drotrecogin alfa (activated), glucocorticoid treatment for septic shock, intensive insulin therapy, and goal-directed resuscitation. More refined supportive care, including the elucidation of target physiologic parameters and specific interventions most effective at achieving them, should result in wider implementation and increased survival. Interventions directed at the inflammatory and coagulation cascade continue in development and need to be further studied. Newer strategies targeting anti-inflammatory mediators and their role in causing immune suppression in sepsis need to be explored. Given the increasing number of elderly and immune-suppressed patients and the increasing prevalence of antibiotic resistance, antibiotic therapy alone is unlikely to improve mortality from sepsis. Accordingly, the substantial utilization of health care resources associated with severe sepsis and septic shock will likely increase.

Staphylococcal Infections

Introduction

Within the genus *Staphylococcus*, a single species, *Staphylococcus aureus*, and a group of species known as coagulase-negative staphylococci (CoNS) cause significant human disease. *S. aureus* is the most virulent of all staphylococcus species and is one of the most important of all human bacterial pathogens. It is a major cause of serious nosocomial as well as community-acquired infections that include skin and soft tissue infections (SSTIs), septicemia, endovascular infections, and infections of indwelling catheters or implanted prosthetic devices. Infections due to methicillin-resistant *S. aureus* (MRSA) have emerged as “super bugs” and are associated with excess morbidity, mortality, and increasing health care costs. Once relatively isolated to health care environments, MRSA is increasingly being acquired and spread within the community. CoNS, of which *Staphylococcus epidermidis* constitutes the major pathogen, are the most common bacteria isolated from blood cultures. Although most often a contaminant, *S. epidermidis* has emerged as a true cause of infection in hospitalized patients with implanted foreign bodies and in immunocompromised hosts. Resistance of staphylococcal organisms to many of the available classes of antibiotics is widespread and represents a serious challenge for clinicians. The mainstays of treatment are the appropriate choice and length of antibiotic treatment, removal of infected tissues or foreign objects, and surgical drainage of infected fluid collections.

Epidemiology

S. aureus is a human commensal organism most commonly recovered from the anterior nares. Studies show that asymptomatic carriers of *S. aureus* are relatively common, representing between 20% and 40% of adults, and suggest that 50% of adults will be colonized at some time during their life. Cross-sectional studies in high-risk populations, including those with diabetes mellitus or chronic exfoliative skin conditions and those receiving chronic hemodialysis, have demonstrated carriage rates as high as 90%. Health care workers and users of intravenous drugs are also at greater risk for colonization. The clinical relevance of asymptomatic carriage is underlined by several studies that have demonstrated both an increased risk for infection in colonized patients and for the transfer of strains from colonized health care workers to patients.

The nosocomial spread of *S. aureus* has significant impact on both clinical outcomes and health care costs. *S. aureus* is the most commonly reported cause of hospital-acquired infection and is estimated to cause clinical disease in 2% of all patients that are admitted. Patients with nosocomial *S. aureus* infection have about twice the length of

hospital stay and are at an increased risk for dying during the hospitalization. The widespread transmission of strains resistant to β -lactam antibiotics is of particular concern. Virtually all the isolates recovered from both hospital and community-acquired infections are resistant to penicillin, and recent reports indicate that 55% to 59% of isolates from hospitals and long-term care facilities are resistant to methicillin. Risk factors associated with hospital-acquired MRSA include prolonged hospitalization (often greater than 14 days), preceding antimicrobial therapy (especially with cephalosporins or fluoroquinolones), presence in an intensive care unit or burn unit, hemodialysis, having a surgical site infection, and proximity to a patient colonized or infected with MRSA.

In the community, *S. aureus* represents the most common cause of SSTIs, and community-acquired methicillin-resistant *S. aureus* (CA-MRSA) infections are becoming more common. Studies performed between 1997 and 2001 demonstrate that 12% to 22% of all staphylococcal isolates in patients presenting from community settings were methicillin resistant. In a study performed in 2004, 59% of staphylococcal isolates obtained strictly from SSTIs were characterized as CA-MRSA. Risk factors that have

been associated with CA-MRSA infection include African American race, HIV infection, recent antibiotic therapy within the past 6 months, and skin trauma. That the infection appears to spread in circumstances that involve close contact between people and their sharing of equipment is supported by the frequency with which CA-MRSA outbreaks have been reported among incarcerated individuals, military personnel, football players, and family members.

CoNS are found among the normal flora of human skin and mucous membranes. Historically, the isolation of CoNS in blood cultures has been viewed as a contaminant occurring through percutaneous venous blood sampling. Reports show that up to 50% of positive blood culture isolates are CoNS. However, in recent years, paralleling advances in medicine, CoNS have emerged as true pathogens. Risk factors associated with infection are indwelling central venous catheters, implanted prosthetic devices, and immunocompromised hosts, most frequently patients with hematologic malignancies. Misinterpretation of a positive blood culture has important implications. CoNS are virtually resistant to penicillin and the antistaphylococcal penicillins, so positive blood cultures necessitate therapy with vancomycin most frequently. An important study by Tokars helped to clarify which cultures are likely contaminants versus true pathogens in patients without obvious signs and symptoms of sepsis and is dependent on number of cultures drawn, the site of phlebotomy, and length of time to positivity.

Pathogenesis

S. aureus is a very robust organism, able to persist on surfaces at wide ranges of temperature, pH, and salt concentrations. Several bacterial products are associated with the ability of the organism to persist in the environment and cause disease. These are grouped into substances that allow the organism to persist on surfaces in vivo and toxins and enzymes that appear to be important in tissue invasion and destruction.

A hallmark of *S. aureus* infection is its ability to colonize and persist on both implanted and indwelling foreign bodies such as intravenous catheters or prosthetic joints. The organism is also commonly found on disrupted native endovascular epithelium such as abnormal cardiac valves or thrombosed blood vessels. Attachment of the organism is mediated by a number of bacterial products, including teichoic acid. Once the organism adheres to a surface, its persistence at that site is supported by several factors that interfere with immune clearance. These include factors that inhibit neutrophil access to the organisms (coagulase), limit phagocytosis (capsule or slime layer), inhibit opsonization (clumping factor and protein A), and interfere with intracellular killing (catalase).

After adherence, a group of enzymes and toxins allow the organism to destroy involved tissue. These include several extracellular enzymes that are directly involved in

tissue destruction through a disruptive effect on cellular membranes.

Secreted toxins that act at a distance and are responsible for many of the clinical manifestations of *S. aureus* infection are particularly important. These toxins are grouped into those that produce tissue destruction directly (A-, B-, C-, and D-toxins) and those that act by producing immune dysregulation (toxic shock syndrome [TSS] toxins, enterotoxins, and exfoliative toxins). Many of the staphylococcal toxins act as superantigens. These bacterial proteins interact with major histocompatibility class II receptors outside of the antigen-binding groove. This high-affinity binding activates a large number of T lymphocytes, which in turn produce large amounts of cytokines. Elaboration of these cytokines plays a critical role in the pathogenesis of many of the clinical manifestations of *S. aureus* infection, including TSS, scalded skin syndrome, and staphylococcal food poisoning syndrome.

A prominent feature of the genome is the presence of mobile genetic elements that can carry genes involved in pathogenicity and drug resistance. These have typically been called *pathogenicity islands* and are able to move between bacteria. Of current interest are the SCC $_{mec}$ cassettes that carry methicillin resistance as well as a virulence factor, the Pantone-Valentine leukocidin toxin. Sequence-specific types of SCC $_{mec}$ cassettes (types I to IV) have been instrumental in epidemiologic tracking of hospital-versus community-acquired MRSA.

Clinical Presentation

The clinical manifestations of *S. aureus* infection are protean and reflect the interaction between host and bacterial factors. Host factors predispose a patient to infection as well as influence the course of the disease and its presentation. Quantitative and qualitative defects in phagocytic function and conditions that disrupt the integrity of the skin increase the risk for infection. Among patients with phagocytic defects, those with deficiencies in neutrophil chemotaxis (e.g., Job's syndrome and Chediak-Higashi syndrome) and intracellular killing (e.g., chronic granulomatous disease) are at greatest risk. Patients with poorly controlled diabetes mellitus are also at increased risk for serious infection.

Skin and Soft Tissue Infections

Staphylococcal infection of the skin and soft tissues presents with a range of syndromes. Most characteristic is the tendency of the organism to form abscesses. Infections may progress from superficial, relatively benign infections of the hair follicle (folliculitis) to invasion of the tissue surrounding the follicle (furuncles). These small abscesses may coalesce and form larger collections of pus (carbuncles). Uncommonly, the underlying muscle and fascia become involved (pyomyositis and necrotizing fasciitis).

Patients experiencing these deep-seated syndromes are generally febrile, complain of pain in the involved area, and appear ill. They require surgical intervention as well as appropriate antibiotic therapy. Staphylococcal wound infections associated with the presence of a foreign body such as a suture or surgical drain are of particular concern. The milder manifestations may be treated conservatively with oral antibiotics. Myositis and necrotizing fasciitis require aggressive surgical intervention for drainage and removal of infected tissue. Although there is a trend to greater incidence of MRSA SSTIs in the community, there is no difference in clinical outcomes compared with sensitive organisms when there is appropriate intervention.

Staphylococcal Scalded Skin Syndrome

A bullous disease seen almost exclusively in children, staphylococcal scalded skin syndrome is associated with infection with an exfoliative toxin-producing *S. aureus*. Pathologically, the disease is associated with splitting of the granular layer of the epidermis. Generally, infected children are younger than 5 years of age and present with fever and irritability. Sloughing of apparently uninvolved skin (Nikolsky's sign) is characteristic. Upon rupture of the fluid-filled bullae, large areas of epidermis may be disrupted, producing potentially serious volume and electrolyte losses, particularly in very young children. Therapy includes antibiotics and supportive care for electrolyte and volume loss.

Staphylococcal Toxic Shock Syndrome

This toxin-mediated syndrome was initially described in menstruating women using tampons (Fig. 91-1). Staphylococcal TSS has since been recognized in men and in women who are not menstruating. TSS initially presents as rash, fever, myalgias, diarrhea, and a depressed level of consciousness. Renal failure, hepatitis, and shock may rapidly follow these initial signs and symptoms within 24 to 48 hours. The shock may be severe and produce digital necrosis. TSS is often accompanied by the appearance of a desquamative rash, commonly on the hands and feet.

Unlike menses-associated TSS seen most commonly in young women, nonmenstrual TSS is often associated with surgical procedures and may occur in the absence of frank evidence of active infection. A high level of suspicion for TSS must be maintained for patients with a sunburn-appearing rash and a rapidly evolving shock picture following a surgical intervention. Patients with TSS should receive antibiotics active against *S. aureus* as well as supportive care for shock and organ failure. For life-threatening disease, intravenous immunoglobulin is often given in concert with standard therapy. Any potential site of ongoing bacterial replication and toxin production (i.e., infected surgical suture, tampon) should be removed.

Staphylococcal Food Poisoning

S. aureus is associated with about 10% to 20% of the reported outbreaks of food-borne disease in the United States. The syndrome results from ingestion of any of the several heat-stable bacterial exotoxins. Because the preformed toxin is present in the food and does not require ongoing bacterial replication, rapid onset and resolution of symptoms mark the illness. Nausea and vomiting usually occur within 6 hours of ingesting the contaminated food, and symptoms generally resolve within 12 hours. Patients are not febrile, but may appear quite ill from the hypovolemia associated with often explosive diarrhea and vomiting. Outbreaks are usually associated with the ingestion of partially cooked food (e.g., potato salad). Therapy is supportive; antibiotics are not required.

Pneumonia

S. aureus is an important cause of purulent pneumonia (Fig. 91-2). The organism gains access to the lungs either through aspiration of nasopharyngeal contents colonized with staphylococci or hematogenous spread (e.g., metastatic spread from bacteremia or septic emboli from right-sided endocarditis). Staphylococcal pneumonia tends to be fulminant and is often associated with infiltrative lesions that progress to cavitation as well as to pleural empyemas. *S. aureus* is also a common cause of secondary bacterial pneumonia following infection with influenza virus. Anti-staphylococcal antibiotics are usually effective in clearing the infection; however, surgical drainage may be required in cases of pleural empyema.

Endocarditis

S. aureus, the second most common etiologic agent in infective endocarditis, is responsible for between 20% and 30% of the cases (Fig. 91-3). Although the aortic and mitral valves are most likely to be involved, there is an increased prevalence of tricuspid valve involvement among intravenous drug users. As is the case for other organisms, *S. aureus* is more likely to infect heart valves with underlying abnormalities (e.g., degenerative valvular disease, rheumatic heart disease, or congenital abnormalities). However, the valves may be normal in as many as one third of all cases. Staphylococcal endocarditis is also associated with the use of indwelling vascular catheters.

In comparison with endocarditis due to the viridans streptococci, staphylococcal endocarditis tends to be more aggressive and has an acute presentation. Myocardial abscesses are more frequent in the setting of *S. aureus* endocarditis, as are valve ring abscesses, which often require surgical repair. Emboli to large organs occur in nearly half of all cases.

Treatment includes appropriate antibiotics active against the organism. Surgical replacement of the infected valve may be required because of serious conduction dis-

Figure 91-1 Toxic Shock Syndrome.

turbances, myocardial abscesses, evidence of valvular instability, multiple large organ emboli, ongoing bacteremia despite appropriate antibiotic therapy, and refractory congestive heart failure.

Differential Diagnosis/ Diagnostic Approach

Infection with *S. aureus* may be indistinguishable from other bacterial infections. Culture of the organism from infected tissue or blood is the basis of diagnosis. Given the

aggressive nature of many staphylococcal infections, however, a high level of suspicion should be maintained in the presence of predisposing conditions such as defects in phagocytic function and in patients with diabetes mellitus.

Management and Therapy

Optimum Treatment

Drainage of infected material and antibiotics are the mainstays of therapy. Organisms resistant to many of the

available antimicrobial agents are routinely recovered in the hospital as well as in the community setting.

Resistance may be due to either elaboration of β -lactamase or alterations in one of the penicillin-binding proteins (PBPs). The β -lactamase enzyme is secreted extracellularly and acts by cleaving the β -lactam ring, thereby inactivating the compound. Organisms using this mode of resistance may be treated with β -lactamase stable antibiotics such as nafcillin or oxacillin. In organisms with altered PBPs, represented by methicillin-resistant strains, penicillins and cephalosporins are ineffective. These β -

lactam antibiotics directly target the PBPs to interfere with cell wall integrity. In the methicillin-resistant strains, there are different drug susceptibility profiles that are seen in hospital- versus community-acquired isolates. There is also a difference in patterns of drug resistance depending on geography. It is therefore important to tailor treatment according to regional antibiotic susceptibility patterns.

The appearance of strains of *S. aureus* that have reduced susceptibility to the glycopeptide antibiotics (e.g., vancomycin) is a particular concern. Several such isolates have been reported from Japan and the United States. Thus far,

these organisms show only intermediate levels of resistance to vancomycin and retain susceptibility to the newer classes of antistaphylococcal antibiotics, the oxazolidinones, quinupristin-dalfopristin, the cyclic lipopeptide daptomycin, and the glycylcycline tigecycline.

Newer approaches to therapy involve decolonization to prevent person-to-person transmission and to break the cycle of recurrent outbreaks of MRSA SSTIs in a single individual. Currently no clear consensus guidelines exist, and evidence from controlled trials is limited. However,

general measures include intranasal mupirocin, topical antiseptic washes (i.e., chlorhexidine gluconate) during daily showers and weekly chlorine baths (about 1 tsp per gallon of bath water with a 10-minute soak). Personal hygiene measures include keeping nails trimmed short and scrubbed daily with soap, single use only of bath towels and garments, and washing clothes in hot water. If a single patient has recurrent MRSA outbreaks, then oral antibiotics are often used in conjunction. Also, all members of the household should be treated with the general decoloniza-

tion measures. A recent study was the first to show that a combination of intranasal mupirocin, chlorhexidine gluconate washes, and rifampin and doxycycline treatment for 7 days was effective in the eradication of MRSA colonization in hospitalized patients for at least 3 months.

Avoiding Treatment Errors

Appropriate management of every infectious disease involves early recognition of the presence of infection, inclusion of the causative organism in the differential diagnosis, and when possible, treatment with antimicrobials active against the infecting organisms for a sufficient duration to achieve the desired outcome. Because most serious infections caused by staphylococci are not subtle, pitfalls in the management of these infections typically involve the failure to consider staphylococci as the infectious agent and lack of consideration for the drug-resistance potential of this organism. Cultures of material (e.g., wound drainage, sputum, blood) are essential for the establishment of the diagnosis and the determination of drug susceptibilities to guide therapeutic management.

A common error in the management of endovascular infections caused by *S. aureus* is the assumption that detection of this organism in the urine indicates only a urinary tract infection. Isolation of *S. aureus* in the urine should prompt evaluation for the presence of endocarditis or other endovascular infection because this organism commonly enters the genitourinary system hematogenously.

Future Directions

Future studies are likely to yield a more thorough understanding of the pathogenetic mechanisms of staphylococcal disease. Of special interest are insights that should arise from studies of whole bacterial genomes, with an emphasis placed on the further elucidation of the mobile genetic elements.

Epidemiologic studies of drug resistance will also be of continued importance. Although the newer classes of antibiotics have enhanced the ability to treat resistant strains of *S. aureus*, and resistance to these agents appears to be uncommon, it is anticipated that resistant organisms will become prevalent as the use of these antibiotics becomes widespread. Therefore, prevention of infection is of paramount importance. Strategies involving decolonization regimens of chronic carriers need further investigation but are showing promise. Vaccine development and targeted antiadhesion strategies are areas of ongoing study.

EVIDENCE

1. Foster TJ: The *Staphylococcus aureus* "superbug." *J Clin Invest* 114:1693-1696, 2004.

This article reviews the factors contributing to Staphylococcus aureus virulence. These include its altered PBP, adhesion molecules present on its surface, and ability to produce exotoxins that are capable of promoting inflammation and cellular injury.

2. Miller LG, Quan C, Shay A, et al: A prospective investigation of outcomes after hospital discharge for endemic, community-acquired methicillin-resistant and -susceptible *Staphylococcus aureus* skin infection. *Clin Infect Dis* 44(4):483-492, 2007.

The authors report on a prospective trial comparing the 30-day outcome of CA-MRSA vs. CA-MSSA skin and soft tissue infections. They found no significant differences between the groups when appropriate incision and drainage of abscesses was performed. However, there was a trend noted toward close contacts of persons with CA-MRSA developing an infection.

3. Moran GJ, Krishnadasan A, Gorwitz RJ, et al: Methicillin-resistant *S. aureus* infections among patients in the emergency department. *N Engl J Med* 355(7):666-674, 2006.

This paper reports the prevalence of MRSA as a cause of skin infections among adult patients presenting to emergency departments in several geographically diverse, metropolitan areas in the United States. It also presents data on antimicrobial-resistant patterns and strain genotypes.

4. Simor A, Phillips E, McGeer A, et al: Randomized controlled trial of chlorhexidine gluconate for washing, intranasal mupirocin, and rifampin and doxycycline versus no treatment for the eradication of methicillin-resistant *Staphylococcus aureus* colonization. *Clin Infect Dis* 44:178-185, 2007.

This is the second randomized controlled trial performed to assess the efficacy of eradication of MRSA colonization. Such therapies are often offered to patients with recurrent infections despite the lack of evidence. The results of this study, using a combination of topical and oral systemic antimicrobial agents, indicate that MRSA decolonization in hospitalized patients may be achieved for prolonged periods of time and that such treatment is generally well tolerated without significant adverse effects.

5. Tokars JI: Predictive value of blood cultures positive for coagulase-negative staphylococci: Implications for patient care and health care quality assurance. *Clin Infect Dis* 39(3):333-341, 2004.

The author presents a mathematical model for the interpretation of whether blood cultures positive for CoNS are likely to represent true bacteremia vs. contamination and thus necessitate antimicrobial therapy. These clinical guidelines are very useful in daily practice.

Cellulitis

Introduction

Cellulitis is an infection of the skin that may extend into the subcutaneous tissues. Despite being a common clinical entity, the incidence and epidemiology have not been well delineated. Cellulitis accounted for 2.2% of office visits in an analysis of a large health care plan.

Etiology and Pathogenesis

Cellulitis represents a subset of skin and soft tissue infections (Fig. 92-1). The epidemiology, pathogenesis, clinical manifestations, pathogens, and treatment differ by the depth of infection. Cellulitis is an acute, spreading infection of the dermis that may involve the subcutaneous tissues. Erysipelas is a distinct form of superficial cellulitis that is associated with marked swelling of the skin and does not involve subcutaneous tissues. The margins of involved and normal tissues are sharply demarcated, particularly at bony prominences, in contrast to cellulitis, in which the margins are generally not distinct. Cellulitis is distinct from primary pyodermas such as impetigo (a superficial vesiculopustular skin infection), folliculitis (infection of the hair follicles), furuncles (inflammatory nodule of the hair follicles), and carbuncles (abscesses of the subcutaneous tissue that drain through hair follicles). These infections differ from cellulitis in that they are usually caused by *Staphylococcus aureus* as opposed to streptococci, often respond to local measures (topical agents and drainage), and rarely require hospitalization. Infections deeper in the soft tissues include fasciitis (infection between the subcutaneous tissue and muscle) and myositis (infection in the muscle).

Cellulitis generally results from a breach in the skin due to trauma (e.g., cut), underlying disorders of the skin (e.g., psoriasis, eczema), ulcers (e.g., diabetic or decubitus ulcers), or superficial dermal infections (dermatoses, particularly tinea pedis). Major predisposing factors include venous (e.g., venous insufficiency, prior saphenectomy) or lymphatic compromise (e.g., prior pelvic radiation, filariasis, radical mastectomy). Previous cellulitis is also a predisposing factor. Recurrent bouts of cellulitis are common in

patients with impaired lymphatic drainage following radical mastectomy or associated with morbid obesity.

Erysipelas is almost always caused by group A β -hemolytic streptococcus. Less commonly, erysipelas may develop secondary to group C and G streptococcal infection, especially in patients with underlying venous or lymphatic compromise. Rarely, *Staphylococcus aureus* (including methicillin-resistant strains), *Streptococcus pneumoniae*, enterococci, or aerobic gram-negative bacilli may cause erysipelas. Group A β -hemolytic streptococcus is the most common causative organism in cellulitis. Other streptococci, including groups B, C, and G, are also common causes. After streptococci, *Staphylococcus aureus* is the most common pathogen in cellulitis. However, there are a variety of other pathogens (Table 92-1).

Clinical Presentation

Cellulitis is generally an easily recognized clinical syndrome. Typical local findings include macular erythema that is generally confluent and blanching with associated swelling, warmth, and tenderness of the involved area. Lymphangitis with tender regional lymphadenopathy is common. Cellulitis most commonly occurs in the lower extremities, followed by the upper extremities and then head and neck. Systemic findings are common, especially fever and chills. Patients may complain of myalgias and fatigue.

In general, the onset is subacute with enlargement of the erythematous area over several days. Progression is generally proximal. In some patients, the onset of symptoms may be abrupt with high fever and pronounced rigors. Disorientation or an altered mental status may occur, especially in elderly patients.

Figure 92-1 Cross-Section of the Skin Showing Layer and Types of Infections.

Table 92-1 Uncommon Pathogens Causing Cellulitis and Their Risk Factors

Pathogen	Risk Factors
<i>Aeromonas hydrophilia</i>	Swimming in fresh or brackish waters: trauma in the water or contamination of open wounds. Use of medicinal leaches
Community-associated MRSA	Participant in contact sports (e.g., football), inmate of a correctional institute, injection drug use, recipient of a tattoo (failure to use aseptic technique), household member with <i>S. aureus</i> colonization or infection, and poor personal hygiene. Recent studies have noted that community-associated MRSA may occur in the absence of identifiable risk factors
<i>Erysipelothrix rhusiopathiae</i>	Wound with occupational exposure to infected animals including swine, sheep, horses, cattle, chickens, crabs, fish, dogs, and cats
<i>Pasteurella multocida</i>	Cat scratches or bites, dog bites
<i>Pseudomonas aeruginosa</i>	Puncture wounds on plantar surfaces of foot; water exposure
<i>Vibrio vulnificus</i>	Swimming in brackish or marine waters: trauma in the water or contamination of open wounds

MRSA, methicillin-resistant *Staphylococcus aureus*.

Table 92-2 Specific Anatomic Variants of Cellulitis and Causes of Predisposition

Anatomic Variant of Cause of Predisposition	Location	Likely Bacterial Cause
Periorbital cellulitis	Periorbital (origin may be sinuses or dental)	<i>Staphylococcus aureus</i> , pneumococcus, group A streptococcus
Buccal cellulitis	Cheek	<i>Haemophilus influenzae</i>
Cellulitis complicating body piercing	Ear, nose, umbilicus	<i>S. aureus</i> , CA-MRSA, group A streptococcus
Mastectomy (with axillary node dissection) for breast cancer	Ipsilateral arm	Non-group A hemolytic streptococcus
Lumpectomy with radiation (with limited axillary node dissection) for breast cancer	Ipsilateral arm	Non-group A hemolytic streptococcus
Harvest of saphenous vein for coronary artery bypass	Ipsilateral leg	Group A or non-group A hemolytic streptococcus
Liposuction	Thigh, abdominal wall	Group A streptococcus, peptostreptococcus
Postoperative (very early) wound infection	Abdomen, chest, hip	Group A streptococcus
Injection drug use ("skin popping")	Extremities, neck	<i>S. aureus</i> , CA-MRSA, streptococci (groups A, C, F, G)
Perianal cellulitis	Perineum	Group A streptococcus, enteric gram-negative bacilli
Crepitant cellulitis	Trunk, extremities	<i>Clostridium</i> species, mixed infections (anaerobes and gram-negative bacilli)

CA-MRSA, community-associated methicillin-resistant *Staphylococcus aureus*.

Adapted from Swartz MN: *Clinical practice: Cellulitis*. *N Engl J Med* 350:904-912, 2004.

Differential Diagnosis

The distinctive appearance of cellulitis usually leads to an accurate clinical diagnosis. Occasionally, the rash of erythema migrans in Lyme disease leads to diagnostic confusion.

Severe pain in a limb, frank necrosis, blebs, or crepitus should suggest gangrenous cellulitis or fasciitis. Necrotizing fasciitis is a medical emergency that requires emergent surgical débridement and intravenous antibiotics. Type I fasciitis is an acute, rapidly developing infection of deep fascia, characterized by severe pain, tenderness, swelling, bullae, and necrosis of the skin. It is often accompanied by crepitus in a mixed infection caused by anaerobes plus facultative species such as streptococci or enteric gram-negative bacilli. A clinical pearl worth committing to memory is that necrotizing fasciitis should remain high on the differential in any patient with pain out of proportion to the clinical findings on physical examination.

Type II fasciitis is an acute infection, often accompanied by toxic shock syndrome. Physical examination reveals rapid progression of marked edema to violaceous bullae and necrosis of subcutaneous tissue without associated crepitus. Type II fasciitis is generally caused by group A streptococci.

Deep venous thrombosis (DVT) in the lower extremities may mimic cellulitis because patients with DVT often present with erythema overlying the involved veins with associated tenderness and swelling. Fever may also accompany DVT. Other noninfectious syndromes that may lead to diagnostic confusion include contact dermatitis, insect

bites or stings, drug reactions, venous stasis, and foreign body reactions. Less common syndromes may also mimic cellulitis: cutaneous larva migrans, pyoderma gangrenosa, leukemia, lymphoma, Paget's disease, panniculitis, sarcoidosis, Sweet's syndrome (acute febrile neutrophilic dermatosis), systemic lupus erythematosus, and urticaria.

Diagnostic Approach

The diagnosis of cellulitis depends on the appearance of the skin and, in most cases, does not require an attempt to establish a microbial etiology. Moreover, attempts to establish an etiologic or microbiologic diagnosis by culturing blood, skin aspirates, or skin biopsy samples are rarely successful. In one study of more than 500 patients with cellulitis, blood cultures were positive in only 2% of cases. In patients with environmental exposures, it may be useful to try to isolate the causative pathogen by blood cultures or skin biopsy (Table 92-2). Skin biopsy and blood cultures are indicated for cellulitis in patients who are highly immunocompromised (e.g., neutropenia associated with therapy for malignancies). In such patients, fungal and other systemic infections (e.g., candidiasis, histoplasmosis, and blastomycosis) may present with cellulitis.

Physical examination should focus on determining the extent of disease. It is mandatory to completely undress the patient to allow maximal visualization of all skin areas. The examiner should delineate the area of cellulitis with a marking pen to allow assessment of the extent of spread after the initiation of therapy. The observation of blebs,

necrosis, decreased sensation, or crepitus should suggest fasciitis or myositis. Such infections are medical emergencies and require prompt institution of therapy, evaluation of the extent of disease using computed tomography or magnetic resonance imaging, and prompt assessment for emergent surgery to achieve drainage and removal of necrotic material. For cellulitis involving an extremity, the distal web spaces should be examined for superficial bacterial or fungal infection such as tinea pedis. Treatment of these superficial infections reduces the risk for recurrent cellulitis. Documentation of both venous and arterial blood flow in the involved limb is especially important given the association of venous or arterial insufficiency as a risk factor both for infection and failure to respond to antibacterial therapy. Structures adjacent to the area of cellulitis such as joints and bones should be evaluated for septic involvement. In patients with facial cellulitis, evaluation for sinusitis or dental infection is important given the association of these infections with cellulitis.

The only laboratory test generally useful is a white blood cell count with differential. If the antibiotic chosen is appropriate, the patient's fever and white blood cell count should respond.

Management and Therapy

Optimum Treatment

In most patients with cellulitis, outpatient therapy with oral antibiotics is adequate. A complicating abscess requires drainage with Gram stain and culture of the aspirated contents. Patients who have the following risk factors require consideration for inpatient admission and therapy: failure to respond to oral therapy within 72 hours, inability to take oral medication, and severe underlying diseases such as chronic renal or liver failure or insulin-dependent diabetes. Signs and symptoms of systemic toxicity (e.g., tachycardia [heart rate >100 beats/min], hypotension [systolic blood pressure <90 mm Hg or 20 mm Hg below baseline]) are also indications for admission. Patients who require hospitalization should have the following laboratory tests: two blood cultures, complete cell count with differential, blood urea nitrogen and creatinine, bicarbonate, and creatinine phosphokinase.

Clues to potentially severe, deep, soft tissue infection include pain disproportionate to the physical findings; violaceous bullae, cutaneous hemorrhage; skin sloughing or necrosis; hypesthesia of the involved skin; rapid progression; and the presence of gas in the tissues. These patients should have an emergent surgical consultation. Computed tomography or magnetic resonance imaging is often useful to determine the extent of infection if myositis or necrotizing fasciitis is suspected; however, prompt surgery should not be delayed to obtain scans unless the diagnosis is in doubt. In patients with staphylococcal or streptococcal

toxic shock, clindamycin rapidly turns off toxin production and is ordered in conjunction with other antibiotics used to treat streptococcal (e.g., penicillin) or staphylococcal (e.g., oxacillin or vancomycin) infections.

Topical mupirocin is effective for mild erysipelas. Bacitracin and neomycin are considered less effective therapy. Patients who have numerous lesions or who are not responding to topical agents should receive an oral antibiotic active against both *Streptococcus pyogenes* and *S. aureus*. Such agents include dicloxacillin (adult dose, 250 mg 4 times per day orally), cephalexin (adult dose, 250 mg 4 times per day orally), clindamycin (adult dose, 300 to 450 mg 3 times per day orally), or amoxicillin-clavulanate (adult dose, 875/125 mg 2 times per day orally). Therapy should be continued for 7 days. Penicillin is the drug of choice in patients who require hospitalization.

Cellulitis that is associated with furuncles, carbuncles, or abscesses is usually caused by *S. aureus*. In such patients, the abscess requires drainage, and the aspirate should be sent for Gram stain and bacterial culture. Community-associated methicillin-resistant *S. aureus* (CA-MRSA) should be strongly considered in these patients. Initial outpatient therapy should include an agent likely effective against CA-MRSA such as trimethoprim-sulfamethoxazole (adult, 2 double-strength tablets 2 times per day orally) or clindamycin (adult dose, 300 to 450 mg 3 times per day orally). The culture results should provide a guide for optimal antibiotic selection. For inpatients, initial therapy should include a drug with activity against MRSA such as vancomycin, daptomycin, linezolid, or tigecycline.

Cellulitis that is diffuse or unassociated with a defined portal is most commonly caused by streptococcal species. Treatment with dicloxacillin (adult dose, 250 mg 4 times per day orally) or cephalexin (adult dose, 250 mg 4 times per day orally) is usually effective in these patients. For penicillin-allergic patients, clindamycin (adult dose, 300 to 450 mg 3 times per day orally) is the recommended alternative. Important clinical clues to other causes of cellulitis include physical activity, trauma, water contact, animal bites, insect bites, and human bites. In such patients, antibiotics with a wider spectrum or multiple antibiotics may be required. Treatment with intravenous cefazolin or oxacillin is reasonable in patients who require hospitalization; however, the possibility of MRSA infection warrants consideration of initial therapy with vancomycin, daptomycin, linezolid, or tigecycline. The length of therapy is 7 to 10 days, depending on the response. However, conversion to oral therapy is possible when the cellulitis is stable (not progressing) and the patient is clinically responding, as evidenced by decrease in pain, resolution of fever, and shrinkage of the area of cellulitis (it helps to demarcate the extent of initial involvement with a marking pen, as previously noted). An important adjuvant in therapy is to elevate the involved limb to reduce swelling and to promote healing.

Avoiding Treatment Errors

Patients with simple cellulitis managed as outpatients require close follow-up. Failure to respond within 72 hours, progressive spread of infection, or development of systemic signs requires hospitalization. Cellulitis associated with bite wounds (antibiotic depends on biting species), intravenous drug use, infection associated with injury in water, and postoperative surgical wound infections requires a broader spectrum of therapy or different agents. Initial hospitalization and broad-spectrum antibiotics are usually required for patients who have cellulitis and are immunocompromised; demonstrate evidence of systemic toxicity; have suspected necrotizing cellulitis, fasciitis, or myositis; have arterial or venous insufficiency in the infected limb; or have underlying disorders such as insulin-dependent diabetes, renal failure, or liver failure.

Future Directions

The epidemiology of CA-MRSA has not been completely defined. It is likely that the increasing prevalence of CA-MRSA will require alterations in the standard empiric therapy for cellulitis. Management of these patients, once their initial infection has resolved, from the standpoint of personal hygiene and potential decolonization is still evolving. At present, there is no recommendation to attempt to decolonize such patients after a single bout of CA-MRSA skin infection.

New drugs active against MRSA have recently been introduced, including linezolid, daptomycin, and tigecycline. Although all are approved by the U.S. Food and Drug Administration for the therapy of skin and soft tissue infections, when to use these newer agents is incompletely defined. Additional agents with activity against MRSA are likely to be available in the near future.

Rapid tests (e.g., polymerase chain reaction) to detect MRSA are becoming clinically available. Such tests have been used primarily to detect colonization in newly hospitalized patients to determine whether contact precautions are indicated. Whether such tests will have a role in aiding in the choice of therapy for treating skin infections has not been evaluated.

Attempts to develop a vaccine to prevent *S. aureus* infections continue. To date, such vaccines have not been effective.

Infective Endocarditis

Introduction

Infective endocarditis (IE) is an infection of the endocardial surface of the heart and implies the presence of microorganisms in the lesion. Despite advances in medical and surgical interventions, IE continues to be associated with high morbidity and mortality, especially given the evolution of antimicrobial resistance. Early diagnosis, prompt and appropriate antimicrobial therapy, echocardiographic evaluation, and timely surgical intervention are cornerstones of successful management.

Etiology and Pathogenesis

The three main bacterial causes of IE are streptococci, staphylococci, and enterococci. *Staphylococcus aureus* has now replaced viridans group streptococci as the leading cause owing to an increased frequency of oxacillin-resistant *S. aureus* in tertiary centers and community-acquired infections. IE typically occurs in the setting of a previously damaged valve surface. This provides a suitable site for bacterial colonization and adherence, allowing replication to a critical mass and the formation of mature, infected vegetation.

Clinical Presentation

Any organ system can be involved in patients with IE, and thus the clinical presentation is highly variable. Four processes contribute to the clinical manifestations of IE: (1) the infectious process on the valve causing local intracardiac complications (e.g., perivalvular abscess, incompetent valve, conduction disturbances, congestive heart failure [CHF]) (Fig. 93-1); (2) vascular phenomena (e.g., septic pulmonary or arterial emboli, mycotic aneurysm, intracranial hemorrhage); (3) bacteremic seeding of remote sites (e.g., osteomyelitis, psoas or perirenal abscess) (Fig. 93-2); and (4) immunologic phenomena (e.g., glomerulonephritis, Osler's nodes, Roth spots, positive rheumatoid factor, and antinuclear antibodies).

The presentation of IE is straightforward when the classic signs and symptoms are present: fever, bacteremia or fungemia, valvular incompetence, peripheral emboli, and immune-mediated vasculitis as is seen in subacute IE.

However, acute IE may evolve too quickly for immunologic phenomena to develop, and patients may present only with fever or severe manifestations such as those related to valve incompetency. In both acute and subacute IE, fever is the most common presenting symptom.

Frequently, the diagnosis can be made clinically if a careful physical examination is performed. Attention should be given to the conjunctiva (petechial hemorrhages), dilated funduscopy exam (Roth spots), complete cardiovascular exam (new or changing murmur, especially aortic, mitral or tricuspid regurgitation, and signs of CHF), splenomegaly, and extremities (splinter hemorrhages, septic emboli, Janeway's or Osler's nodes) (Fig. 93-3). The comprehensive physical examination can be complemented by several nonspecific yet suggestive laboratory findings including (but not limited to) anemia, thrombocytopenia, leukocytosis, an active urinary sediment, an elevated sedimentation rate, hypergammaglobulinemia, positive rheumatoid factor, antinuclear antibodies, hypocomplementemia, and false-positive Venereal Disease Research Laboratory and Lyme disease serology.

Differential Diagnosis

Almost any disseminated severe bacterial, fungal, mycobacterial, viral, parasitic, or spirochete infection can manifest some of the features of IE. Several connective tissue or autoimmune diseases and hematologic malignancies can also mimic IE. By using the expertise of the microbiologist and the cardiologist early in the process, a definitive positive diagnosis will alert the clinician to any potential

Figure 93-1 Bacterial Endocarditis.

complications and therapeutic interventions. Conversely, a negative echocardiogram will allow alternative diagnoses to be explored more rapidly.

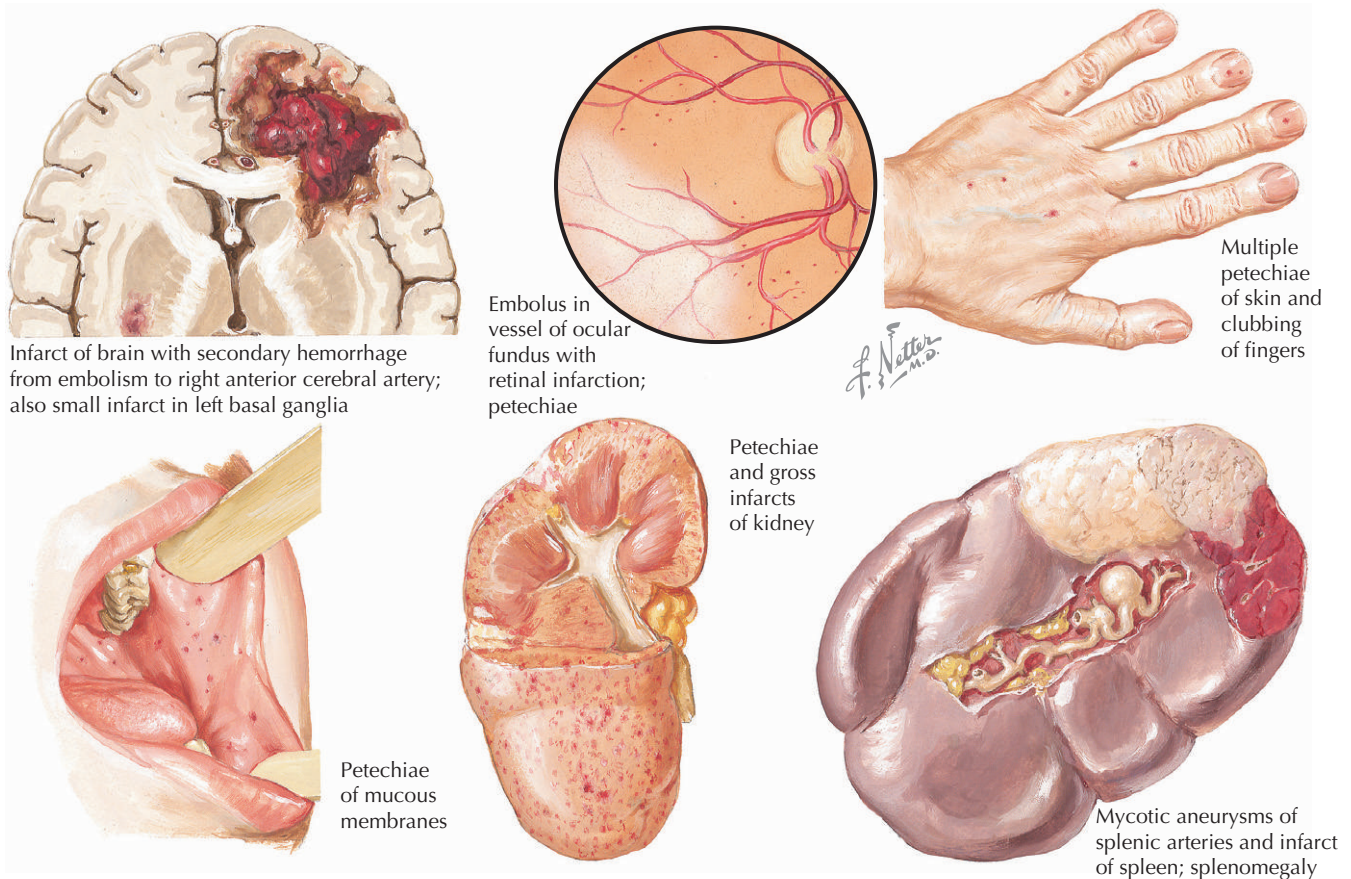

Diagnostic Approach

Since 1994, the Duke criteria have been the diagnostic strategy most consistently used in stratifying patients suspected of IE into definite, possible, or rejected categories. Most recently, these criteria have been modified to include newer diagnostic methods. Although the modified Duke

criteria can provide a primary diagnostic schema, they should not replace clinical judgment.

Microbiology

The first definitive test obtained should be at least three sets of routine blood cultures during the first 24 hours of observation. More cultures may be necessary if the patient has received antibiotics in the preceding weeks. Almost 50% of culture-negative IE can be attributed to antibiotic use before obtaining cultures. Organisms, such as the HACEK group (*Haemophilus* species, *Actinobacillus*

Figure 93-2 Bacterial Endocarditis: Remote Embolic Effects.

actinomycetemcomitans, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species) and *Brucella* species are slow growing and require extended incubation of cultures (4 weeks). Special culture techniques or media may be required for some organisms (e.g., *Legionella* species). Blood culture results are negative in more than 50% of fungal endocarditis cases. Serologic studies are frequently necessary to diagnose Q fever, brucellosis, legionellosis, and psittacosis and are now included as a surrogate marker in lieu of positive blood cultures for diagnosis.

Specific Pathogens

Staphylococcal Endocarditis

Staphylococci are now the most common cause of IE, especially *S. aureus* native valve IE. Increasing rates of methicillin-resistant *S. aureus* are being reported. The course of *S. aureus* is typically fulminant with myocardial and valve-ring abscesses and widespread metastatic infection common. Thirty percent of patients experience neurologic manifestations. IE caused by oxacillin-resistant *S. aureus* is particularly common in injection drug users (IDUs) or patients with nosocomial infection. Coagulase-negative staphylococci are an important cause of prosthetic

valve endocarditis (PVE). Right-sided IE is more commonly seen in IDUs and may be either oxacillin sensitive or resistant.

Streptococcal Endocarditis

Streptococci are now the second most common causative agents of IE, with the viridans streptococci the most common subgroup. The cure rate exceeds 90%, but complications are seen in about 30% of cases.

Streptococcus pneumoniae IE is rare and usually involves the aortic valve. It frequently has a fulminant course and is often associated with perivalvular abscess, pericarditis, and concurrent meningitis. Penicillin resistance is increasing. Valve replacement may be beneficial in preventing early death.

S. anginosus has a predilection to disseminate and form abscesses and may require a longer course of therapy compared with other α -hemolytic streptococci. *S. bovis* IE should prompt a colon malignancy evaluation.

IE due to nutritionally variant streptococci typically is indolent in onset and associated with previous heart disease. Special media are required for microbiologic identification. Therapy is difficult because of systemic embolization and frequent relapse.

Figure 93-3 Common Portals of Bacterial Entry in Bacterial Endocarditis.

Enterococcal Endocarditis

Enterococcus faecalis and *Enterococcus faecium* IE usually affect older men after genitourinary tract manipulation or younger women after an obstetric procedure. Classic peripheral manifestations are uncommon. There is a rapidly increasing rate of penicillin-resistant enterococcus in tertiary care centers.

Gram-Negative Endocarditis

Persons using injection drugs, prosthetic valve recipients, and patients with cirrhosis are at increased risk for gram-negative endocarditis. CHF is common.

Salmonella species IE usually involves abnormal valves and is associated with significant valvular destruction, atrial thrombi, myocarditis, and pericarditis. Valve replacement

after 7 to 10 days of antimicrobial therapy is typically required.

Pseudomonas species IE is almost exclusively seen in IDUs and often affects normal valves. Embolic phenomena, inability to sterilize valves, neurologic complications, ring and annular abscesses, splenic abscesses, bacteremic relapses, and progressive heart failure are common. Early surgical intervention is recommended for left-sided involvement.

Neisseria gonorrhoeae rarely causes IE and typically follows an indolent course, with aortic valve involvement, large vegetations, valve-ring abscesses, CHF, and nephritis.

HACEK Endocarditis

The gram-negative bacilli of the HACEK group account for 5% to 10% of cases of native valve IE. All are fastidious and may require 3 weeks or more for primary isolation. HACEK endocarditis is more common in patients who have dental infections or in IDUs who contaminate the injection with saliva.

Fungal Endocarditis

Candida and *Aspergillus* species are the most common cause of fungal IE. *Candida* species are more common in persons with central venous catheters or parenteral nutrition. Both can be seen following prosthetic valves. Other *Candida* species, *C. parapsilosis* and *C. tropicalis*, predominate in IDUs. Blood culture results are usually negative in *Aspergillus* species IE. Surgical intervention is almost always required, especially with prosthetic valves, following a course of antifungal agents. Lifelong antifungal suppressive therapy is frequently considered.

Culture-Negative Endocarditis

Culture-negative IE is common. Causes include recent administration of antimicrobial agents; slow growth of fastidious organisms, such as the HACEK group; fungal endocarditis; *Coxiella* species; intracellular parasites, such as *Bartonella* or *Chlamydia* species; and noninfectious endocarditis.

Prosthetic Valve Endocarditis

PVE occurs in up to 10% of patients during the lifetime of the prosthesis. Early PVE (within 60 days after implantation) usually results from valve contamination during the perioperative period. Late PVE (after 60 days) results from transient bacteremia. Clinical manifestations are similar to those of native valve IE; however, new or changing murmurs are more common. Persistently positive blood culture results and valvular dysfunction by echocardiography are the hallmarks. Transesophageal echocardiography (TEE) is recommended for diagnosis and assessment of complications such as perivalvular abscess, regurgitation, and so forth. Coagulase-negative staphylococci are the dominant cause of PVE in the first year. After 1 year, the

causative organisms are similar to those of native valve IE. Therapy is, by necessity, aggressive. Rifampin and gentamicin can be added to nafcillin for methicillin-sensitive *S. aureus* or to vancomycin for methicillin-resistant *S. aureus*. For culture-negative PVE, vancomycin and gentamicin should be used to provide broad bactericidal coverage.

Echocardiography

Echocardiography is an essential tool in the diagnosis and management of patients with IE and should be performed in all patients with suspected and confirmed IE (Fig. 93-4). An oscillating vegetation or mass, annular abscess, prosthetic valve dehiscence, and new regurgitation are all major Duke criteria and, as such, confirm IE. Transthoracic echocardiography (TTE) is rapid, noninvasive, and has excellent specificity for vegetations (98%); however, sensitivity is less than 60%. TTE should be performed initially when the suspicion is low. TEE allows imaging of very small vegetations and is the procedure of choice for assessing the pulmonic valve, prosthetic valves, and perivalvular areas for abscesses. TEE has a substantially higher sensitivity (76% to 100%) and specificity (94%) than TTE for perivalvular extension of infection. TEE should be obtained initially when clinical suspicion is high, especially when PVE is suspected or when images obtained by TTE will be poor (i.e., severe pulmonary disease or obesity). If clinical suspicion of IE persists after an initially negative TEE, a repeat study is warranted within 7 to 10 days. The combination of a negative TEE and a negative TTE confers a 95% negative predictive value.

Management and Therapy

Optimum Treatment

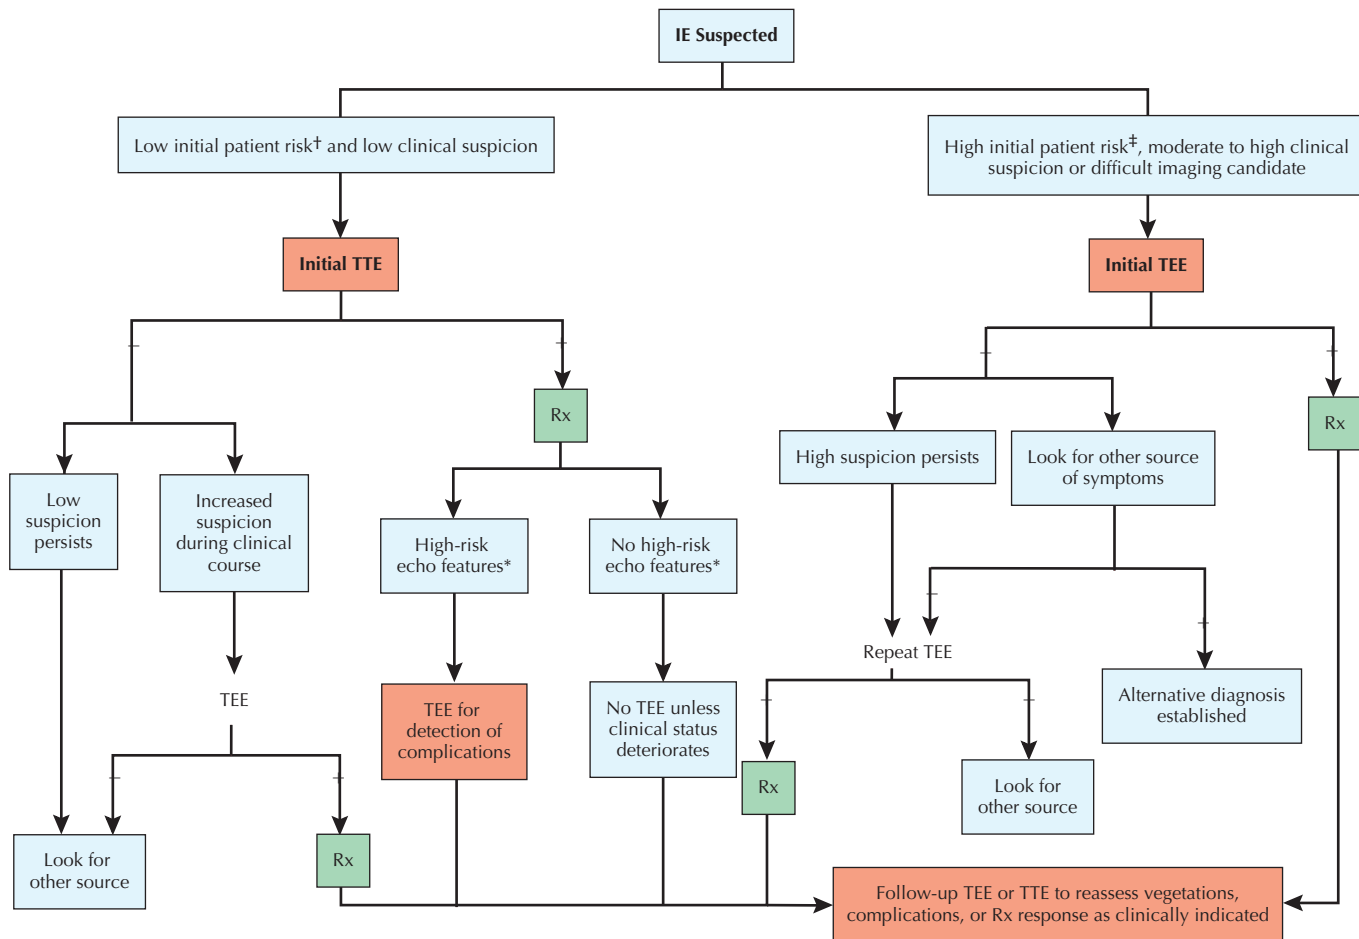

Antimicrobial Therapy

After initial empiric therapy, antimicrobial agents should be selected based on susceptibility testing of the isolated causative microbe (Table 93-1). Prolonged administration of antimicrobial agents is required, almost always through the parenteral route. Bactericidal agents or antibiotic combinations that produce synergistic, rapidly bactericidal effects are the agents of choice. Serum concentrations must be closely monitored when using aminoglycosides. Blood culture specimens should be obtained early in therapy to ensure eradication of the bacteremia and throughout therapy when persistent or recurrent fever is present. Patients with IE complicated by cardiac arrhythmias and CHF require close observation in an intensive care unit. Anticoagulation is contraindicated in patients with native valve IE.

Many of the newer antimicrobial agents may not have been specifically evaluated in IE patients. Daptomycin, a cyclic lipopeptide antibiotic, is bactericidal in vitro against most gram-positive bacteria, especially oxacillin-sensitive

Figure 93-4 Echocardiography in the Diagnosis and Management of Infective Endocarditis.

IE, infective endocarditis; Rx, antibiotic treatment for endocarditis; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography. *High-risk echocardiographic features include large and/or mobile vegetations, valvular insufficiency, suggestion of perivalvular extension, or secondary ventricular dysfunction.

†For example, a patient with fever and a previously known heart murmur and no other stigmata of IE.

‡High initial patient risks include prosthetic heart valves, many congenital heart diseases, previous endocarditis, new murmur, heart failure, or other stigmata of endocarditis. Rx indicates antibiotic treatment for endocarditis.

and oxacillin-resistant *S. aureus*. Recently, daptomycin was shown to be noninferior to standard therapy for bacteremia and right-sided IE. There were too few subjects with left-sided IE to demonstrate noninferiority.

Echocardiography

After the initial diagnosis, echocardiography is useful in management, identifying those patients at high risk for complications, and assessing the need for surgery. Findings that indicate increased risk for complications or need for surgical intervention include the following:

- Persistent vegetation after embolization
- Vegetations larger than 10 mm, especially those on the anterior mitral leaflet (greater risk for embolization)
- Large vegetations
- Vegetations that increase in size while on therapy

- Acute aortic or mitral insufficiency with CHF
- CHF unresponsive to therapy
- Valve perforation or rupture
- Large abscess or abscess unresponsive to therapy
- New heart block
- Valvular dehiscence

Cardiac Surgery

Appropriate, timely surgical intervention can reduce morbidity and mortality substantially. Relatively substantiated indications for surgical intervention include the following:

- Refractory CHF
- More than one serious systemic embolic episode
- Fungal IE, especially involving prosthetic valve
- IE with antibiotic-resistant bacteria or ineffective antimicrobial therapy

Table 93-1 Antimicrobial Therapy for Infective Endocarditis*

Etiology	Antimicrobial Therapy
Viridans streptococci and <i>S. bovis</i> penicillin-susceptible (MIC <0.2 µg/mL)	Penicillin G, 12-18 million U/24 hr IV in 6 doses [†] for 4 wk <i>or</i> Ceftriaxone, 2 g IV once daily for 4 wk, <i>or</i> Penicillin G, 12-18 million U/24 hr IV in 6 doses [†] for 2 wk <i>with</i> gentamicin, 3 mg/kg IV every day for 2 wk <i>or</i> Vancomycin, 30 mg/kg/24 hr IV in two divided doses for 4 wk (recommended only for patients allergic to β-lactams)
Viridans streptococci and <i>S. bovis</i> relatively resistant to penicillin (MIC, 0.1-0.5 µg/mL)	Penicillin G, 24 million U/24 hr IV continuously or 6 doses for 4 wk <i>with</i> gentamicin, 3 mg/kg IV every day for 2 wk (first-generation cephalosporins may be substituted for penicillin in patients with penicillin hypersensitivity not of the immediate type), <i>or</i> Vancomycin, 30 mg/kg/24 hr IV in two divided doses for 4 wk (only recommended for patients allergic to β-lactams)
Enterococci (and viridans streptococci with penicillin MIC >0.5 µg/mL, nutrient variant viridans streptococci)	Penicillin G, 18-30 million U/24 hr IV in 6 doses <i>with</i> gentamicin, 1 mg/kg IV every 8 hr for 4-6 wk, <i>or</i> Ampicillin, 12 g/24 hr in six doses <i>with</i> gentamicin, 1 mg/kg IV every 8 hr for 4-6 wk, <i>or</i> Vancomycin, 30 mg/kg/24 hr IV in two divided doses for 4-6 wk <i>with</i> gentamicin, 1 mg/kg IV every 8 hr for 4-6 wk (only recommended for patients allergic to β-lactams; cephalosporins are not acceptable alternatives for patients allergic to penicillins)
Staphylococci (penicillin-susceptible)	Penicillin G, 20 million U/24 hr IV in six doses for 6 wk [†]
Staphylococci (methicillin-susceptible, penicillin-resistant)	Nafcillin (or oxacillin), 2 g IV every 4 hr [†] for 6 wk <i>with</i> gentamicin, 1 mg/kg IV every 8 hr for 3-5 days, [†] <i>or</i> Cefazolin (or other first-generation cephalosporin), 2 g IV every 8 hr for 6 wk <i>with</i> gentamicin, 1 mg/kg IV every 8 hr [†] for 3-5 days
Staphylococci (methicillin-resistant)	Vancomycin, 30 mg/kg/24 hr IV in two divided doses for 6 wk
HACEK microorganisms	Ceftriaxone, 2 g once daily IV for 4 wk, <i>or</i> Ampicillin-sulbactam, 12 g/24 hr IV in 4 doses for 4 wk
Culture-negative (native valve)	Ampicillin-sulbactam, 12 g/24 hr IV in 4 doses for 4-6 wk <i>with</i> gentamicin, 3 mg/kg each day for 4-6 wk, <i>or</i> Vancomycin, 30 mg/kg in 2 doses for 4-6 wk <i>plus</i> gentamicin, 1 mg/kg in 3 doses for 4-6 wk <i>with</i> ciprofloxacin, 1000 mg/24 hr PO or 800 mg/24 hr in 2 doses IV for 4-6 wk
Prosthetic valve endocarditis	Refer to 2005 American Heart Association endocarditis guidelines

MIC, minimum inhibitory concentration.

* Antibiotic dosages for adult patients with normal renal and hepatic function. Test infecting strain of *Enterococcus* for resistance to aminoglycosides. High-level resistance means loss of synergy, and thus aminoglycosides should not be used in these instances. Therapy should be prolonged to 8-12 wk.

[†] Dosing of penicillin, nafcillin, and oxacillin is frequent and often problematic for home therapy patients. Because these drugs are stable for 24 hr at room temperature, they may be given through a pump that remains with the patient, requiring adjustment only once every 24 hr. Aminoglycosides are used for synergy in gram-positive infections. Requires continuous therapy.

- Persistent positive blood cultures following 1 week of antibiotic therapy
- Left-sided IE with *Pseudomonas* or *Salmonella* species
- Prosthetic valve IE of 12 months' or less duration after initial replacement
- Echocardiographic findings listed earlier

Avoiding Treatment Errors

Effective treatment of IE requires a multidisciplinary approach with input from infectious disease specialists, cardiology, and cardiothoracic surgery. Although guide-

lines and criteria such as the Duke criteria have been established, treatment should be individualized based on clinical judgment.

After a person is put on appropriate antimicrobial therapy, it is imperative to ensure that repeat blood cultures are negative. If not, one should reevaluate therapy and look for complications. Blood cultures should be repeated near the end of antimicrobial therapy and shortly after completing therapy to ensure resolution, and a new baseline echocardiogram should be obtained. It is imperative to educate patients regarding signs of symptoms of IE. Often overlooked are the need for thorough dental evaluation and treatment for substance abuse.

Prophylaxis

Antimicrobial prophylaxis is recommended for patients with increased risk of endocarditis due to underlying cardiac conditions undergoing invasive procedures likely to generate bacteremia. Detailed prophylaxis recommendations are available on the American Heart Association website.

Future Directions

Some clinicians believe that the size of the vegetation and other echocardiographic characteristics predict who is at risk for poor outcome and needs early surgery. At the present time, specific echocardiographic criteria have not been demonstrated. Future studies will help to determine whether echocardiographic findings other than perivalvular or myocardial abscesses are added to the current list of indications for surgery.

Meningitis

Introduction

Meningitis is an inflammation of the meninges, characterized by cellular pleocytosis in the cerebrospinal fluid (CSF). It manifests as headache, fever, meningismus (painful stiff neck), seizures, focal neurologic deficits, and disturbances of consciousness. Meningitis is an infectious disease emergency, requiring prompt evaluation and treatment. Because many bacterial and nonbacterial pathogens can cause meningitis, early broad-spectrum treatment and diagnostic testing are of great importance.

Etiology and Pathogenesis

Patients with meningitis can present acutely or chronically, the distinction helping determine likely etiologies. The most common acute presentations result from bacterial and aseptic meningitis. Aseptic meningitis may occur in patients with viral infections or in association with an adverse drug reaction. A subacute picture, in which CSF pleocytosis persists for longer than 4 weeks, is more likely to be associated with fungal or vasculitic meningitis.

Acute Bacterial Meningitis

The most common causes of bacterial meningitis in most case series are *Streptococcus pneumoniae*, which accounts for about 50% to 60% of community-acquired cases, and *Neisseria meningitidis*, which accounts for 14% to 37% of reported community-acquired cases, based on numerous studies on the etiology of bacterial meningitis. Other frequent causes are *Haemophilus influenzae* (3% to 4%) and *Listeria monocytogenes* (4% to 11%). Rarely, bacterial meningitis is associated with other bacteria, including gram-negative bacilli, other streptococci, *Staphylococcus aureus*, anaerobes, and diphtheroids. Elderly or immunocompromised patients are more likely than others to develop infection due to *Listeria* and gram-negative bacilli. Patients with prior neurosurgery are more likely to develop infection with skin organisms such as *Staphylococcus aureus* and *Staphylococcus epidermidis*, and somewhat less commonly, *Pseudomonas aeruginosa* and other gram-negative bacilli.

Acute Viral Meningitis

Viral meningitis is most commonly caused by Coxsackie virus and echoviruses. West Nile virus, HIV, arboviruses, herpes simplex virus types 1 and 2, adenovirus, cytomegalovirus, varicella-zoster virus, Epstein-Barr virus, lymphocytic choriomeningitis virus, and influenza virus are other causes.

Other Causes of Acute and Chronic Meningitis

Other infectious causes of meningitis include cryptococcosis, tuberculosis, leptospirosis, syphilis, Lyme disease, other fungi, and amebic meningoencephalitis. With the exception of amebic meningoencephalitis, subacute or chronic presentations are more common with these etiologies.

Aseptic meningitis can be caused by a number of drugs and can also be a manifestation of certain rheumatologic or other systemic disorders (Box 94-1). Carcinomatous meningitis is frequently seen in hematologic malignancies and in some adenocarcinomas.

Clinical Presentation

Signs and Symptoms

Headache, fever, and neck stiffness are the hallmarks of meningitis. The headache is usually severe and frontal and can be accompanied by photophobia and vomiting. More severe and acute symptoms suggest a bacterial cause, although the ability of the patient to mount immune

Box 94-1 Etiology of Aseptic Meningitis**Viral**

Echovirus, coxsackievirus, arboviruses, herpes simplex type 2, HIV, lymphocytic choriomeningitis, adenovirus, mumps, influenza, parainfluenza, cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, West Nile virus, others

Drugs

Nonsteroidal anti-inflammatory drugs, trimethoprim-sulfamethoxazole, isoniazid, penicillin, ciprofloxacin, OKT3, azathioprine, immunoglobulin, carbamazepine, cytosine arabinoside, others

Systemic

Sarcoidosis, Behçet's syndrome, systemic lupus erythematosus, central nervous system vasculitis, Vogt-Koyanagi-Harada syndrome, Wegener's granulomatosis, carcinomatous meningitis, others

Other Infectious Syndromes in which Cerebrospinal Fluid Cultures Can Be Negative

Rocky Mountain spotted fever, typhus, human ehrlichiosis, endocarditis, amebiasis, others

responses must be kept in mind when assessing severity of symptoms. Immunocompromised patients may have a more subtle presentation, yet these patients are at very high risk for poor outcome. In bacterial meningitis, the temperature usually exceeds 37.7° C. Low-grade fever is more often present in viral meningitis. Fever may be entirely absent in immunocompromised patients. Neck stiffness is a specific sign and has a sensitivity of about 70%. Mental status changes occur in bacterial meningitis in 44% of cases but are found in only 3% of viral meningitis cases. Seizures occur in the range of 20% to 25% of patients with bacterial meningitis, and focal findings such as cranial nerve deficits are even somewhat more common, occurring in 25% to 30% of these patients. Unfortunately, the classic triad of fever, neck stiffness, and mental status changes occurs in less than half of patients even in bacterial meningitis. However, in one series, 95% had at least two of the four symptoms of headache, fever, neck stiffness, and mental status changes. In *Neisseria* meningitis especially, symptoms can progress from onset to death in a matter of hours, with sepsis symptoms preceding meningeal symptoms.

The clinical presentation and course of viral meningitis are often less severe than in bacterial meningitis. In viral meningitis, examination of the CSF often shows a lymphocytic pleocytosis, and the illness most commonly has a self-limited course of 5 to 7 days. Some less common causes of viral meningitis, such as West Nile virus in particular, can cause a mixed meningoencephalitic picture and present with profound changes in mentation.

A thorough history may elicit clues to more unusual causes of meningitis. The meningitis of leptospirosis often occurs in patients with a history of exposure to rodent,

dog, or livestock urine, and these patients often have associated jaundice and renal dysfunction. Both syphilis and Lyme disease present with the clinical picture of aseptic meningitis during their secondary phases and are almost always associated with relevant exposures when a complete history can be obtained. Amebic disease secondary to *Naegleria fowleri* and *Acanthamoeba* species is fulminant and usually occurs in persons with exposure to fresh-water lakes.

Physical Examination

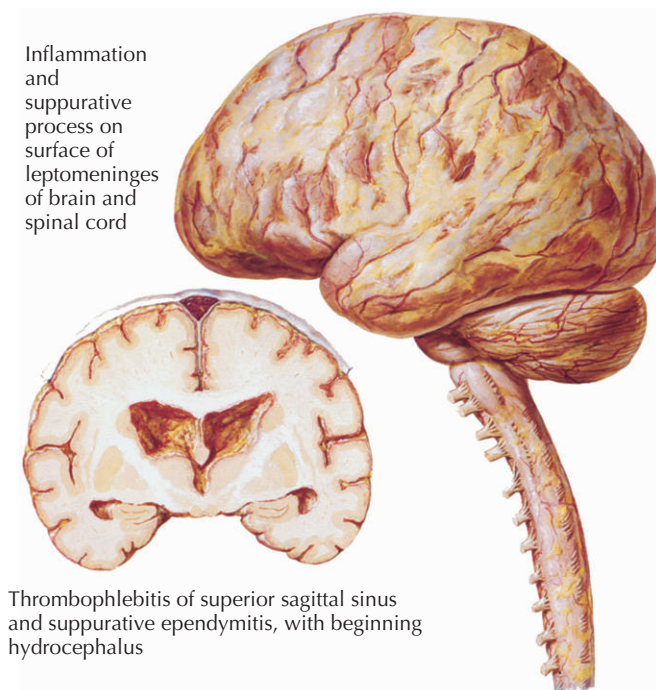

Meningeal signs, most commonly meningismus, are present in about 88% of cases of bacterial meningitis. Other classic signs are Kernig and Brudzinski signs (Fig. 94-1). The Kernig sign is pain in the back upon passive extension of one leg at the knee and the thigh. The Brudzinski sign is flexion of the legs at the thighs when the patient's neck is flexed. Jolt accentuation of headache is a very sensitive finding for meningitis. This is elicited by having the patient turn the head rapidly horizontally a number of times per second to assess for worsening of the headache.

A thorough neurologic examination should be performed, with attention given to accurate assessment of the level of consciousness, presence or absence of cranial nerve deficits, assessment for papilledema, and documentation of any focal motor or sensory defects. The skin should be carefully examined for lesions. Purpura strongly suggests meningococcal disease. Petechiae are almost as frequently seen as purpura in meningococcal meningitis and can occur in rickettsial diseases and sometimes in pneumococcal meningitis. Embolic phenomena such as splinter hemorrhages, Janeway's lesions, and Roth's spots suggest endocarditis, both a cause and a mimic of meningitis. A note should be made of CSF shunts, prior neurosurgical procedures, or head trauma because all predispose to meningitis.

Patients can also present with evidence of potentially contiguous infections associated with bacterial meningitis, such as sinusitis, otitis media, and mastoiditis, and with complications of meningitis, such as cavernous sinus thrombosis and thrombophlebitis of the cranial sinuses (Fig. 94-2).

Differential Diagnosis

The differential diagnosis for patients presenting with fever, headache, and altered mental status includes encephalitis, focal brain lesion, and systemic infections, including endocarditis and rickettsial infections. Encephalitis is classically distinguished from meningitis by the absence of meningeal symptoms and the presence of diffuse neurologic deficits such as altered mentation, confusion, and seizures. Brain lesions (infectious or malignant) are more likely to present with focal neurologic complaints and can

Figure 94-1 Kernig's Sign and Brudzinski's Neck Sign.**Figure 94-2 Bacterial Meningitis.**

be detected by computed tomography (CT) imaging. Blood culture to detect systemic bacteremia and consideration of rickettsial diseases is always warranted. In tropical countries, cerebral malaria must also be excluded.

Diagnostic Approach

The diagnosis of meningitis is made by lumbar puncture (Figs. 94-3 and 94-4). It is important to document the opening pressure and appearance of the CSF. CSF should be sent for cell count and differential, glucose, protein, Gram stain, and culture in all cases (Table 94-1). The addition of a Venereal Diseases Research Laboratory (VDRL) and a cryptococcal antigen is helpful when an

immunocompromised state is possible or in a subacute presentation. Other important tests include viral polymerase chain reaction (PCR) for herpes family viruses and enteroviruses; examination for acid-fast organisms and tuberculosis PCR; and CSF cell cytology. Cytology and mycobacterial culture usually require 10 mL of fluid. Table 94-1 shows typical results for the various type of meningitis using CSF results immediately available.

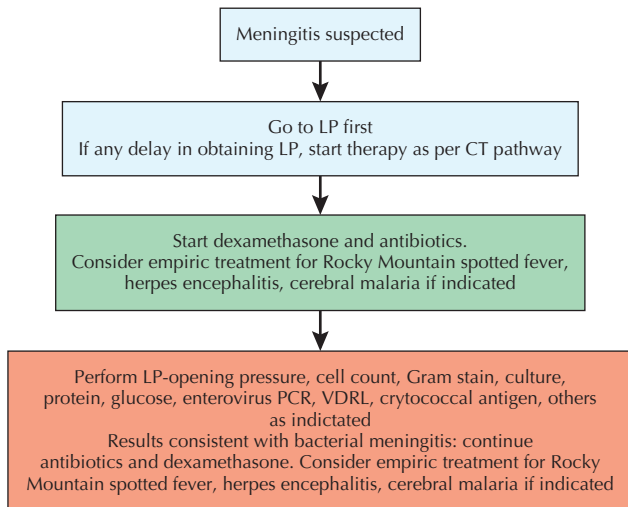

Some confusion surrounds the appropriate use of imaging studies and the timing of antibiotics. Meningitis, and suspected meningitis, should be considered an infectious emergency. If the lumbar puncture is to be delayed at all, empiric antibiotics should be started immediately. CSF cultures are often sterile for bacterial pathogens if taken after antibiotics have been given. CSF cell count and makeup are not affected to any great degree if taken within the first 24 hours of treatment. The risk for causing herniation in a patient by performing a lumbar puncture is no more than 6% and probably only happens when the intracranial pressure is not evenly distributed because of mass effect. The current recommendation is to obtain a CT scan before doing lumbar puncture on all comatose patients, those with focal deficits or papilledema, those with prior central nervous system (CNS) disease or new-onset seizures, and HIV-positive patients.

Culture is the gold standard for making a diagnosis of bacterial meningitis. Latex agglutination tests for bacterial pathogens can be considered; however, because the sensitivity of these tests is only about 70%, a negative test does not rule out a bacterial cause. False-positive agglutination tests have also been reported.

CSF PCR for enteroviruses such as Coxsackie virus and echoviruses and the herpes viruses (herpes simplex virus, varicella-zoster virus, cytomegalovirus) are available and are useful in cases of suspected viral meningitis. CSF PCR and serologic studies for West Nile virus and arboviruses, such as Venezuelan equine encephalitis and Eastern equine encephalitis, should be considered during the summer and fall or given the possibility of mosquito exposure.

Figure 94-3 Bacterial Meningitis.**Figure 94-4 Diagnostic Algorithm.**

CT, computed tomography; PCR, polymerase chain reaction; LP, lumbar puncture; VDRL, Venereal Diseases Research Laboratory. Modified from Tunkel AR, Hartman BJ, Kaplan SL, et al: *Practice guidelines for the management of bacterial meningitis*. *Clin Infect Dis* 39(9):1267-1284, 2004.

Neurosyphilis is associated with a mild CSF pleocytosis, and the CSF VDRL test result is positive in only 60% of cases. The diagnosis of leptospirosis is made by serology. CSF and serum serologies can be ordered for suspected Lyme disease with CNS involvement, but are best ordered in the setting of an appropriate clinical picture and the results must be interpreted with care as both false-positive and false-negative are common. The diagnosis of amebic disease requires CSF examination for motile amebas.

Management and Therapy

Optimum Treatment

Treatment is directed toward covering likely pathogens until bacterial meningitis has been ruled out (Tables 94-2 and 94-3). The current recommendation is to use a third-generation cephalosporin such as ceftriaxone, 2 g given intravenously every 12 hours, plus vancomycin, 1 g given intravenously twice a day (maintaining trough levels of 15-20 µg/mL) plus dexamethasone. Dexamethasone has been shown to reduce adverse outcomes in adults with bacterial meningitis. Dexamethasone should be given in a dose of 0.15 mg/kg intravenously every 6 hours if bacterial meningitis is suspected; it should be given before or concomitant with first dose of antibiotics. It can be continued for 4 days if bacterial meningitis is confirmed.

Listeria monocytogenes is not optimally treated with ceftriaxone. At-risk patients such as those older than 50 years or with immune compromise and any ill patient with meningitis not responding to therapy should receive ampicillin, 2 g intravenously every 4 hours, in addition to empiric therapy while awaiting cultures. Doxycycline, 100 mg twice daily, should be added to the treatment regimen in any patient with meningitis and an illness consistent with Rocky Mountain spotted fever in an endemic area. Often empiric treatment with intravenous acyclovir to cover for herpes encephalitis is begun because the presentation may be similar to meningitis. Treatment with an agent active against *Pseudomonas* species such as ceftazidime or cefepime in place of ceftriaxone, along with vancomycin, can be given as empiric therapy for neurosurgical or head trauma patients. All empiric treatment should be modified as appropriate cultures and antibiotic sensitivities become available. Tuberculous meningitis is treated with four drugs and the consideration of adding steroids. Cryptococcal meningitis requires amphotericin B therapy, usually along with 5-fluorocytosine (5FC).

The duration of therapy for bacterial meningitis depends on the isolated pathogen as well the patient's response. At a minimum, intravenous antibiotics should be administered for at least 7 days and extended to 14 days for pneumococcus, less common bacteria such as gram-negative rods, and *S. aureus* and to at least 21 days for *Listeria* species. In low resource settings, single-dose ceftriaxone has been shown to be effective in outbreaks of meningococcal disease.

Prevention

Vaccination against three organisms that cause meningitis has been shown to be an effective means toward preventing meningitis. Vaccination against *H. influenzae* type B should be part of the routine immunization schedule for children. Vaccination with pneumococcal polysaccharide vaccine protects against invasive disease and is helpful in reducing cases of pneumococcal meningitis in at-risk populations. It

Table 94-1 Typical Cerebrospinal Fluid Findings in Meningitis

	Normal	Bacterial	Viral	Fungal	Tuberculosis	Other
WBC count	0-5/mm ³	100-10,000/mm ³	5-3000/mm ³	5-500/mm ³	5-500/mm ³	—

Tobramycin ^b	5 mg/kg (12)	7.5 mg/kg (8)	7.5 mg/kg (8)	5 mg/kg (8)
TMP-SMZ ^f	—	—	10-20 mg/kg (6-12)	10-20 mg/kg (6-12)
Vancomycin ^g	20-30 mg/kg (8-12)	30-45 mg/kg (6-8)	60 mg/kg (6)	30-45 mg/kg (8-12)

^a Small doses and longer intervals of administration may be advisable for very-low-birth-weight neonates (<2000 g).

^b Need to monitor peak and trough serum concentrations.

^c Higher dose recommended for patients with pneumococcal meningitis.

^d No data on optimal dosage needed in patients with bacterial meningitis.

^e Maximum daily dose of 600 mg.

^f Dosage based on trimethoprim component.

^g Maintain serum trough concentrations of 15-20 μg/mL.

TMP-SMZ, trimethoprim-sulfamethoxazole.

From Tunkel AR, Hartman BJ, Kaplan SL, et al: Practice guidelines for the management of bacterial meningitis. Clin Infect Dis 39(9):1267-1284, 2004.

should be given to all adults older than 65 years, persons with chronic diseases, and those with asplenia. The heptavalent pneumococcal polysaccharide protein conjugate vaccine is given to children as part of the routine childhood immunization schedule.

A polysaccharide vaccine against *Neisseria meningitidis* serogroup A, C, Y, and W-135 is available and is currently recommended for use in 11 to 12 year olds, in disease outbreaks, and in persons with complement deficiencies and functional asplenia. This vaccine should also be offered to matriculating college freshmen, military recruits, and travelers to endemic areas of sub-Saharan Africa.

Prophylaxis

Close contacts of persons with meningococcal meningitis should receive one dose of ciprofloxacin, 500 mg orally, or four doses of rifampin, 600 mg orally every 12 hours, to eradicate colonization of the pharynx. *Close contacts* are those who live in the same household or have other significant or prolonged contact.

Avoiding Treatment Errors

The most common and devastating treatment error is delay in initiating appropriate antibiotics. If meningitis is suspected, treatment and evaluation must begin immediately. Initial broad coverage is wise and can then be narrowed based on diagnostic results. Early consideration of an immunocompromised state that would necessitate treatment for *Listeria* or fungal etiologies is crucial. Patients with bacterial meningitis need close and frequent neurologic assessment, especially of cranial nerves; any changes should prompt evaluation for herniation, cavernous sinus thrombosis, or other catastrophic sequelae.

Future Directions

The prevalence of pneumococcal meningitis may begin to change now that children are being routinely vaccinated using the conjugate vaccine. The use of magnetic resonance imaging in diagnosing meningitis is under further study but will probably not supplant the need for lumbar puncture. The usefulness of such tests as C-reactive protein and procalcitonin in differentiating between bacterial and viral meningitis is being explored.

Septic Arthritis

Introduction

Septic arthritis is a bacterial infection of the synovial space that can occur in both native and prosthetic joints. It usually presents with monoarticular involvement but can be polyarticular. Septic arthritis deserves prompt attention to prevent morbidity and mortality. Although the focus of this chapter is septic arthritis, viruses and other systemic infections can also cause arthritis, usually of the polyarticular type and occurring as part of a syndromic presentation. These illnesses are discussed in relation to the differential diagnosis of suspected septic arthritis.

Etiology

Risk factors for septic arthritis include specific characteristics of a joint that increase its susceptibility to infection when seeded by bacteria and specific host factors that increase the risk for infection. Preexisting joint disease is a major risk factor. Rheumatoid arthritis (RA) and prosthetic joints pose the highest risks, but diseases like osteoarthritis also carry elevated risk. Host factors that increase risk include diabetes mellitus, chronic renal failure, age greater than 80 years, and immunocompromised states.

The leading cause of all cases of septic arthritis is *Staphylococcus aureus*—about 40% to 60% of cases. *S. aureus* is the main cause in RA patients and in those with polyarticular septic arthritis. Streptococci are the second in frequency at 14% to 18%, including group A, as well as groups B, C, and G, and less commonly *Streptococcus pneumoniae*. Gram-negative organisms account for about 7% to 12% of cases. *Haemophilus influenzae* was a leading cause in the past, especially in children, but the incidence has declined dramatically in countries with the *H. influenzae* vaccine. *Neisseria gonorrhoeae* can account for about 5% of cases. Other important pathogens include *Kingella* and *Brucella* species and tuberculosis. Fungal joint infections occasionally occur and include coccidiomycosis, blastomycosis, and those secondary to other soil fungi.

Certain conditions lead to an elevated risk for particular pathogens. Diabetic and elderly patients are more likely to have arthritis due to gram-negative organisms. Immunocompromised hosts can develop septic arthritis due to mycobacteria and fungi and other unusual organisms like *Listeria* species.

Certain exposures also confer risk for particular pathogens. *N. gonorrhoeae* is the most likely etiology of septic arthritis in sexually active young adults in the United States. Intravenous drug users and persons with indwelling catheters can have septic arthritis from hematogenous spread of organisms such as *S. aureus*. Exposure to soil organisms from trauma can lead to fungal arthritis.

Prosthetic joint infections are caused by, in decreasing order of frequency, *Staphylococcus epidermidis* and other coagulase-negative staphylococci, *S. aureus*, streptococci, gram-negative rods, enterococci, and anaerobes. In about 10% of cases of prosthetic joint infections, multiple organisms are isolated.

Clinical Presentation

Joint pain is the most common presenting symptom. In the classic scenario, patients present with the recent onset of pain and associated swelling in one joint. Less than half of all patients have fever. The knee is the most commonly affected joint, followed by the hip. Other joints may be involved, and a polyarticular presentation is not unusual, especially in bacteremic patients and those with RA.

RA patients may experience a more insidious onset, and a high index of suspicion is needed to distinguish septic arthritis from a RA flare. New pain in a previously unaffected joint, pain in one joint out of proportion to others, and the new onset of joint disease in two or more joints are clues to septic arthritis in these patients. A chronic presentation with less acute, more insidious symptoms is also more common in septic arthritis caused by tuberculous or fungal infection.

The physical exam usually demonstrates a warm, erythematous joint with effusion and a limited range of motion. The examination of all other joints is key to excluding polyarticular involvement. The skin should be examined for rashes; disseminated gonorrhea is associated with pustular or papular lesions that can be few and easy to miss. The examiner should carefully observe for conjunctivitis, uveitis, and enthesopathies that are characteristic of a viral or reactive arthritis syndrome. Cardiac examination and search for embolic phenomena should be done carefully to eliminate endocarditis as a cause of the septic arthritis.

Many patients have a leukocytosis. C-reactive protein (CRP) is almost always elevated, and the erythrocyte sedimentation rate (ESR) is usually but not invariably high. Plain films usually do not show any changes in native joints, but they may show prosthesis loosening in prosthetic joints. Magnetic resonance imaging (MRI) is not diagnostic but can suggest the diagnosis when synovial enhancement is seen. Joint effusions are seen by MRI in about 70% of cases.

Prosthetic infection presentations can be classified as early, occurring less than 3 months from surgery, or late. Prosthetic joint infections that occur early typically present with more inflammation and are more likely to be secondary to highly virulent pathogens like *S. aureus*. Later presentations of prosthetic joint infections may have a more insidious onset of pain and swelling or simply instability of the joint and be due to less virulent organisms. A draining sinus tract may be the first presentation.

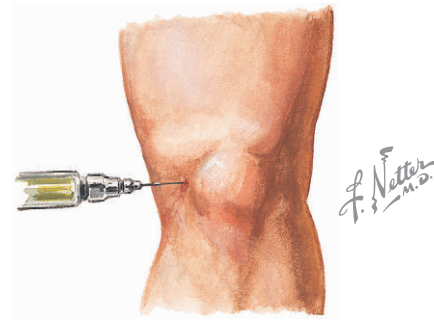

Differential Diagnosis

The differential diagnosis of acute arthritis includes crystal-induced arthritis such as gout and pseudogout, lupus erythematosus, RA, seronegative arthritis syndromes such as psoriatic arthritis, Reiter's syndrome, and other reactive arthritis such as that occurring in poststreptococcal infection. Other noninfectious causes of arthritis include sarcoidosis, but this is typically more insidious and polyarticular. Other infectious causes that predominantly cause polyarticular disease but should be considered are viral infections, Lyme disease, and mycoplasmal infection. Viral causes of arthritis include hepatitis A, hepatitis B, hepatitis C, parvovirus, and mumps. Globally, the mosquito-borne viruses that cause febrile arthritis syndromes are important and include the alphaviruses-Ross River, chikungunya, o'nyong-nyong, and Sindbis viruses. Common viruses that uncommonly cause arthritis are adenovirus, Coxsackie virus, echovirus, and Epstein-Barr virus. Acute HIV infection can also present with arthritis.

Diagnostic Approach

The diagnosis of septic arthritis is made from synovial fluid analysis (Fig. 95-1). Synovial fluid should be sent for cell

Figure 95-1 Septic Joint Aspiration.

Sample of joint fluid aspirated for culture

count, Gram stain and culture, and crystal examination. Usually, synovial white blood cells exceed 50,000 cells/mm³; often, frank pus is aspirated. Crystal examination is important to exclude gout or pseudogout, which can present identically to septic arthritis. The Gram stain is critical to guiding initial antibiotic therapy.

Blood cultures are frequently positive in septic arthritis (about 50% of all patients) and should always be obtained. Other routine blood work has limited utility for diagnosing or excluding septic arthritis. Leukocytosis is found in only about 40% of cases. An elevated ESR is usually found but is nonspecific, and the sedimentation rate can occasionally be normal. Reported sensitivities for elevation of CRP routinely seem to be about 100%; however, the test has poor specificity because it can also be elevated in other types of inflammatory arthritis. One study found that serum procalcitonin levels higher than 0.5 ng/mL had a 55% sensitivity but a 94% specificity for septic arthritis compared with crystal-induced arthritis or RA, but current clinical application of this test remains limited. Arthrocentesis is mandatory to diagnose and guide treatment in suspected cases of septic arthritis.

Certain etiologies require specific diagnostic considerations. Gonococcal arthritis can be culture negative from the joint fluid, but urethral, cervical, rectal, and pharyngeal swabs cultured on Thayer-Martin media are often positive and yield the diagnosis. Brucellosis warrants consideration in persons with sacroiliitis and a history of occupational animal exposure; the diagnosis often requires holding cultures for up to 35 days and sending for brucella serologies. Fungal arthritis should be considered in cases of soil exposure secondary to penetrating trauma and in immunocompromised hosts. The diagnosis should also be considered in areas endemic for coccidiomycosis and blastomycosis. Mycobacterial arthritis can be caused by tuberculosis and by atypical mycobacteria, including *Mycobacterium marinum*. In *M. marinum* infection, the patient often gives a history of fish or water contact. Likewise, fungal or mycobacterial arthritis should be considered in any patient not responding to antibiotics. Joint fluid should

be sent for fungal and mycobacterial culture in these cases.

Serologies for hepatitis A, B, and C, parvovirus serologies, and serum parvovirus DNA polymerase chain reaction can be ordered in patients with polyarticular arthritis. These patients should also have an evaluation for rheumatologic diseases beginning with rheumatoid factor and antinuclear antibodies and other subsequent evaluations as appropriate. Lyme disease is a complex diagnosis that requires a positive Western blot in the appropriate clinical setting. *Mycoplasma* can often be diagnosed by serology.

Prosthetic joint infections are strictly diagnosed using one of the following criteria: growth of a pathogen from synovial fluid, growth of a low-virulence organism from two synovial fluid or surgical specimens, purulent synovial fluid, inflammation on histopathologic examination of periprosthetic tissue, or presence of a sinus tract. However, many joint infections exist that do not meet these criteria, and a symptomatic patient may warrant treatment.

Management

Optimum Treatment

Empiric antibiotic therapy is guided by classifying the patient into three different groups: sexually active adults, non-sexually active adults, and persons with prosthetic joints.

Sexually active adults should have initial therapy directed at gonorrhea and gram-positive organisms with ceftriaxone; vancomycin should be added for better gram-positive coverage if the Gram stain reveals gram-positive cocci. Persons at low risk for gonorrhea should start vancomycin and either a third-generation cephalosporin or a quinolone to cover staphylococci and streptococci species, as well as gram-negative organisms. Persons with prosthetic joints should have therapy directed also at staphylococcal and streptococcal species with vancomycin; however, in prosthetic infections in particular, therapy should ideally be started after cultures are obtained. Once culture results are available, therapy should be modified as needed based on speciation and sensitivity data.

Parenteral antibiotic therapy that is tailored to the specific organism should continue for at least 2 and possibly 4 weeks.

If gonococcal arthritis is diagnosed, ceftriaxone may be switched to oral quinolones to complete 7 days of treatment. As with any sexually transmitted disease, testing for HIV and syphilis and treatment for chlamydia should also be provided.

Antibiotic treatment of prosthetic joints may include the addition of rifampin to vancomycin for staphylococcal infections to improve penetration into biofilms. Any patient receiving rifampin needs monitoring of liver function tests and a complete blood count periodically, as well as attention to the multidrug interactions of rifampin.

In native joints, repeated arthrocentesis to drain the joint effusion is often advisable, especially in purulent infections. In joints such as the hip and sometimes the shoulder, this usually requires arthroscopic or open procedures. The role of routine surgery for native joints is debated. There has been no randomized trial examining this question. Although some series have pointed to increased morbidity in joints treated surgically, this may correlate only with more aggressive disease.

Conversely, septic arthritis in a prosthetic joint requires surgical removal of the prosthesis for cure. The prosthesis is removed, and parenteral antibiotics are administered for about 6 weeks guided by culture. Reimplantation can be scheduled after cure of the infection is confirmed. A single-stage procedure has been advocated by some authors in settings where the pathogen is of low virulence, such as coagulase-negative staphylococci; the prosthesis is well seated; and the surrounding tissue is intact. This one-stage strategy may work better for hip prostheses than knee joints. The known difficulties of eradicating infection in the presence of foreign materials and the subsequent higher risk for treatment failure and its consequences suggest that a two-stage removal would usually be optimal; however, this must be balanced with other surgical considerations, such as the technical feasibility of and the patient's ability to tolerate repeated surgeries.

The treatment of other infectious causes of arthritis obviously depends on the particular diagnosis. Lyme arthritis is treated with doxycycline, 100 mg by mouth twice daily for 30 days. Treatment of fungal or mycobacterial arthritis is directed at the specific pathogen. Symptomatic treatment is given for reactive or viral arthritis.

Avoiding Treatment Errors

Making the correct diagnosis is the first step in avoiding treatment errors. This means maintaining a high index of suspicion for septic arthritis and obtaining joint fluid for analysis and culture. Treatment should be directed at the most common pathogens but must be tailored to the culture results. Optimal antibiotic dosing must be given so that adequate synovial and bone drug levels are achieved; this usually requires at least 2 weeks of parenteral therapy. The patient's clinical and microbiologic response should always guide the duration of therapy because longer courses may be required. If no organism has been identified and the patient is not responding, therapy may need to be broadened or an alternative diagnosis reconsidered. Prosthetic joint infections usually require surgical removal of the prosthesis because any other strategy results in lower cure rates. Although early and appropriate use of antibiotics can be life saving, clinicians must always be familiar with the patient's allergy history and the known side effects of antibiotics and monitor appropriately to avoid adverse events.

Future Directions

Further studies may refine the use of serologic and radiographic tests that distinguish septic from other causes of arthritis; however, joint fluid culture will probably not be abandoned in the near future. Evolving patterns of resistance should be monitored to guide initial treatment, especially in gram-positive organisms and gonococci.

Osteomyelitis

Introduction

Bone infection is associated with significant morbidity and is often not effectively treated solely with antibiotics. Infected bone regenerates slowly and can represent an ischemic compartment that is poorly penetrated by antibiotics or the immune system. The incidence of osteomyelitis is likely to increase as a result of changing health care practices, an aging population, and evolving pathogens. Trends such as the increasing use of prosthetic joint implantation and an increased use of central venous catheters (with the attendant risk for bacteremia) may translate to higher rates of osteomyelitis. There is evidence that the development of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) as a pathogen may increase the rates of bone and joint infections.

Osteomyelitis can be secondary to hematogenous seeding, a contiguous focus of infection, open fractures, or vascular insufficiency of an extremity. Chronic osteomyelitis is associated with retained, avascular bone and is ineffectively treated with antibiotic therapy alone. The spectrum of bone infections is so vast that no rule of thumb applies to treatment. Medical therapy alone is sometimes sufficient, but surgical therapy is often necessary, and the treatment team may involve the primary care physician, orthopedic surgeon, plastic surgeon, infectious diseases specialist, and vascular surgeon.

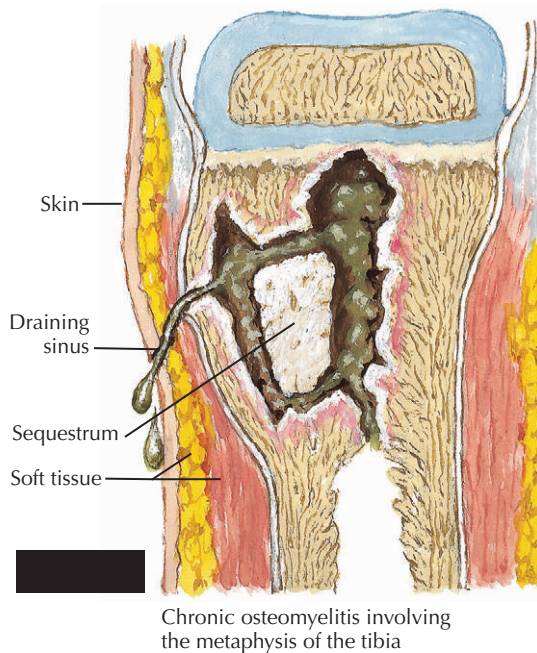

Etiology and Pathogenesis

The disease state of osteomyelitis is due to both an infecting microorganism and an associated host inflammatory response. An infecting organism can reach the bone through direct inoculation (such as a penetrating injury), a hematogenous route, or contiguous spread from infection in adjacent tissue. In the case of acute hematogenous osteomyelitis of the long bones, the initial infection is endosteal, with subsequent extension to cortical bone and the periosteum, whereas other forms of osteomyelitis may first affect cortical bone. As acute osteomyelitis progresses to chronic osteomyelitis (generally over months to years), there is retained dead bone and frequently extension through cortical bone with sinus tracts draining to the skin (Fig. 96-1).

The Waldvogel system is most commonly used to classify osteomyelitis and describes three categories based on the underlying etiology of bone infection. The first is hematogenous osteomyelitis, a type that occurs in both adults and children. In adults, the vertebrae are more often involved; in contrast, the long bones are more often involved in children. The hematogenous source of infec-

tion may be due to overt septicemia but often is secondary to subclinical bacteremia related to a remote site of infection (Fig. 96-2). A second category is osteomyelitis secondary to a contiguous focus of infection. This includes osteomyelitis secondary to trauma, implanted hardware (prosthetic joints, external or internal fixation), adjacent soft tissue infection, dental infection, and pressure ulcers (Fig. 96-3). The last category is osteomyelitis secondary to vascular insufficiency, which is most often associated with soft tissue infection. This is exacerbated by poor tissue perfusion due to large or small vessel disease. Most patients in this category have diabetes mellitus, and the bones of the feet (especially the phalanges and metatarsals) are most often involved.

The Cierny-Mader system is also used to classify osteomyelitis and is more anatomic in description; it is composed of four stages. Stage 1 is medullary osteomyelitis; examples include acute hematogenous endosteal infections or infections associated with intramedullary rods. Stage 2 is superficial osteomyelitis, such as contiguous infection involving the cortical surface of bone. Stage 3 is full-thickness involvement of the bone that can be debrided without compromising bone. Stage 4 is diffuse osteomy-

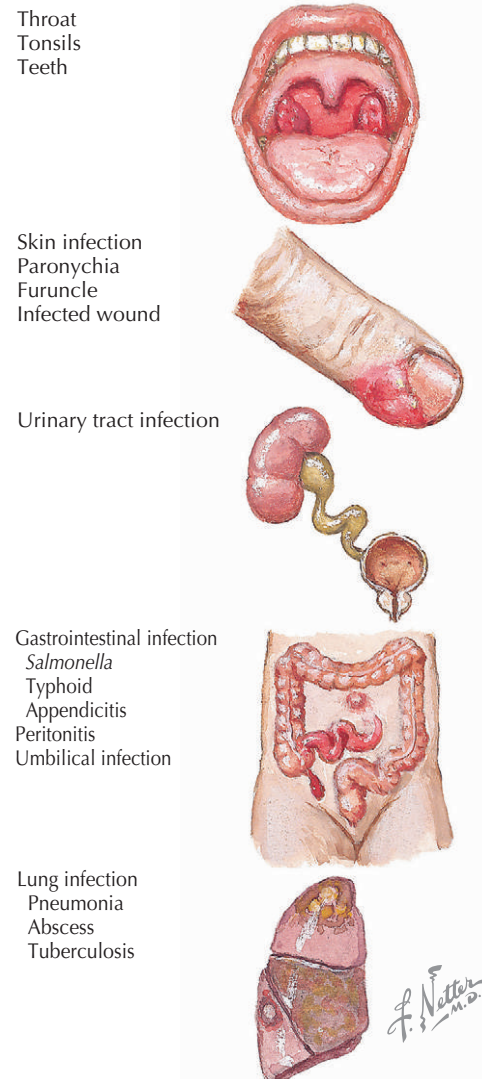

Figure 96-1 Chronic Osteomyelitis Involving the Metaphysis of the Tibia.

elitis that either will result in bony instability after debridement or has through-and-through involvement that requires transection of a bone segment.

The pathogens that most often cause osteomyelitis are aerobic gram-positive cocci and various gram-negative bacteria. *S. aureus* is the most common pathogen and is seen in all types of osteomyelitis. Enterobacteriaceae and *Pseudomonas* species are commonly encountered gram-negative pathogens. Anaerobic bacteria can also infect bone and may do so alone or as part of a mixed infection. Fungi—most often *Candida albicans*, but less commonly endemic mycoses, *Cryptococcus* species, or filamentous fungi—can also cause osteomyelitis. In adults, *Mycobacterium tuberculosis* is well known to cause disease in the axial (rarely the appendicular) skeleton. In the final analysis, any microorganism that can cause invasive disease is capable of causing osteomyelitis, and the literature contains many case reports of osteomyelitis due to less commonly encountered pathogens. This breadth of potential pathogens speaks to the importance of establishing a culture diagnosis whenever possible. Unique associations are listed in Table 96-1.

Clinical Presentation

The clinical presentation varies based on the etiology of disease. In many cases, the patient does not present with sepsis, and the degree of fever and leukocytosis is mild. Pain is almost always present unless masked by neuropathy or obtundation, and this can be an important clue. Statisti-

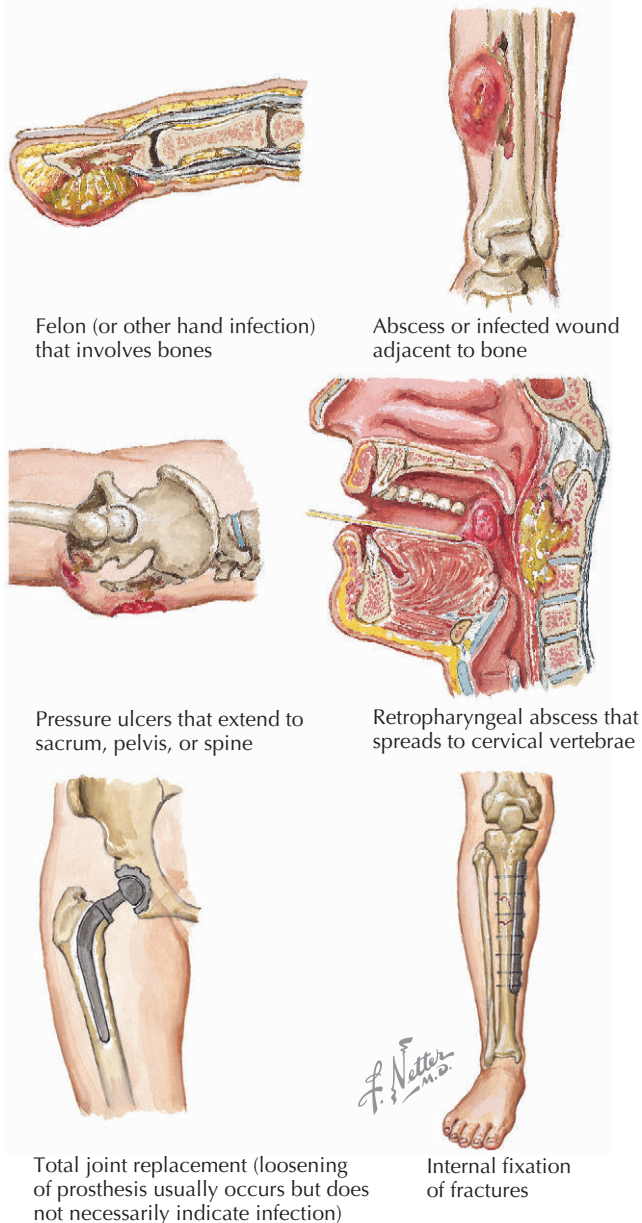

Figure 96-2 Hematogenous Osteomyelitis.

Hematogenous osteomyelitis may be secondary to subclinical bacteremia associated with numerous infections, including tonsillitis, cellulitis, pyelonephritis, intra-abdominal infections, and pneumonia

cally, most patients with symptoms of focal limb, joint, or back pain do not have bone infection, and therefore it is not surprising that in cases of hematogenous or other forms of osteomyelitis, pain may initially be attributed to other more common causes.

Hematogenous osteomyelitis in adults can affect the long bones but more often affects the vertebrae. The lumbar spine is involved more often than the thoracic spine, and cervical spine disease (rarely the dens) is seen in a small minority of cases. Patients always have associated pain, and this can range from mild to severe. In the absence of systemic symptoms, it is difficult to differentiate early vertebral osteomyelitis from benign lumbago. Fever may be present, and in cases of advanced disease or associated epidural abscess, neurologic deficits may develop. One

Figure 96-3 Examples of Contiguous Infections That May Be Associated with Osteomyelitis.

should consider this diagnosis in patients with new-onset back pain that steadily worsens or does not improve.

Osteomyelitis associated with vascular insufficiency presents with concurrent soft tissue infection in most cases. Detecting the subset of diabetic foot ulcers with accompanying osteomyelitis can be challenging. Patients may note fever, erythema, and draining ulcers overlying involved bone. Most patients have few systemic symptoms, and many do not complain of pain. In patients who neglect early symptoms, secondary sepsis and bacteremia may result with overt rigors and fever. In advanced cases, bone may be visible in the bed of the wound.

Prosthetic joint infections represent a form of osteomyelitis secondary to a contiguous infection. These patients uncommonly have fever or systemic symptoms. The primary clinical finding is pain, especially with weight bearing. It is common to encounter patients with worsening pain over an extended period of time (months) who are ultimately diagnosed with a prosthesis infection. Delay in diagnosis may be related to initial neglect of pain and to the similarity of symptoms to those experienced in aseptic loosening or mechanical dysfunction.

Chronic osteomyelitis often presents with overlying pain and erythema. Draining sinus tracts can be found adjacent to the infected bone. Most such patients describe chronic pain and drainage and have a known history of osteomyelitis.

Differential Diagnosis

The differential diagnosis of osteomyelitis is not broad but can be challenging to establish. The degree of diagnostic difficulty depends on the form of osteomyelitis being considered. Issues in diagnosing bone infection range from failing to consider the diagnosis (as in early hematogenous osteomyelitis) to being uncertain how to confirm a suspected case (as in the setting of an infected soft tissue ulcer in close proximity to bone). Differentiating between Charcot's foot (neuropathic osteoarthropathy) and osteomyelitis in the diabetic foot often presents a special challenge. In addition, osteomyelitis in patients with sickle cell disease can be difficult to differentiate from bone infarction.

The diagnosis of vertebral osteomyelitis requires a high index of suspicion. Herniated intervertebral disks, vertebral compression fractures, muscular strain, and arthritis can all present with similar pain.

Osteomyelitis of the diabetic foot ranges from a subtle to obvious diagnosis; this depends on the degree of soft tissue infection and bone destruction. The differential diagnosis may include diabetic foot ulcer (with no underlying bone infection), Charcot's foot, crystal arthropathy, degenerative joint disease, and bone fracture.

In the setting of prosthetic joint infection, the differential diagnosis is narrow. Diagnostic considerations include aseptic loosening, mechanical dysfunction (such as patellofemoral instability), infection, and rarely, secondary sarcoma.

Diagnostic Approach

Given the various clinical presentations of osteomyelitis, there is no commonly accepted algorithm to guide diagnosis. A careful initial history and physical examination is key. The diagnosis may be further substantiated by laboratory studies, pathology, culture, and radiologic imaging. Ultimately, it is the clinician's thoughtful synthesis of this material that leads to a diagnosis of confirmed or probable osteomyelitis.

Table 96-1 Common Osteomyelitis Pathogens and Clinical Associations

Clinical Setting	Pathogen	Comments
Hematogenous osteomyelitis	<i>Staphylococcus aureus</i> , Enterobacteriaceae, <i>Pseudomonas aeruginosa</i>	A single pathogen is most often isolated
Prosthetic joint–associated osteomyelitis	Coagulase-negative staphylococci, <i>S. aureus</i> , Enterobacteriaceae	Blood cultures are rarely positive; joint aspirates and multiple operative cultures can aid diagnosis
Vertebral osteomyelitis	See “Hematogenous osteomyelitis”; <i>Mycobacterium tuberculosis</i>	Tuberculosis should be considered, although it is responsible for a small minority of cases
Osteomyelitis associated with diabetic foot infections	<i>S. aureus</i> , <i>Streptococcus agalactiae</i> and other streptococci, Enterobacteriaceae, anaerobes, <i>Pseudomonas</i> and <i>Enterococcus</i> species, coagulase-negative staphylococci	Almost always a polymicrobial infection
Osteomyelitis associated with sickle cell disease	<i>Salmonella</i> species, Enterobacteriaceae, <i>S. aureus</i>	Hematogenous source
Unique endemic pathogens	<i>Brucella</i> species, endemic mycoses (<i>Blastomyces</i> , <i>Coccidioides</i> , and <i>Histoplasma</i> species), melioidosis (<i>Burkholderia pseudomallei</i>)	Osteomyelitis occurs in a small subset of infections due to these pathogens

Certain elements of the history and physical exam are useful in diagnosing osteomyelitis. Pain at the involved site is frequently seen. When accompanied by fever, the clinician’s index of suspicion should increase. When bone is visible in the bed of an infected ulcer, or if encountered by gentle probing of the wound, osteomyelitis, as a rule, is diagnosed. Draining fistulas often accompany chronic osteomyelitis, and most such patients carry a previous diagnosis of osteomyelitis.

The white blood cell count (WBC) is often elevated (with neutrophilic predominance), but a normal WBC count should never be used to exclude the diagnosis. In cases of chronic osteomyelitis and late prosthetic joint infections, a normal WBC is especially common. The erythrocyte sedimentation rate is high in most cases of bone infection but is slow to change over time, and it can also be elevated with other disease states. C-reactive protein (CRP) changes more quickly with response to therapy, but a normalized CRP does not equate with cure.

Culturing an etiologic pathogen is often diagnostic and, along with antibiotic susceptibility testing, is important in guiding treatment decisions. Samples for culture can include blood, bone, joint aspirates, or deep samples of soft tissue adjacent to a focus of osteomyelitis. In cases of hematogenous osteomyelitis, positive blood cultures can provide a diagnosis and obviate the need for biopsy. The importance of holding antibiotic therapy until cultures are obtained warrants emphasis. A single blood culture positive for a pathogen that might represent a skin contaminant (e.g., coagulase-negative staphylococci, *Propionibacterium acnes*, or corynebacteria) is not diagnostic. Cultures from draining sinus tracts can be misleading, although the growth of *S. aureus* is usually dependable. Surface swab cultures from an ulcer contiguous to osteo-

myelitis are also often misleading. Bone biopsy cultures obtained by surgical or computed tomography (CT)-guided biopsy are the most specific. All samples should be sent for aerobic and anaerobic culture, and in certain circumstances (prior negative cultures, suggestive pathology, or a compatible clinical scenario), samples should be sent for mycobacterial and fungal culture. In vertebral osteomyelitis with negative blood cultures, CT-guided biopsy is often used for diagnosis. If the biopsy culture is negative, undertaking repeat CT-guided biopsy or open biopsy, or in certain cases, proceeding to empiric treatment, is indicated. In the setting of prosthetic joint infection, multiple samples from periprosthetic bone and soft tissue (up to five) should be sent for culture. Some orthopedic surgeons rely on intraoperative frozen section pathology during joint revision surgery to suggest persistent infection (>10 neutrophils per high-power field).

Plain radiographs should routinely be done when there is clinical suspicion of osteomyelitis. Although plain radiography has poor sensitivity, it often can help support the diagnosis and is also useful for future comparison. Plain films may show narrowing of the joint space, periosteal elevation, and osteopenia or lytic changes. In acute osteomyelitis, it takes several weeks or more for any visible abnormalities to be visible on plain films, and it is not uncommon to diagnose osteomyelitis despite unremarkable plain radiographs.

CT and magnetic resonance imaging (MRI) can provide better delineation of bony anatomy and are useful in making the diagnosis. CT provides excellent imaging of cortical bone and adjacent soft tissue and, in chronic osteomyelitis, adequately detects sequestra. When there are implanted metal devices in the viewing field, scatter artifact seriously limits the quality of imaging. Implants may also

interfere with MRI interpretation. MRI is superior in detecting acute osteomyelitis because of its ability to detect marrow edema (which appears white on T2-weighted sequences and black on T1). In cases of vertebral osteomyelitis, MRI is also useful in the diagnosis of epidural abscess. Charcot's osteoarthropathy and marrow changes secondary to sickle cell anemia are difficult to separate from osteomyelitis on MRI. MRI is also less useful in following response to therapy because marrow changes often persist after the infection has been successfully treated.

Three-phase bone scans are done using technetium-99m bound to phosphate, an isotope that accumulates in areas of new bone formation. This scanning technique is useful in suspected cases of osteomyelitis with normal plain films. False-positive findings can occur in the setting of post-traumatic injury, noninfectious inflammatory bone disease, and healed osteomyelitis. Radionuclide-labeled WBC scans are less sensitive and uncommonly used in diagnosing osteomyelitis.

Management and Therapy

The treatment of osteomyelitis should take into account the host status, etiologic pathogens, and extent of bone involvement. Optimal care often requires multidisciplinary input. Although medical therapy alone is appropriate in many circumstances, there are numerous situations that require surgical intervention.

Certain principles should be kept in mind. First, when treating bone infection in association with implanted hardware, osteomyelitis is seldom cured without removal of the hardware (plate and screw fixation, intramedullary nails, prosthetic joints). Early prosthetic joint infection treated with débridement and prosthesis retention may be an exception, but this, too, may cause persistent infection without hardware removal. Second, debridement is most often indicated in diabetic foot infection with contiguous osteomyelitis; dogma has generally been that diseased bone should be debrided to healthy, bleeding bone, although some suggest that limited debridement or antibiotic treatment alone can be successful. Third, chronic osteomyelitis is a surgical disease that is not cured with antibiotic therapy. Antibiotics may be used in conjunction with surgical treatment or as short-course therapy to effect symptomatic improvement. Fourth, when amputation is carried out well above the level of infection (i.e., below the knee amputation to treat a refractory diabetic foot infection), antibiotic therapy should be discontinued in the absence of disseminated infection. Fifth, in patients with arterial insufficiency and osteomyelitis in an extremity, consideration should be given to revascularization.

The appropriate length of antibiotic treatment remains an area of some uncertainty. For cases of acute hematogenous osteomyelitis, most physicians treat with a 6-week course of antibiotics. This is based on time for bone regeneration and on the body of clinical experience in treating

osteomyelitis. There are scenarios in which a shorter or longer course of antibiotics is appropriate. In diabetic foot infections with associated osteomyelitis, a shorter course of antibiotics is often effective, about 4 weeks, if there has been aggressive debridement of soft tissue and resection of osteomyelitic bone. In contrast, some patients with vertebral osteomyelitis due to difficult pathogens, such as MRSA, are treated with longer courses of antibiotics; this is especially the case in patients with complicated infections involving epidural or paravertebral abscesses. In such cases, some physicians treat with an extended course of parenteral antibiotics (8 to 12 weeks), and others attempt a switch to extended oral antibiotics after an initial 6- to 8-week course of parenteral antibiotics.

Whether to give intravenous or oral antibiotics is also a common question. In most cases, treatment is with parenteral antibiotics. There are, however, situations in which oral therapy is appropriate. Fluoroquinolones have excellent bioavailability and bone penetration, and in infections due to susceptible gram-negative rods (*Pseudomonas* species excluded), monotherapy with an oral fluoroquinolone is appropriate. Although patients with *S. aureus* osteomyelitis have been successfully treated using a combination oral regimen of rifampin and a fluoroquinolone, this approach has not become the standard of care. Clindamycin can be used to treat *S. aureus* infections that have no evidence of constitutive or inducible resistance. It offers excellent bioavailability and good bone penetration and is appropriate to use orally or parenterally. In treating adults with *S. aureus* osteomyelitis, oral clindamycin can be used to de-escalate from initial treatment with a parenteral antibiotic. Linezolid is a newer antibiotic that is highly bioavailable and has good gram-positive activity and good bone penetration; extended use can be associated with neuropathy and more commonly with cytopenia, and these complications have tempered its utility in treating osteomyelitis.

Antibiotic regimens appropriate for common pathogens are listed in Table 96-2. When indicated based on drug metabolism and excretion, renal or hepatic insufficiency requires dose adjustments. In cases of enterococcal infections, an aminoglycoside dosed for synergy can be used through all or part of the treatment course. Oral rifampin can be added as an adjunctive agent in treating *Staphylococcus* osteomyelitis associated with hardware. Dual antibiotic therapy for *Pseudomonas* osteomyelitis is often used for part or all of treatment.

Optimum Treatment

In vertebral osteomyelitis, medical therapy is the standard. Culture and antibiotic susceptibility testing should always guide the selection of antibiotics. In the unusual circumstance when cultures are negative, concern about fastidious pathogens, fungi, and mycobacteria should increase. Empiric treatment in these cases is most often with a regimen that covers gram-positive and gram-negative

Table 96-2 Accepted Antibiotic Treatment Options for Selected Osteomyelitis Pathogens

Pathogen	Antibiotics of Choice	Alternative Treatment
Methicillin-sensitive <i>Staphylococcus aureus</i>	Oxacillin or nafcillin (2 g IV every 4-6 hr)	Cefazolin (1-2 g IV every 8 hr) Clindamycin ^a (600-900 mg IV every 8 hr; 300-450 mg by mouth every 6 hr) Vancomycin (1 g IV every 12 hr) Rifampin ^b (600 mg by mouth every day or 300 mg by mouth twice a day)
Methicillin-resistant <i>S. aureus</i>	Vancomycin (1g IV every 12 hr)	Teicoplanin (400 mg IV every 12 hr for 1 day, then every 24 hr) Rifampin ^b (600 mg by mouth every day or 300 mg by mouth twice a day)
Streptococci (groups A, B, C, F, G)	Penicillin G (12-20 mU IV daily in six doses or as continuous infusion)	Clindamycin ^a (600-900 mg IV every 8 hr; 300-450 mg by mouth every 6 hr) Vancomycin (1g IV every 12 hr)
<i>Enterococcus</i> species	Ampicillin (2 g IV every 4 hr), or Penicillin G (as above)	Gentamicin ^c (1 mg/kg IV every 8 hr) Vancomycin (1 g IV every 12 hr)
<i>Enterobacteriaceae</i> ^d	Fluoroquinolone (i.e., ciprofloxacin [400 mg IV every 12 hr; 750 mg by mouth twice a day]), or Third-generation cephalosporin (i.e., ceftriaxone [2 g IV every 24 hr])	Cefepime (2 g IV every 12 hr) Imipenem ^e (500 mg IV every 6 hr)
<i>Pseudomonas aeruginosa</i>	Piperacillin (2-4 g IV every 4-6 hours), or piperacillin-tazobactam (3.375-4.5 g IV every 6 hr), or ceftazidime (2 g IV every 8 hr) and gentamicin (once daily dosing) ^f , or ciprofloxacin (400 mg IV every 12 hr; 750 mg by mouth twice a day)	Cefepime (2 g IV every 8-12 hr), or Imipenem (500 mg IV every 6 hr), and Ciprofloxacin, or Gentamicin (once-daily dosing)

^aIf no evidence of constitutive or inducible resistance.

^bNot to be used as a single agent.

^cConsider using ampicillin, penicillin, or vancomycin *and* an aminoglycoside dosed for synergy during part or all of treatment.

^dCephalosporin monotherapy should be used with caution in *Enterobacter* or *Serratia* species infections.

^eFor use in resistant isolates.

^fGentamicin may be discontinued after several weeks to decrease the risk of vestibular, oto- or nephrotoxicity.

pathogens. Treatment duration is for a minimum of 6 weeks. In patients with spinal instability, associated neurologic symptoms, a large paravertebral infection not responding to medical treatment, or extensive epidural abscess, surgical intervention may be necessary. Surgery usually involves a two stage procedure: initial anterior debridement followed by delayed posterior instrumented fusion.

In osteomyelitis associated with diabetic foot infection, large vessel disease is often an underlying problem that requires revascularization to maximize the chances for treatment success. In patients who present with sepsis and an advanced, neglected foot infection, immediate amputation may offer the only alternative to decrease morbidity. Fortunately, most patients can be treated with debridement of soft tissue and infected bone. After debridement, wound management is critical and may involve negative-pressure dressings and skin grafting. Such infections are almost always polymicrobial, and surface-swab cultures are inadequate guides to therapy.

For most patients with prosthetic joint infections, the standard of care is a two-stage procedure. The first stage consists of removal of the infected prosthesis, debridement, and placement of a spacer containing antibiotic

impregnated cement; many orthopedic surgeons will use an articulating spacer that allows the patient to bear weight and maintain limited joint mobility. Parenteral antibiotics are administered for 6 or more weeks and then discontinued. Subsequently, a new arthroplasty is implanted unless there are findings to suggest persistent infection.

Chronic osteomyelitis requires surgical treatment for patient recovery. Patients who are not acceptable operative candidates may be treated with intermittent antibiotics for symptomatic flares. Surgical treatment is complicated, especially for through-and-through infection of bone. Management of dead space after resection of sequestrum is a primary issue in treatment and often requires multiple-stage procedures. Management by both orthopedic and plastic surgery may be required, and local or free flap repair is sometimes used to manage dead space. Adjunctive antibiotic treatment is indicated and should be guided by bone culture.

Avoiding Treatment Errors

In making therapeutic decisions for patients with osteomyelitis, the physician must carefully consider the patient's ability to tolerate ideal therapy. When osteomyelitis is

associated with adjacent decubitus ulcers, depending on the level of patient debility, it may be appropriate to treat associated sepsis with minor debridement and a short course of antibiotics but not seek to treat curatively. In patients with late prosthetic joint infections, often there is the temptation to treat with debridement but to retain the prosthesis. This approach may be appropriate in frail patients, but in general, retention of the prosthesis leads to chronic infection, even with aggressive parenteral antibiotic treatment. The treating physician should always realize the limitations of antibiotic therapy; in patients with osteomyelitis associated with a contiguous infection, an extended course of antibiotics is inappropriate if critical ischemia is not addressed or if necrotic, devitalized tissue is not debrided.

Future Directions

S. aureus is the single-most important bacterial pathogen causing osteomyelitis, and MRSA has steadily become more predominant. Clinical anecdotes have suggested a poor response to vancomycin in some cases. Rarely, treatment failure has been due to frank vancomycin resistance or to intermediate resistance related to increased cell wall thickness. Some have described “hetero-resistant” MRSA as a cause of vancomycin treatment failure, and others have suggested that dysfunction in the *S. aureus* accessory gene regulator (*agr*) may be associated with vancomycin treatment failure. At the moment, vancomycin continues to be

first-line treatment for significant disease due to MRSA; future research should focus on developing techniques to predict MRSA isolates that respond poorly to vancomycin and explore alternate antibiotic therapy for such infections.

Intravascular Catheter Infections

Introduction

The Centers for Disease Control and Prevention (CDC) estimates that health care–associated infections account for 2 million infections, 90,000 deaths, and \$4.5 billion in excess health care costs annually. Hospital-acquired bloodstream infections have been estimated at 250,000 infections per year with 26,250 associated deaths—the eighth leading cause of death in the United States. A prospective analysis of data from 49 hospitals evaluated 24,179 nosocomial bloodstream infections between 1995 and 2002 and found an incidence of 60 cases per 10,000 hospital admissions. About 51% of cases occurred in the intensive care unit. Intravascular devices were the most common predisposing factor; a central venous catheter (CVC) was in place in 72%, a peripheral intravenous catheter in 35%, and an arterial catheter in 16%.

This chapter addresses the prevention and management of intravascular catheter-related infections.

Types of Intravascular Catheters and Their Use

Intravascular catheters are widely used in medicine to provide fluid replacement, allow hemodynamic monitoring, and administer medication (Table 97-1). CVCs are intravascular catheters whose tip lies within a great vessel such as the vena cava (Fig. 97-1).

Intravascular Catheter-Related Complications

Complications associated with peripheral venous catheters include phlebitis, bleeding, infiltration, and infection. Of these, sterile phlebitis is the most common. Generally, removal of the catheter and warm soaks is sufficient to bring relief. Complications of CVCs differ depending on the type and location of the central catheter but include thrombosis, air embolism, catheter misplacement, vein laceration, and local and systemic infection. Pneumothorax and hemothorax are risks with subclavian and to a lesser extent with internal jugular placement. Subclavian artery puncture may occur with subclavian vein placement. Complications of pulmonary artery placement include cardiac arrhythmias and pulmonary infarction. Rarely, during

manipulation, a piece of a CVC may shear off, resulting in catheter embolization.

Etiology and Pathogenesis of Catheter-Related Infections

All intravascular catheters represent an infection risk because the skin must be breached during insertion and use. Catheter-related infections develop by several mechanisms (Fig. 97-2). Migration of skin organisms at the insertion site into the cutaneous catheter tract with colonization of the catheter tip is the most common route of infection for percutaneously inserted, short-term catheters. Contamination of the catheter hub with bacterial invasion through the lumen (i.e., colonization of the internal surface of the catheter) contributes substantially to colonization of CVCs. Occasionally, catheters might become hematogenously seeded from another focus of infection. Rarely, intrinsic (i.e., from the manufacturer) or extrinsic (i.e., during manipulation at the health care facility) contamination of the infusate leads to catheter-related bloodstream infection. Safdar and Maki assessed the mechanism of catheter-related bloodstream infections with noncuffed short-term CVCs and reported that 45% of infections were extraluminally acquired, 26% were intraluminally

Table 97-1 Types of Intravascular Devices and Comments on Their Use

Type of Intravascular Device	Comments
Peripheral venous catheter	Usually inserted into veins of the forearm or the hand; most commonly used short-term intravascular device; rarely associated with bloodstream infection
Peripheral arterial catheter	For short-term use; commonly used to monitor hemodynamic status and to determine blood gas levels of critically ill patients; risk for bloodstream infections may approach that of central venous catheters (CVCs)
Midline catheter	Peripheral catheter (size, 7.6-20.3 cm) is inserted via the antecubital fossa into the proximal basilic or cephalic veins, but it does not enter central veins; it is associated with lower rates of phlebitis and infections than are CVCs
Nontunneled CVC	Most commonly used CVC; accounts for an estimated 90% of all catheter-related bloodstream infection; increased risk for infection with internal jugular or femoral vein site of infection
Pressure-monitoring system	Used in conjunction with arterial catheter; associated with both epidemic and endemic nosocomial bloodstream infections; source is often fluid column in the tubing between the patient's intravascular catheter and the pressure-monitoring apparatus, contaminated infusate, or nondisposable transducers
Peripherally inserted CVC (PICC)	Provides an alternative to subclavian or jugular vein catheterization; is inserted via the peripheral vein into the superior vena cava, usually by way of the basilic or cephalic veins; is easier to maintain; and is associated with fewer mechanical complications (e.g., hemothorax) than are nontunneled CVCs. However, PICC-associated venous thrombosis is noted in about 2.5% of inserted lines
Pulmonary artery catheter	Inserted through a Teflon introducer (e.g., Cordis) and typically remains in place for an average duration of only 3 days; most catheters are heparin bonded to reduce catheter thrombosis and microbial adherence to the catheter
Tunneled CVC	Surgically implanted CVC (e.g., Hickman, Broviac, Groshong, or Quinton catheter) with the tunneled portion exiting the skin and a Dacron cuff just inside the exit site; the cuff inhibits migration of organisms into the catheter tract by stimulating growth of surrounding tissue, thus sealing the catheter tract; used to provide vascular access to patients who require prolonged intravenous chemotherapy, home-infusion therapy, or hemodialysis
Totally implantable catheter	A subcutaneous port or reservoir with self-sealing septum is tunneled beneath the skin and is accessed by a needle through intact skin; low rates of infection
Intra-aortic balloon pump (IABP)	An IABP is a catheter with a balloon position in the descending thoracic aorta that is used to provide temporary support of cardiac function
Phoresis catheter, Vas-Cath, PermCath	These are larger and sturdier catheters used for high flow blood withdrawals for apheresis or dialysis
Powercath	This is a central catheter that allows high flow rate and pressure for rapid injection of contrast media

acquired through the ports, and the mechanism of infection was indeterminate in 29%.

Biofilm formation on the surfaces of indwelling catheters is central to the pathogenesis of infection in indwelling catheters. The distinguishing feature of biofilms is the presence of extracellular polymeric substances, primarily polysaccharides, surrounding and encasing the microbes. Virtually all percutaneous CVCs are colonized by microorganisms embedded in a biofilm matrix. The organisms most commonly isolated from catheter biofilms are coagulase negative staphylococci, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Candida albicans*. Although biofilm formation on CVCs is universal, the extent and location of biofilm formation depend on duration of catheterization: short-term catheters (<10 days) have greater biofilm formation on the external surfaces; long-term catheters (30 days) have greater biofilm forma-

tion on the catheter inner surfaces. Pathogens contained within biofilms exhibit increased resistance to antimicrobial therapy.

Epidemiology and Microbiology of Catheter-Related Infections

The prevalence of bloodstream infections has been described in a prevalence study of 10,038 patients in 1447 European intensive care units; on the date of the study, 247 patients (2.5%) were being treated for a hospital-acquired bloodstream infection. Risk factors for infection included pulmonary artery catheters (odds ratio, 1.2) and CVCs (odds ratio, 1.35). The incidence of catheter-related bloodstream infections occurring in intensive care units is available from the Center for Disease Control and Prevention (CDC) National Nosocomial Infection Surveillance

Figure 97-1 Catheter Placement.

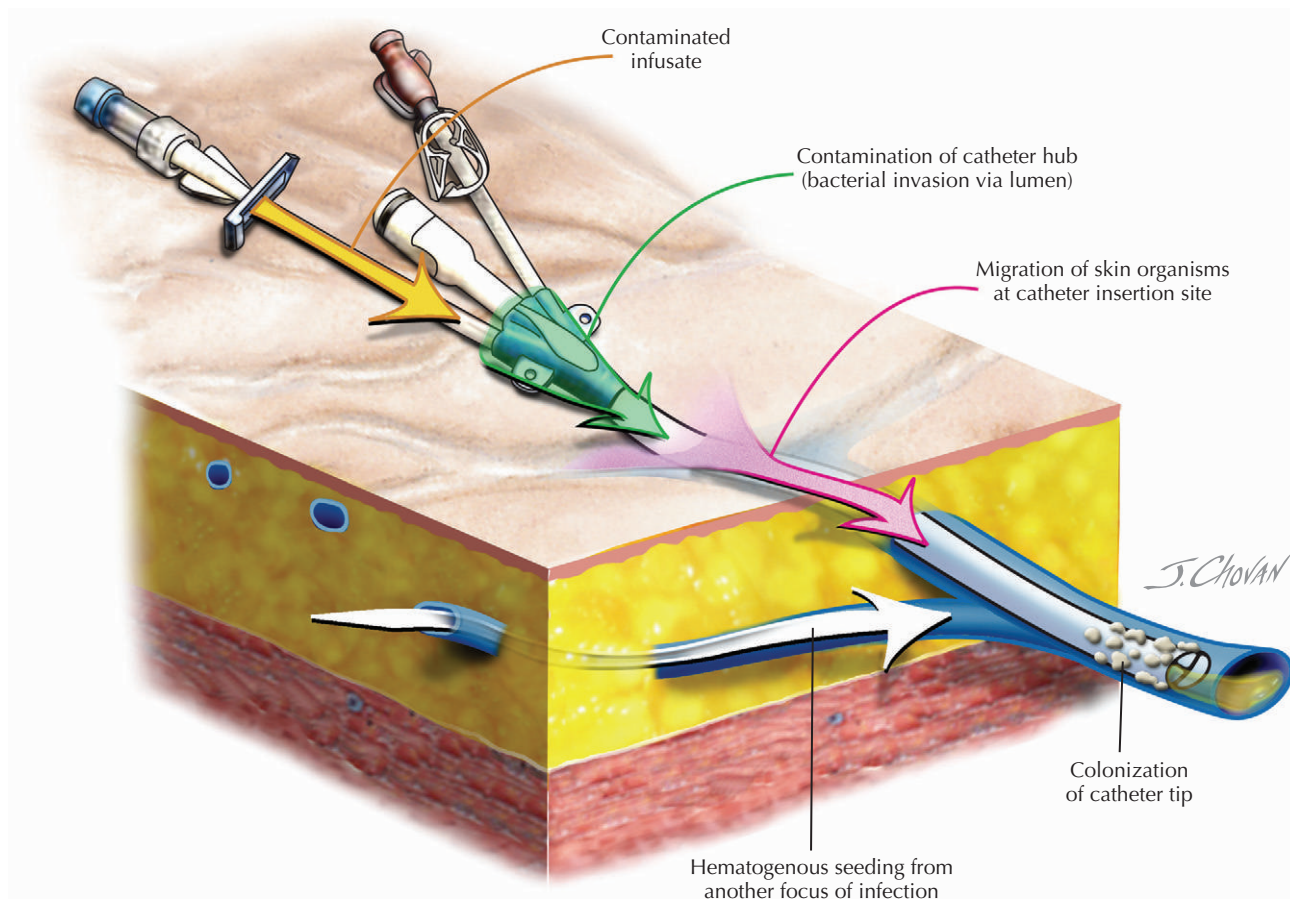

(NNIS). The incidence of infections (per 1000 catheter-days), June 2002 through June 2004, ranged from 2.7 to 7.4 depending on the type of intensive care unit. A meta-analysis has reported the rates of catheter-related bloodstream infections by type of catheter (Table 97-2).

The microbiology of CVC-related bloodstream infections has been reported. The most common pathogens are coagulase-negative staphylococci, *S. aureus*, *Enterococcus* species, enteric gram-negative bacilli (*Escherichia coli*, *K. pneumoniae*, *Enterobacter* species), *Pseudomonas aeruginosa*, and *Candida* species (Table 97-3).

The incidence of catheter-related bloodstream infections varies considerably by type of catheter, frequency of catheter manipulation, and patient-related factors (e.g., underlying disease and acuity of illness). Duration of catheterization is the most important risk factor. Risk factors

associated with a higher incidence of peripheral venous catheter-related infections are placement in lower extremity (lowest risk with placement into hand veins), failure to rotate the site every 72 to 96 hours, and use of steel needles. Risk factors associated with a higher incidence of CVC-related bloodstream infection include the following:

- Hospital characteristics
 - Teaching hospital versus nonteaching hospital
 - Larger hospitals
- Patient characteristics
 - Severity of underlying disease
 - Active infection at other site
 - Care in an intensive care unit
 - Immunosuppression (e.g., HIV, organ transplant)
 - Surgery patient

Figure 97-2 Pathogenesis of Infection.

- Features of insertion
 - Emergent placement
 - Location of insertion (femoral site > internal jugular site > subclavian site)
 - Multilumen catheters
 - Failure to use maximal barrier precautions (sterile drape that covers entire body; sterile gloves and gown, and mask for physician)
 - Nontunneled catheters
- Features of maintenance
 - Duration of catheterization
 - Colonization of catheter hub
 - Parenteral nutrition
 - Inappropriate catheter use

Prevention of Intravascular Catheter-Related Infections

Key measures to prevent intravascular catheter-related infections include strict adherence to aseptic insertion and maintenance, preparation of the insertion site with an antiseptic, and prompt removal when the catheter is no longer medically necessary. There is no evidence that prophylac-

tic antibiotics are successful in preventing catheter-related infections. Antiseptic and antibiotic impregnated CVCs have been demonstrated to reduce the incidence of catheter colonization and catheter-related bloodstream infections. Their use should be considered for prolonged catheterization. Implantable CVCs warrant consideration if central venous access is required for more than 30 days. Peripherally inserted central catheter (PICC) lines are useful for prolonged venous access when central venous access through the subclavian or internal jugular sites is not required. Based on currently available data, central venous or PICC catheters do not require changes at set intervals. Recommendations for the prevention of intravascular catheter-related infections have been published (Box 97-1).

Clinical Presentation

Catheter-related infections include both local and systemic infections. Exit-site infections, tunnel infections, and pocket infections constitute the local infection group. Erythema, induration, and tenderness within 2 cm of the catheter exit site are the usual manifestations of exit-site

Table 97-2 Risk for Catheter-Related Bloodstream Infections by Type of Catheter

	CR-BSI Pooled Mean (95% CI) per 100 Catheters	CR-BSI Pooled Mean (95% CI) per 1000 Catheter-Days
Peripheral venous catheters		
Plastic catheters	0.1 (0.1-0.2)	0.5 (0.2-0.7)
Steel needles	2.0 (0.0-4.3)	8.6 (0.0-18.2)
Venous cutdown	3.7 (0.0-10.8)	9.0 (0.0-26.6)
Midline catheters	0.4 (0.0-0.9)	0.2 (0.0-0.5)
Arterial catheters for hemodynamic monitoring	0.8 (0.6-1.1)	1.7 (1.2-2.3)
Peripherally inserted central catheters		
Inpatient and outpatient	3.1 (2.6-3.7)	1.1 (0.9-1.3)
Inpatient	2.4 (1.2-3.6)	2.1 (1.0-3.2)
Outpatient	3.5 (2.8-4.1)	1.0 (0.8-1.2)
Short-term noncuffed central venous catheters		
■ Nonmedicated		2.7 (2.6-2.9)
Nontunneled	4.4 (4.1-4.6)	1.7 (1.2-2.3)
Tunneled	4.7 (3.2-6.2)	1.6 (1.3-2.0)
■ Medicated		1.2 (0.3-2.1)
Chlorhexidine-silver-sulfadiazine	2.6 (2.1-3.2)	4.7 (1.5-8.0)
Minocycline-rifampin	1.0 (0.3-1.8)	3.3 (1.7-5.0)
Silver impregnated	5.2 (1.7-8.7)	4.8 (2.1-7.5)
Silver iontophoretic	4.0 (2.1-6.0)	3.7 (2.4-5.0)
Benzalkonium chloride	4.3 (1.9-6.7)	
Pulmonary artery catheters	1.5 (0.9-2.0)	
Hemodialysis catheters		
Temporary, noncuffed	8.0 (7.0-9.0)	4.8 (4.2-5.3)
Long-term, cuffed and tunneled	21.2 (19.7-22.8)	1.6 (1.5-1.7)
Cuffed and tunneled central venous catheters	22.5 (21.2-23.7)	1.6 (1.5-1.7)
Subcutaneous venous ports		
Central	3.6 (2.9-4.3)	0.1 (0.0-0.1)
Peripheral	4.0 (2.4-5.6)	0.1 (0.1-0.2)
Intra-aortic balloon pumps	3.0 (0.0-6.3)	7.3 (0.0-15.4)
Left ventricular assist devices	26.1 (19.2-33.0)	2.1 (1.5-2.7)

CI, confidence interval; CR-BSI, catheter-related bloodstream infection.

infections. Other associated signs and symptoms of infection include fever or pus emerging from the exit site. Tunnel infections are characterized by tenderness, erythema, and induration more than 2 cm from the catheter exit site, along the subcutaneous tract of a tunneled catheter (e.g., Hickman or Broviac catheter). Pocket infections are defined as infected exudate in the subcutaneous pocket of a totally implanted intravascular device. They are often associated with tenderness, erythema, and induration over the pocket. Spontaneous rupture and drainage, or necrosis of the overlying skin, may also occur. Local infections may be associated with concomitant bloodstream infection. Systemic signs are common and may be categorized as constitutional (fever, rigors, hypotension, shock), respiratory (hyperventilation, respiratory failure), gastrointestinal (abdominal pain, vomiting, diarrhea), and neurologic (confusion, seizures).

Clinical findings are unreliable for establishing a diagnosis of intravascular catheter-related infection, because of their poor sensitivity and specificity. Symptoms and signs suggestive of intravascular catheter-related sepsis include

Box 97-1 Selected Recommendations for Placement of Intravascular Catheters in Adults and Children**Hand Hygiene**

- A. Perform hand hygiene procedures by washing hands with conventional antiseptic-containing soap and water or with waterless alcohol-based gels or foams. Observe hand hygiene before and after palpating catheter insertion sites, as well as before and after inserting, replacing, accessing, repairing, or dressing an intravascular catheter. Palpation of the insertion site should not be performed after the application of antiseptic, unless aseptic technique is maintained (IA).

Aseptic Technique during Catheter Insertion and Care

- A. Maintain aseptic technique for the insertion and care of intravascular catheters (IA).
 B. Wear clean or sterile gloves when inserting an intravascular catheter as required by OSHA (IC). Wearing clean gloves rather than sterile gloves is acceptable for the insertion of peripheral intravascular catheters if the access site is not touched after the application of skin antiseptics. Sterile gloves should be worn for the insertion of arterial and central catheters (IA).
 C. Wear clean or sterile gloves when changing the dressing on intravascular catheters (IC).

Catheter Insertion

- A. Do not routinely use arterial or venous cutdown procedures as a method to insert catheters (IA).

Selection and Placement of Intravascular Catheters

- A. Select the catheter, insertion technique, and insertion site with the lowest risk for complications (infectious and noninfectious) for the anticipated type and duration of intravenous therapy (IA).
 B. Promptly remove any intravascular catheter that is no longer essential (IA).
 C. Do not routinely replace central venous or arterial catheters solely for the purpose of reducing the incidence of infection (IB).
 D. Replace peripheral venous catheters at least every 72 to 96 hours in adults to prevent phlebitis. Leave peripheral venous catheters in place in children until intravenous therapy is completed, unless complications (e.g., phlebitis and infiltration) occur (IB).
 E. When adherence to aseptic technique cannot be ensured (i.e., when catheters are inserted during a medical emergency), replace all catheters as soon as possible and after no longer than 48 hours (II).
 F. Use clinical judgment to determine when to replace a catheter that could be source of infection (e.g., do not routinely replace catheters in patients whose only indication is fever). Do not routinely replace venous catheters in patients who are bacteremic or fungemic if the source of infection is unlikely to be the catheter (II).

- G. Replace any short-term central venous catheter if purulence is observed at the insertion site, which indicates infection (IB).
 H. Replace all central venous catheters if the patient is hemodynamically unstable and a catheter-related bloodstream infection is suspected (II).
 I. Do not use guidewire techniques to replace catheters in patients suspected of having catheter-related infection (IB).

Prophylactic Antibiotics

- A. Do not administer intranasal or systemic antimicrobial prophylaxis routinely before insertion or during use of an intravascular catheter to prevent catheter-related colonization or bloodstream infection (IA).

Peripheral Venous Catheters**Selection of Peripheral Venous Catheters**

- A. Select catheters on the basis of the intended purpose and duration of use, known complications (e.g., phlebitis and infiltration), and experience of individual catheter operators (IB).
 B. Avoid the use of steel needles for the administration of fluids and medications that might cause tissue necrosis if extravasation occurs (IA).
 C. Use a midline or PICC when the duration of intravenous therapy will likely exceed 6 days (IB).

Selection of Peripheral Catheter Insertion Site

- A. In adults, use an upper instead of lower extremity site for catheter insertion (IA).
 B. In pediatric patients, the hand, the dorsum of the foot, or scalp can be used as the catheter insertion site (II).

Central Venous Catheters**General Principles**

- A. Use a central venous catheter with the minimum number of ports or lumens essential for the management of the patient (IB).
 B. Use totally implantable access devices for patients who require long-term, intermittent vascular access. For patients requiring frequent or continuous access, a PICC or tunneled central venous catheter is preferable (II).

Selection of Catheter Insertion Site

- A. Weigh the risks and benefits of placing a device at a recommended site to reduce infectious complications against the risk for mechanical complications (e.g., pneumothorax, subclavian artery puncture, subclavian vein thrombosis, hemothorax, thrombosis, air embolism, and catheter misplacement) (IA).
 B. Use a subclavian site (rather than a jugular or a femoral site) in adult patients to minimize infection risk for nontunneled central venous catheter placement (IA).

PICC, peripherally inserted central catheter.

IA. Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.

IB. Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies, and a strong theoretical rationale.

IC. Required by state or federal regulations, rules, or standards.

II. Suggested for implementation and supported by suggestive, clinical, or epidemiologic studies or a theoretical rationale.

Adapted from O'Grady NP, Alexander M, Dellinger EP, et al. Guidelines for the prevention of intravascular catheter-related infections. Centers for Disease Control and Prevention. *MMWR Recomm Rep* 51(RR-10):1-29, 2002.

the following: inflammation or purulence at the catheter insertion site; signs of sepsis without an identifiable local infection (e.g., pneumonia, skin or soft tissue infection, urinary tract infection); abrupt onset of shock; signs or symptoms of sepsis plus catheter malfunction; evidence of septic thrombophlebitis of the great veins associated with a CVC; bloodstream infection caused by staphylococci (especially coagulase-negative staphylococci) or *Corynebacterium*, *Candida*, or *Bacillus* species; high-grade bacteremia or candidemia (multiple positive blood cultures); and sepsis refractory to appropriate antimicrobial therapy.

Diagnostic Approach

All patients who develop a fever or other signs of infection and have a vascular catheter in place require evaluation for catheter-related infection. The area around the catheter exit site should be evaluated for erythema, tenderness, and purulence. Examination of the tunnel track is also important. Patients with suspected intravascular catheter-related infection should have at least two sets of blood samples drawn for culture, with at least one set drawn percutaneously. Catheter-related bloodstream infections are defined as bacteremia or fungemia in a patient who has an intravascular device in place and more than one positive blood culture obtained from a peripheral vein, clinical manifestations of infection (e.g., fever, chills, hypotension), and no apparent source for bloodstream infection other than the catheter. They may be detected by use of semiquantitative (≥ 15 colony forming units [cfu] per catheter segment) or quantitative ($\geq 10^2$ cfu per catheter segment) cultures of a subcutaneous segment of the catheter where the isolate from the catheter cultures and blood cultures is identical. Other diagnostic criteria include simultaneous quantitative cultures of blood obtained from the catheter and peripherally with a ratio of at least 5 : 1 (CVC versus peripheral) and a differential time to a positive blood culture (i.e., a positive result of culture from a CVC is obtained at least 2 hours earlier than is a positive result of culture from peripheral blood). In a meta-analysis that evaluated the accuracy of diagnostic tests for diagnosing intravascular catheter-related bloodstream infections, the most accurate test was paired (i.e., one culture drawn through the catheter and a second drawn from a peripheral vein) quantitative blood cultures followed by paired qualitative blood culture. The most accurate diagnostic method that requires removal of the catheter was the catheter segment culture test (segment from the removed catheter is immersed in broth media and incubated for 24 to 72 hours) followed by semiquantitative culture (5 cm segment of catheter is rolled 4 times across a blood agar plate and incubated). Although paired quantitative blood cultures were the most accurate test for diagnosis of catheter-related bloodstream infection, other methods studied showed acceptable sensitivity and specificity (both >0.75) and negative predictive value ($>99\%$). Importantly, catheters should not be removed and

cultured routinely but rather only if catheter-related bloodstream infection is suspected clinically.

Management and Therapy

Optimum Treatment

The choice of initial antibiotic therapy will depend on the severity of the patient's disease, the risk factors for infection, and the likely pathogens associated with the specific intravascular device. In general, therapy will consist of an antibiotic active against staphylococci, especially methicillin-resistant strains, such as vancomycin or daptomycin, and an antibiotic active against gram-negative bacilli, especially *P. aeruginosa*, such as ceftazidime, cefepime, piperacillin-tazobactam, or a carbapenem (i.e., imipenem or meropenem). Initial antimicrobial therapy should be administered intravenously and should be adjusted once culture data are available. The duration of therapy ranges from 10 to 14 days to 4 to 6 weeks and depends on the patient's underlying diseases (e.g., immunosuppression), promptness of response to therapy, and presence of complicated infections (e.g., septic thrombosis, endocarditis, osteomyelitis, or other metastatic seeding). Algorithms are available to aid in the diagnosis and management. Indications for catheter-removal include the following:

- Tunnel or pocket site infection
- Infection with multiple bacteria, *S. aureus* or *Candida*, *Bacillus*, *Corynebacterium* species
- Unexplained sepsis
- Septic thrombophlebitis
- Endocarditis
- Refractory or progressive exit site infection
- Continued bacteremia (i.e., blood cultures remain positive for more than 3 days)

Avoiding Treatment Errors

The determination of the specific pathogen is critical. Patients with suspected intravenous catheter-related infections should have two sets of blood samples drawn for culture, with at least one set drawn percutaneously. For indwelling catheters, patients with evidence of a tunnel infection should have the exudates sent for culture and Gram stain. Antibiotic susceptibility testing of isolated pathogens is especially critical. The Infectious Diseases Society of America (IDSA) Guideline for the Management of Intravascular Catheter-Related Infections provides pathogen-based recommendations for correct antimicrobial therapy.

Patients who have a complicated bloodstream infection (i.e., septic thrombosis, endocarditis, osteomyelitis) with a removable CVC should have the CVC removed and be treated with systemic antibiotics for 4 to 6 weeks (6 to 8 weeks for osteomyelitis). Failure to remove the catheter or to treat for the proper duration is often associated with ongoing sepsis, development of metastatic infection, and

serious morbidity or death. Catheter removal is also required for infections due to *S. aureus*, gram-negative bacilli, and *Candida* species.

Patients with a complicated infection (tunnel infection, port abscess, septic thrombosis, endocarditis, osteomyelitis) who have a tunneled CVC or implantable device-related bacteremia require removal of the catheter or device. In general, as with removal of tunneled CVCs, removal of nontunneled catheters is recommended with infections due to *S. aureus*, gram-negative bacilli, or *Candida* species. However, salvage therapy may be attempted for infections due to *S. aureus* or gram-negative bacilli using systemic antibiotics and antibiotic lock therapy for 14 days. The CVC or intravascular device should be removed if there is clinical deterioration, persisting or relapsing bacteremia, or no response to therapy.

As with all patients on antibiotic therapy, appropriate laboratory tests should be routinely performed to assess for adverse events. These minimally include a complete blood count and platelet count every week and weekly assessment of renal function.

Future Directions

The development of a culture of safety, ongoing surveillance by trained infection control personnel, a supportive education program, and adoption of a five-component intervention have recently been shown by Pronovost and colleagues to lead to a 66% reduction in CVC-related infections in the intensive care unit. The five components of intervention include appropriate hand hygiene, use of chlorhexidine for skin preparation, use of full-barrier precautions during insertion of CVCs, use of the subclavian vein as preferred site for insertion of the catheter, and removal of unnecessary CVCs. Widespread adoption of this intervention could potentially save more than 10,000 lives per year in the United States.

In addition to implementing current CDC recommendations, development of catheters with new materials that inhibit biofilm formation and bacterial adhesion could likely lead to reduced rates of catheter-related infections.

Influenza

Introduction

Influenza is an acute respiratory illness characterized by fever, cough, myalgias, and malaise due to influenza type A or B virus that occurs in epidemics each winter. Influenza's public health importance is largely due to the magnitude of its annual global epidemics and associated morbidity and mortality. Recently, infection with the avian influenza H5N1 virus strain has become endemic among birds in Eurasia; sporadic transmission to humans has generated concern that efficient person-to-person transmission could emerge and become a major public health threat.

Etiology and Pathogenesis

Influenza viruses are ribonucleic acid viruses classified as type A, B, or C on the basis of antigenic differences. All belong to the family Orthomyxoviridae. Influenza C causes only mild illness and does not occur in epidemics, so its public health importance is substantially less than that of types A and B. Influenza A viruses are further subtyped based on two structural proteins: hemagglutinin and neuraminidase. Hemagglutinin binds the virus to cell receptors; neuraminidase promotes release of virus from infected cells following replication as well as spread of virus in the respiratory tract (Fig. 98-1). At least 9 neuraminidases and 15 hemagglutinins have been identified in influenza A viruses. Currently, circulating influenza A viruses include H1N1 and H3N2 strains. Antibodies to these antigens are important determinants of the immune response to influenza virus. The ability of influenza A to cause epidemics is largely due to the propensity of its hemagglutinin and neuraminidase antigens to undergo major antigenic variation, known as *antigenic shifts*, and minor variations, known as *antigenic drifts*. Influenza B only undergoes antigenic drift. As a result of these periodic antigenic variations in circulating influenza virus strains, a large proportion of the population lacks immunity and is left vulnerable to infection.

Transmission occurs predominantly through droplet transmission produced by coughs and sneezes and by other mechanisms, such as hand-to-hand contact. Human influenza A H5N1 transmission has resulted from close contact with infected birds; its transmission from human to human

has been rare. Influenza virus infects the respiratory epithelium, where it replicates within infected cells, causes degenerative changes and cell death, and is then released to infect other cells. Illness severity appears to be related to the amount of viral replication and host defenses. Extrapulmonary viral infection is uncommon. The host immune response is complex and involves an array of defenses, including cell-mediated immunity, local and systemic antibody, and interferon production. Constitutional symptoms, such as myalgias, fever, and headache, may be due to cytokine production because viremia is rare. The increased clinical severity of human influenza H5N1 infection may be partly due to its unusually high levels of serum cytokine induction with resultant increased stimulation of proinflammatory responses.

Clinical Presentation

The illness usually begins abruptly after an incubation period of 24 to 72 hours. Fever, chills, headache, malaise, and myalgias are the predominant symptoms. Respiratory symptoms, such as cough, clear nasal discharge, and sore throat, are typically present but less prominent than the systemic manifestations. The presentation varies widely, from the classic presentation described previously to minimal or no symptoms. Elderly patients may present with only fever, confusion, and weakness. Typically, the physical examination is notable for a toxic-appearing patient with pharyngeal erythema but no exudate and tender cervical lymphadenopathy. Fever and systemic

Figure 98-1 Influenza Virus and Its Epidemiology.

From Kilbourne ED: *The molecular epidemiology of influenza. J Infect Dis* 127:478-487, 1973.

symptoms usually last about 3 days, but convalescence is often marked by malaise and weakness. Complete recovery may require several weeks.

A variety of respiratory tract conditions can complicate influenza, such as tracheobronchitis, croup, and exacerbation of chronic pulmonary disease. Primary influenza viral pneumonia is associated with fever, cough, dyspnea, and respiratory compromise with minimal evidence of bacteria on sputum Gram stain (Fig. 98-2). Sputum culture specimens show growth of only normal oral flora. A common complication, secondary bacterial pneumonia, is usually due to *Streptococcus pneumoniae*, *Haemophilus influenzae*, or less commonly *Staphylococcus aureus*, and is usually seen among elderly patients and those with chronic lung, heart, or renal disease or diabetes mellitus. It tends to occur about 7 days after onset of influenza, usually after the patient appears to be recovering. Recently, community-associated methicillin-resistant *S. aureus* (CA-MRSA) has been reported to follow influenza. Such infections have been characterized by high fever, hemoptysis, shock, multiple pulmonary cavities, and empyema.

Nonpulmonary complications are relatively uncommon but include myositis, myocarditis, pericarditis, Guillain-Barré syndrome, encephalopathy, and toxic shock syndrome from secondary staphylococcal or streptococcal infection. Reye's syndrome is now a rare complication of influenza because of recognition of aspirin as a risk factor in children and recommendations to avoid aspirin use in children with influenza.

The H5N1 strain has caused particularly severe clinical disease with high mortality rates. Common features include fever, pneumonia and respiratory symptoms, and gastrointestinal symptoms. Laboratory studies have revealed pancytopenia and increased serum aminotransferase levels.

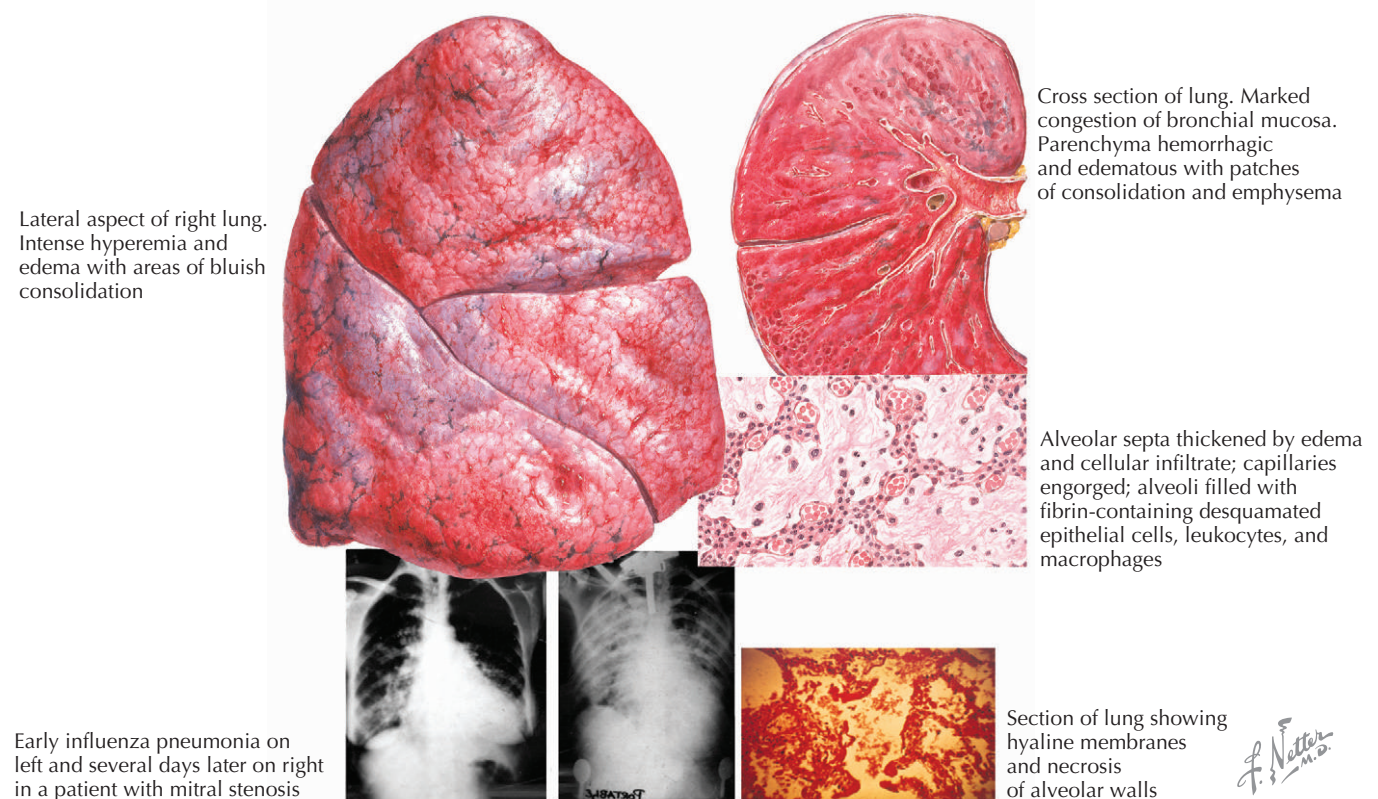

Differential Diagnosis

Because a variety of infectious diseases are associated with abrupt onset of fever, headache, malaise, and myalgias, the differential diagnosis is generally based on epidemiologic evidence of an illness characteristic of influenza occurring during a confirmed outbreak. The differential diagnosis includes adenoviruses, respiratory syncytial virus, parainfluenza, *Mycoplasma pneumoniae*, *Legionella* species, and *Chlamydia psittaci*.

The diagnosis of avian H5N1 virus infection should be considered for patients with pneumonia or severe respiratory distress syndrome whose cause has not been determined if they have traveled to a country with H5N1 infection in poultry or humans within 10 days of the onset of symptoms. The differential diagnosis of avian influenza includes the pathogens listed earlier and potentially may include severe acute respiratory syndrome.

Diagnostic Approach

The most useful laboratory techniques for diagnosis of infection due to human influenza virus in the setting of acute illness involve either virus isolation or detection of viral antigen in respiratory secretions. Nasal swabs or washes, throat swabs, or sputum samples provide acceptable specimens. Virus can be detected in culture within 3 to 7 days by cytopathic effect or hemadsorption. The time for diagnosis can be decreased to 1 or 2 days by centrifuging specimens onto cells in shell vials and using either immunofluorescence or enzyme-linked immunosorbent assay to detect antigen. Some assays yield results within a few hours with comparable sensitivity and specificity to culture results. In contrast, the diagnosis of avian influenza

Figure 98-2 Influenza Pneumonia.

H5N1 can be made by viral culture or polymerase chain reaction assay for influenza H5N1. When this diagnosis is suspected, clinicians should alert laboratory personnel so that appropriate biosafety measures can be used to process specimens.

Serologic testing of acute and convalescent sera by complement fixation or hemagglutination assays is sensitive and specific but is not useful in treating acute illness.

Management and Therapy

Uncomplicated cases of influenza usually require only supportive care and therapy for relief of symptoms. Appropriate recommendations include rest, maintenance of adequate hydration, and if needed, use of acetaminophen for relief of fever and headache. Children should not receive aspirin because of its association with Reye's syndrome.

Optimum Therapy

Antiviral therapy is available for treatment of influenza. The neuraminidase inhibitors, zanamivir and oseltamivir, have activity against both influenza A and B. Amantadine and rimantadine are active against influenza A. Because of the marked increase in resistance to amantadine and rima-

tadine among influenza A isolates obtained during the 2005-2006 influenza season in the United States, the Centers for Disease Control and Prevention has recommended that these drugs not be used for treatment of influenza in the United States; oseltamivir or zanamivir is recommended instead. Oseltamivir is recommended for treatment of influenza H5N1 because isolates from Southeast Asia had amino acid substitutions that rendered them resistant to amantadine and rimantadine.

When given to otherwise healthy adults within 2 days of the start of illness, zanamivir and oseltamivir can decrease the duration of uncomplicated influenza A or B by about 24 hours. Zanamivir is given as an inhaled powder at doses of 10 mg twice daily for 5 days. Because zanamivir inhalation can exacerbate bronchospasm among patients with asthma or chronic obstructive pulmonary disease, it is not recommended for persons with underlying airway disease. Oseltamivir is given in doses of 75 mg orally twice daily for 5 days. Its most common adverse effects are nausea and vomiting, which may be reduced by taking the drug with food. Evidence now suggests that treatment of viral influenza may decrease the risk for hospitalization and secondary bacterial pneumonia; thus, oseltamivir administration should be considered for influenza patients with underlying diseases.

Avoiding Treatment Errors

Failure to consider the diagnosis of influenza is probably the most common treatment error. Given the very limited number of treatment options and the need to begin therapy early in the disease course, the importance of considering influenza as the underlying pathogen in patients presenting with toxic upper respiratory illness cannot be over-emphasized. The presence of other documented cases of influenza in the community often helps the clinician to make the correct diagnosis. To be effective, therapy must be initiated within 2 days of the start of illness.

Prevention

The primary method for preventing influenza is annual administration of influenza vaccine. Influenza vaccine is prepared from influenza A and B strains isolated during the previous influenza season and therefore likely to circulate in the United States in the upcoming winter. Immunization is recommended for people at high risk for complications from influenza infection, including children aged 6 to 59 months; persons older than 50 years; and those of any age who have chronic diseases of the heart, lung, or kidneys; diabetes mellitus; immunosuppression; or hemoglobinopathies. Also recommended for vaccination are residents of nursing homes and other facilities that house persons with chronic medical conditions; children and teenagers who receive chronic aspirin therapy and might therefore be at risk for Reye's syndrome; and women who will be pregnant during influenza season. Vaccination of health care workers and household members of persons in high-risk groups is also strongly recommended to decrease risk for influenza transmission. People known to have anaphylactic hypersensitivity to eggs or other vaccine components should not receive influenza vaccine. The optimal time for vaccine administration in the United States is from the beginning of October through mid-November.

Influenza vaccine efficacy depends on the vaccine recipient's age and immunocompetence as well as the degree of similarity between the vaccine virus strains and strains in circulation during influenza season. When vaccine and circulating virus strains are well matched, efficacy in healthy adults younger than 65 years is 70% to 90%. Although the vaccine is less effective among elderly persons living in nursing homes (30% to 40%), its efficacy is about 50% to 60% in preventing pneumonia and 80% in preventing death.

Two influenza vaccine preparations are licensed in the United States: an injectable inactivated vaccine and a live-attenuated vaccine that is administered intranasally. The intranasal live-attenuated vaccine is licensed for use in healthy individuals between the ages of 5 and 49 years but not for immunocompromised patients, pregnant women, persons with a history of Guillain-Barré syndrome, or

those with chronic metabolic, renal, pulmonary, or cardiovascular diseases.

Although the primary method of influenza prevention is vaccination, antiviral agents are important adjuncts. Oseltamivir (75 mg once daily for persons >13 years of age) can be used for chemoprophylaxis of influenza. However, chemoprophylaxis is not a substitute for vaccination. During influenza outbreaks, clinicians should consider antiviral prophylaxis for several target populations: (1) people at high risk for complications of influenza who receive the vaccine after the onset of an influenza outbreak in their community; (2) unvaccinated health care workers, or health care workers, regardless of vaccine status, in an outbreak that is due to a strain that might not be controlled by the vaccine; (3) people who have immune deficiencies; and (4) people at high risk for influenza complications who should not be vaccinated and others who wish to avoid influenza illness. Prophylaxis should be provided for 6 weeks because this would cover the duration of most seasonal influenza outbreaks. When determining the timing and duration for administering influenza antiviral medications for chemoprophylaxis, factors related to cost, compliance, and potential side effects should be considered.

Future Directions

Influenza remains one of the most common and important infectious diseases. Recent threats of potentially more virulent strains in Asia have galvanized efforts to develop effective vaccine and treatment strategies. New therapies directed against influenza are expected to play an important role in both endemic and epidemic situations.

In this randomized, double-blind placebo-controlled trial, oseltamivir treatment reduced the duration of fever, and oseltamivir recipients were able to return to their usual activities 2 to 3 days earlier than those who received placebo.

Infectious Mononucleosis

Introduction

Infectious mononucleosis (IM) is the typical clinical presentation of primary Epstein-Barr virus (EBV), defined by the clinical triad of fever, pharyngitis, and cervical lymphadenopathy, in conjunction with increased circulating atypical lymphocytes. About 95% of all adult populations worldwide will have experienced prior EBV infection. Transmission normally occurs through saliva, and EBV has been called “the kissing disease,” although transmission probably can also occur sexually. Initial infection occurs more commonly during childhood in the developing world and in persons of low socioeconomic status, with more than 80% of such children being seropositive by age 4 years, a much higher rate than in the United States and United Kingdom, where the rate of seropositivity at age 5 years is only 50%. The incidence of primary infection peaks during adolescence and young adulthood in developed countries. Infections in childhood often do not present to medical providers, being subclinical or asymptomatic events, whereas the rare persons who experience primary infection beyond their 30s are more likely to present atypically, but with substantial morbidity. Diagnostic testing is key in distinguishing EBV infection, which is usually a self-limited disease, from other more serious illnesses that may present in a similar manner.

Etiology and Pathogenesis

EBV is a human gamma herpesvirus, which normally is restricted to infecting the pharynx and B cells. Primary EBV infection occurs when an uninfected subject is exposed to EBV virions, usually transmitted in saliva from a persistently infected host to the oropharynx of the susceptible person. Sexual transmission of EBV does also occur, but is less frequent. Viral infection occurs first at the mucosal layer, and quickly infects the circulating B cells present locally. EBV within epithelial and B cells can follow a virally encoded program of lytic replication, producing many lytic viral proteins that are both highly immunogenic and required for generating free virions. Acute infection is followed by viremia and circulating infected B cells. A subset of infected B cells adopt an alternative viral life cycle called *latent replication*, characterized by expression of latent (less immunogenic) viral genes that promote persistence of the host cell, replication of latent virus during mitosis of the host cell, and evasion of immune surveillance. Soon after primary infection, a vigorous cellular-mediated immune response is generated, and the subsequent diffuse immune response occurs. Many of the clinical man-

ifestations of EBV infection occur as a result of immune mechanisms, targeting infected circulating B cells. Large numbers of activated CD8+ T cells are produced, which over several weeks eradicate lytically infected cells. The atypical lymphocytes seen on peripheral blood smears are actually these CD8+ cytotoxic T cells. As seen with many other viral infections, symptoms, physical findings, and laboratory abnormalities (such as elevated liver function tests) arise during the CD8+ T-cell response and resolve as the infection is controlled. Thus, by the time patients show symptoms, they have already generated an initial humoral and cellular response. This pattern of illness is helpful in diagnosis of EBV infection, as discussed later. It is important to note that the latent reservoir is never eradicated. Periodically, the lytic viral genes are reactivated at mucosal surfaces to allow shedding of new virions that may infect a new host. Reactivation is asymptomatic. A great deal has been published regarding the role of latent EBV in a variety of malignancies, including African and spontaneous Burkitt's lymphoma, B-cell lymphomas in patients with compromised T-cell immunity, and nasopharyngeal carcinoma. In contrast, acute EBV infection is rarely associated with the development of cancer (discussed later).

Figure 99-1 Infectious Mononucleosis.

Clinical Presentation

Most often, primary EBV infection is asymptomatic or subclinical, but among cases that present to the clinician, the triad of fever, pharyngitis, and cervical lymphadenopathy is typical. These classic findings, coupled with reactive atypical lymphocytes and an absolute lymphocytosis, define IM syndrome (Fig. 99-1). Primary EBV infection in adolescents and young adults predominantly manifests this way, usually with malaise, and often with inflammation of

vascular reticuloendothelial organs producing mild hepatitis (with abdominal pain, nausea, vomiting, or elevated transaminases) and splenomegaly. Symptoms and laboratory abnormalities usually resolve spontaneously within 4 to 6 weeks of onset, although evidence of EBV infection may last for several months. Significant rashes and other skin findings are not associated with EBV infection alone. However, treatment with antibiotics during acute EBV infection often results in a diffuse maculopapular rash. β -Lactam antibiotics, especially ampicillin and amoxicillin,

are strongly associated with the development of such a rash, but dermatologic reactions have been described with many other antibiotics, including cephalosporins and fluoroquinolones.

Atypical clinical manifestations can occur at any age and involve almost any organ system; cholestatic hepatitis and splenic rupture (following trauma) are among the more severe manifestations seen in clinical practice. Rarely, other complications can occur. These include meningitis or encephalitis, transverse myelitis, Guillain-Barré syndrome, myocarditis, hemophagocytic syndrome, hemolytic anemia, thrombocytopenia, and aplastic anemia (Box 99-1). In middle-aged or older patients, the typical features of fever, pharyngitis, or lymphadenopathy are often absent, whereas more severe complications are more common. Infection generally does not occur in infants until after 8 months of age, perhaps because of protective maternal antibodies. Infection in infants and young children may have a milder presentation, although any of the above syndromes may occur. In addition, severe peritonsillar edema can occur in young children and infrequently results in airway obstruction. Although malignancy is not associated with acute infection in normal hosts, those rare individuals with familial X-linked lymphoproliferative syndrome do not have an effective immune response to EBV and usually succumb to either fulminant IM or develop acute B-cell lymphoma. In extremely rare cases, a chronic active EBV (CAEBV) infection occurs, associated

with chronic IM, multiple organ system disease, progressive illness, and high mortality. CAEBV has been more commonly reported in Japanese populations for unknown reasons. There is a popular misconception that chronic fatigue syndrome (CFS) is related to prior EBV infection, but there is no evidence to support this contention, and CFS is clearly distinguished from CAEBV by fever and objective evidence of organ involvement seen in the latter.

Differential Diagnosis

Many disseminated infections in their acute phase, especially viruses, can produce a clinical syndrome that overlaps with IM. Still, EBV is the most common cause of IM-like syndromes. Cytomegalovirus (CMV), human herpesvirus-6 (HHV-6) and HHV-7 are similar clinically, although in immunocompetent subjects, most atypical sequelae with HHV-6 and HHV-7 are rarely described. HHV-6 causes roseola and is commonly associated with febrile seizures in children. HIV can closely mimic acute EBV infection, sometimes presenting with fever, pharyngitis, lymphadenopathy, or reactive lymphocytes (although often the absolute lymphocyte count may be depressed transiently). Acute HIV may also occasionally produce a mild exanthem, aseptic meningitis, or mild hepatitis. In susceptible or unvaccinated, immunosuppressed women of childbearing age, HIV, CMV, measles, mumps, rubella, and toxoplasmosis should be considered in particular because of the potential ramifications regarding fetal infection and development. In some patients, measles may cause atypical lymphocytes with fever and lymphadenopathy, but frequently a cough is present, and the enanthem (Koplik's spots) and extensive exanthem toward the end of symptoms can be helpful in distinguishing measles from other infections. Similarly, mumps may produce atypical lymphocytes but can be differentiated by parotitis or orchitis. Parvovirus produces slapped-cheek erythema in children and may cause small-joint arthralgias or arthritis in adults. Adenoviral infection can produce upper respiratory infection with atypical lymphocytes. Rubella has few pathognomonic associations in childhood or adult disease. Acute toxoplasmosis may be clinically indistinguishable from EBV infection. When a history of cat exposure can be elicited, acute toxoplasmosis should be strongly considered. Of the hepatitis viruses, transaminase levels in the thousands of units per liter generally distinguish hepatitis A and hepatitis B from acute EBV infection. In hepatitis C, transaminase elevation is often less than 10-fold normal values, similar to EBV. Serologic evaluation can help distinguish the two. In children, Kawasaki's disease must be considered in the differential diagnosis of patients presenting with an IM-like syndrome. Group A streptococcal pharyngitis may also acutely masquerade as IM. In a patient with persistent or progressive fever or lymphadenopathy, exclusion of various malignancies or rheumatologic disease may be indicated.

Finally, some drugs, including dapsone and phenytoin, have been associated not only with fever and elevated liver function tests but also with reactive atypical lymphocytes.

Diagnostic Approach

With EBV being almost universally experienced in children and adolescents, it frequently is diagnosed (non-definitively) from clinical presentation and reactive lymphocytosis alone. Because the differential diagnosis is largely made up of self-limited diseases, this is reasonable in mild cases. A streptococcal test (rapid streptococcal antigen or culture) is usually indicated because treatment of streptococcal pharyngitis is important, but avoidance of amoxicillin with a negative test may spare the patient an EBV-related β -lactam rash. One of the more important viral illnesses to rule out is acute HIV infection, which may present with nonspecific findings. Correct identification of cases is critical to the individual patient and for public health reasons. The clinician needs to maintain a low threshold for initial baseline HIV serology (which may be negative for weeks following acute HIV infection) and follow-up testing. If a patient is deemed at high risk for HIV (recent unprotected sex or unsafe needle use), HIV viral load testing may occasionally be appropriate. As suggested in the prior section, women of childbearing age should have a vaccine and exposure history taken, with possible further testing done.

In atypical or more severe cases of IM, such as evaluation of a fever of unknown origin, a specific identification of acute EBV infection (in addition to HIV exclusion) may be useful in limiting the evaluation. Several blood or serum assays are available.

Heterophile Antibodies (Monospot)

The production of heterophile antibodies is an incompletely understood epiphenomenon of EBV infection of B cells in the acute phase. Polyclonal, nonspecific, nonadaptive antibodies are generated, and these often include antibody species capable of agglutinating erythrocytes of horses and sheep. This phenomenon is common in adolescents with acute EBV infection, with a sensitivity of 90%. However, the specificity and sensitivity are significantly decreased in both children and adults older than 35 years. Thus, the monospot is not an effective means for EBV screening of these populations.

Specific Epstein-Barr Virus Serology

Serologic testing is highly sensitive and specific and is the gold standard for evaluating EBV exposure. There are two immunogenic lytic viral proteins (viral capsid antigen [VCA] and early antigen-D [EA-D]) and one latent viral protein of low immunogenicity (Epstein-Barr nuclear antigen-1 [EBNA-1]) that are routinely assayed in com-

Table 99-1 Interpretation of Epstein-Barr Virus-Specific Serology

Serology	No Prior EBV Infection	Acute IM	Past Infection
VCA IgM	–	+	–
VCA IgG	–	+/-	+
EBNA-1 IgG	–	–	+

EBNA-1, Epstein-Barr nuclear antigen-1; Ig, immunoglobulin; VCA, viral capsid antigen.

mercially available kits. By the time a patient is symptomatic, immunoglobulin M (IgM) to VCA is almost always present, whereas the IgG response develops within the first few weeks and will persist for the life of the subject. EA-D antibodies appear quickly but do not add much to the evaluation. The IgG response to EBNA-1 usually takes several weeks to months to develop, but then is maintained for life, marking persistent infection. Thus, serum taken during the acute phase of an illness can be used to rule out EBV infection, to diagnose early initial infection, or to diagnose prior infection (Table 99-1). Most adults have serologic evidence of prior infection (EBNA-1 IgG antibodies); this is in no way suggestive of CAEBV (described earlier). Because persistent infection and viral reactivation are asymptomatic, disease in a patient with EBNA-1 IgG antibodies is virtually never explained by EBV IM and may require further evaluation.

Epstein-Barr Virus Quantitative Polymerase Chain Reaction (Viral Load)

Quantitative polymerase chain reaction techniques have been evaluated in a variety of EBV-related conditions. Persons who have not been exposed to EBV will have undetectable viral loads. Immunocompetent persons with resolved previous infection will similarly have very low to undetectable levels of EBV DNA circulating in the blood. A markedly elevated level is consistent with acute EBV IM, although the assays commonly available will not distinguish acute infection from other EBV-associated conditions, malignancies in particular. The test is relatively expensive and, thus, appropriate for the investigation of IM only in complicated or difficult to discern circumstances.

Management and Therapy

Patients should be counseled to avoid contact sports or similar activities with risk for trauma because splenic rupture has been frequently reported and is one of the few causes of mortality associated with EBV. Rarely, small children with significant oropharyngeal obstruction may require emergent intubation for protection of the airway. Otherwise, because acute IM is generally self-limited, supportive care is sufficient.

Optimum Treatment

Medical therapy for acute EBV infection has been disappointing. Although acyclovir, a generally well-tolerated antiviral that is active against lytic EBV, is capable of suppressing oropharyngeal shedding of EBV, it is not indicated for treatment of acute EBV infection except under exceptional circumstances. This is based on a number of small randomized studies that have failed to show efficacy. Similarly, because many of the atypical EBV-associated syndromes are thought to result from the exuberant CD8+ T-cell response, treatment with high-dose steroids has been advocated but not proved useful. It is important to note that the studies reported to date have been small and were not powered to detect subtle effects. Additionally, randomized trials have not focused on patients with more severe or atypical disease. Thus, for patients with uncomplicated IM, no specific intervention is indicated. For patients with severe or life-threatening complications, low toxicity regimens such as acyclovir with or without steroids are reasonable to consider.

Avoiding Treatment Errors

Treatment with β -lactam antibiotics should be avoided in IM.

Future Directions

Various novel medical agents have been explored in pre-clinical investigations for treatment of IM, but because symptoms normally resolve without intervention, prospective, appropriately powered, randomized trials are needed to document both efficacy and lack of significant toxicity. Interventions to target atypical EBV disease, with its higher morbidity, are still needed as well. Because of the scarcity of such severe cases, no such trials are currently underway. A vaccine against EBV is an attractive approach, whether for vaccination of only high-risk individuals or larger groups, and such an approach is currently being tested in clinical trials.

Herpes Simplex Virus Infections

Introduction

Genital and oral infections due to herpes simplex virus (HSV) are endemic in the United States. Genital herpes infection is caused by HSV-2 and less frequently by HSV-1. Genital HSV infection causes vesicular and ulcerative disease in adults and severe systemic disease in neonates and immunocompromised individuals.

HSV-2 transmission is almost always sexual, whereas HSV-1 is usually transmitted through nonsexual human contact. The incidence of new HSV-2 infections is estimated at greater than 1.5 million cases annually. HSV-2 seroprevalence, which is extremely rare before 12 years of age, rises sharply with the onset of sexual activity and peaks by the early 40s. The seroprevalence of HSV-2 infection rose 30% between 1978 and 1991 to 21.7%. The national seroprevalence estimates in 1999 to 2004 decreased to 17%. The decrease was primarily seen in persons 14 to 18 years of age. Most individuals with genital HSV infection have undiagnosed initial infections and unrecognized recurrent outbreaks. Orolabial HSV-2 infection is rare and is almost always associated with genital infection.

HSV-1 infection frequently occurs in childhood, with seropositivity in about 20% of children younger than 5 years. The seroprevalence of HSV-1 rises almost linearly with increasing age to about 50%. HSV-1 is increasingly common, with an estimated 50% of incident genital infection attributable to it.

Etiology and Pathogenesis

Primary HSV infection occurs at the mucosal site of inoculation with retrograde infection of sensory nerve ganglia. Following resolution of primary infection, HSV enters a latent state in the sensory nerve ganglia and can reactivate to cause active infection at any mucosal site innervated by the infected ganglia.

During primary HSV infection, natural killer (NK) cells are important effectors of immunity. NK-cell activation depends on the production of several cytokines that have direct and indirect effects important in limiting viral replication. As the immune response matures, clearance of HSV from infected tissues is T-cell mediated and involves cytokine-mediated effector mechanisms and direct cytolysis of virus-infected cells. Both CD4+ and CD8+ T cells are important in resolution of infection.

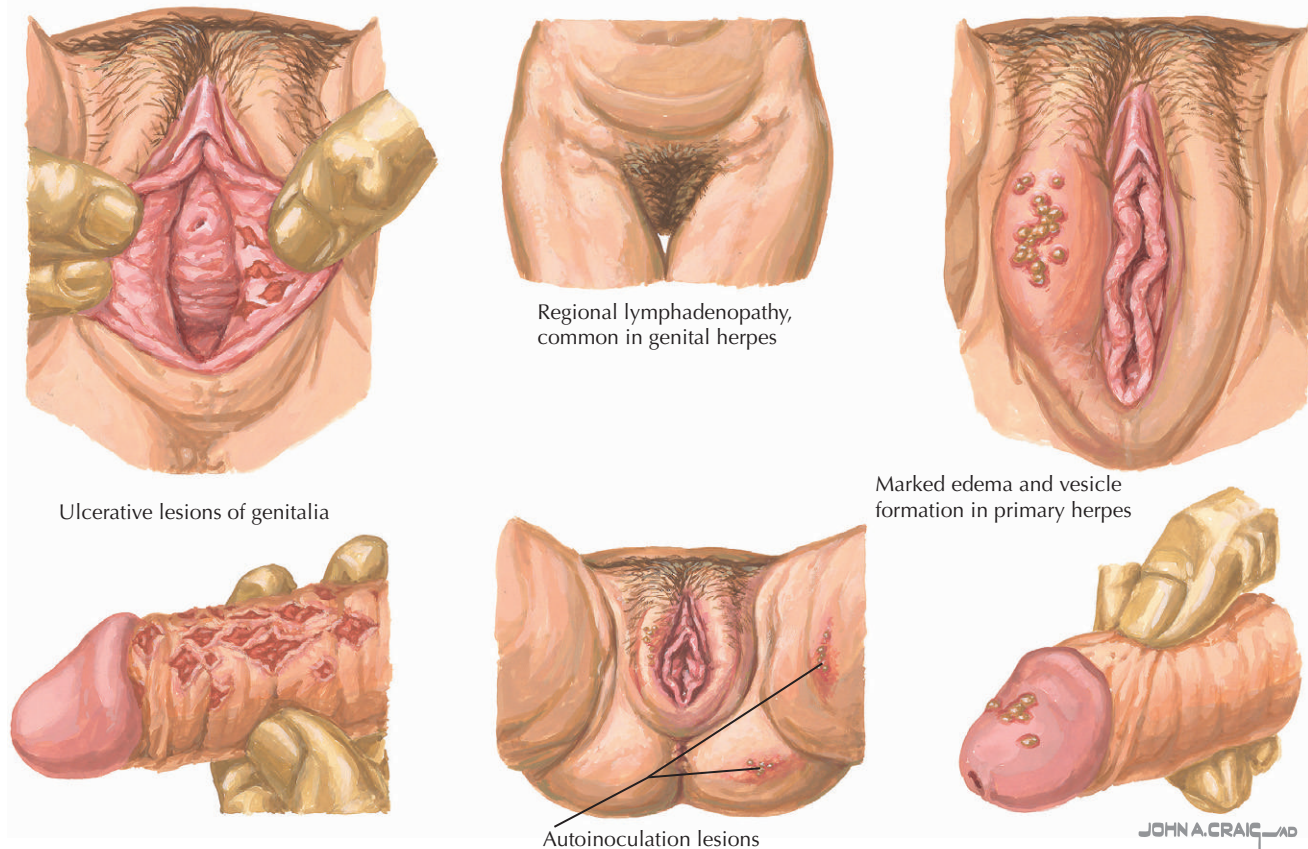

The efficiency of the immune response appears to influence the quantity of virus-established latency in the ganglia. The elements that contribute to this control are not com-

pletely known, but interferon- γ is likely to be important. Initial evidence suggests that immune response may play a supplemental role in maintaining latency of HSV, but this remains to be confirmed.

Clinical Presentation

Genital infection with HSV is classified into five categories.

The primary first episode refers to infection with either HSV-1 or HSV-2 in an individual who has never been infected with a herpes simplex virus. In immunocompetent hosts, this event usually goes unrecognized. After an incubation period of 1 to 14 days (average, 4 days), a papule appears that evolves into a vesicle within 24 hours (Fig. 100-1). These vesicles can be clear or pustular and rapidly evolve into shallow, nonindurated, painful ulcers. Clinical associations include dysuria, inguinal lymphadenitis, vaginal discharge, and cervicitis. Systemic symptoms,

Figure 100-1 Lesions of Herpes Simplex.

including myalgias, malaise, fever, and other flu-like symptoms, may also develop. Crops of lesions occur over 1 to 2 weeks. Crusting and healing require an additional 1 to 2 weeks.

A nonprimary first episode is an infection in an individual who has had a previous infection with either HSV type, typically a previous orolabial infection with HSV-1, in whom a genital HSV-2 infection develops. Generally, it is less severe than the primary first episode because of a partial humoral and cellular immune response. There are fewer lesions, less pain, fewer systemic symptoms, and more rapid resolution of lesions (usually 5 to 7 days). This episode is clinically similar to that of recurrent disease and can be mistaken for recurrent infection.

A first recognized episode is an initial infection, whether it is a first episode or recurrent infection.

A recurrent episode is the second or subsequent episode of genital herpes with the same virus type. HSV-2 accounts for more than 90% of recurrent genital herpes. The median number of recurrences is four, with 38% of individuals having six or more recurrences annually. Recurrent outbreaks are usually not associated with systemic symptoms, are fairly mild, and often go unrecognized, but they may be preceded by a prodrome of paresthesia or dysesthesia.

A cluster of localized vesiculopustular or ulcerative lesions develops and tends to lateralize to one side of the midline. Atypical lesions are common and may be mistaken for excoriation or irritation. Predominant locations of lesions are the glans or shaft of the penis in men, the vaginal introitus or labia in women, and the buttocks and anal area in both sexes. A neuropathic prodrome may occur 6 to 24 hours before the appearance of lesions.

Subclinical shedding refers to the detection of virus in the absence of visible lesions. Our understanding of genital herpes has shifted from that of intermittent outbreaks to one of low-grade continuous shedding of virus that can be detected by viral culture of the genitals and anus 5% to 7% of days and 15% to 20% of days by polymerase chain reaction (PCR). The frequency of subclinical shedding is greatest the first 6 to 12 months after acquiring genital herpes. It is less common in HSV-1. In HSV-2, subclinical shedding occurs in virtually all individuals but is more common in women and diminishes in frequency over time. Many episodes are temporally associated around clinically recognized outbreaks, with virus detected 1 day to several days preceding or following resolution of lesions. The development of symptoms or lesions appears to be most related to duration of viral shedding

and not to the host immune response. Patients who are counseled about the mild signs and symptoms of recurrent outbreaks may learn to recognize some periods when they are at risk for transmitting HSV to partners. Unfortunately, because up to 70% of transmission is attributable to asymptomatic viral shedding, patients are potentially infectious to all sexual partners regardless of signs or symptoms.

Differential Diagnosis

Discrete genital or anal ulcers in sexually active young adults have a relatively narrow differential diagnosis. Chancroid is rare in the United States, and syphilis is at a historical low and highly concentrated in certain geographic areas.

The differential diagnosis should include the following infectious etiologies: genital herpes, syphilis, chancroid, primary HIV, lymphogranuloma venereum, and donovanosis.

Primary syphilis may be distinguished from other ulcers by the presence of a nontender, indurated, nonpurulent ulcer. Other ulcer characteristics are not helpful in distinguishing infectious etiologies but are more likely to be due to herpes. Diagnostic testing is critical to prevent a missed diagnosis of genital herpes for any genital ulcer.

Diagnostic Approach

Viral culture has, until recently, been the gold standard for the diagnosis. It is now known that PCR for HSV DNA is 3 to 4 times more sensitive than viral culture and can increase viral detection from genital lesions by 11% to 70% compared with cell culture. Although PCR is offered by many reference laboratories, it is not commercially available. Viral detection methods, whether culture or PCR, allow the etiologic diagnosis of a genital ulcer. They also permit distinction of HSV-1 from HSV-2, an important consideration for prognosis and counseling. Cultures are most sensitive while lesions are in the vesicular-pustular stage. Sensitivity rapidly declines as lesions ulcerate and crust. Direct immunofluorescent antibody testing is more rapid (4 to 6 hours) than culture, but does not differentiate HSV-1 and HSV-2.

Enzyme-linked immunosorbent assay (ELISA) testing for HSV antigens in clinical specimens is a rapid alternative to culture (results in 3 to 4 hours), but its use is generally confined to large laboratories and teaching institutions. Microscopy of Papanicolaou smears or Giemsa staining (Tzanck test) is insensitive and nonspecific and not recommended for the diagnosis of genital herpes. A type-specific antibody test based on HSV glycoprotein G is the most important and reliable diagnostic tool for HSV infection. Antibody tests based on complement fixation, indirect immunofluorescence, or neutralization technologies do not distinguish antibodies to HSV-1 from HSV-2. A nega-

tive antibody test result is reassuring in that it excludes the diagnosis in a patient who has symptoms suggestive of recurrent herpes. A positive test result that is not HSV glycoprotein G–based is of little diagnostic value because it does not distinguish reliably between type 1 and type 2 infections. Because more than half of U.S. adults are HSV-1 seropositive, a positive test result is not useful in the evaluation of genital ulcer disease. Immunoglobulin M (IgM) antibody is often present with recurrent HSV outbreaks and does not indicate recent infection. IgM antibodies are only indicated for the evaluation and diagnosis of neonatal herpes infection.

New type-specific serologic assays have specificities of more than 98% for the detection of HSV-2 antibody and sensitivities of more than 90%, depending on the population studied. A rapid, office-based assay that can be run on serum or fingerstick analyses and provide results in less than 10 minutes is also available. It is imperative to specify a glycoprotein G–based test when ordering an HSV serologic test.

The following are the current U.S. Food and Drug Administration–approved, type-specific assays: Western immunoblot, HerpeSelect HSV-1 and HSV-2 ELISA (Focus Diagnostics, Cypress, CA), HerpeSelect HSV-1 and HSV-2 immunoblot (Focus Diagnostics, Cypress, CA), BioKit HSV-2 Rapid Assay (Biokit USA, Lexington, MA), and Captia HSV-1 and HSV-2 (Trinity Biotech, Wicklow, Ireland).

Management and Therapy

There is an undeserved stigma attached to genital herpes, and most patients require reassurance and appropriate counseling. This can be given only if one has full access to the facts and myths surrounding this condition.

Pharmacologic and Other Treatment

Antiviral therapy for initial genital herpes prevents new lesion formation and rapidly reduces viral shedding, infectivity, and the risk for autoinfection. However, it has no effect on preventing subsequent recurrences. When taken continuously, it effectively suppresses HSV recurrences and reduces subclinical shedding and the risk for transmission of HSV by about 50%. Episodic treatment shortens the course of recurrences. The current recommended antiviral regimens for genital herpes cause few adverse effects, but serum levels can become elevated when renal function is impaired (requiring a reduction in dosage) (Table 100-1). Acyclovir, famciclovir, and valacyclovir are not approved for use during pregnancy. Some experts recommend the use of suppressive acyclovir therapy during the last month of pregnancy for women with symptomatic recurrent herpes to prevent unnecessary cesarean births by reducing the likelihood of an outbreak near term.

Table 100-1 Drug and Dose for a Specific Type of HSV-2 Infection

Type of Infection or Therapy	Acyclovir	Famciclovir	Valacyclovir
Initial	400 mg tid for 10 days	250 mg PO tid for 10 days	1 g PO bid for 10 days
Recurrent	800 mg PO tid, for 2 days	1000 mg PO bid for 1 day	500 mg PO bid for 3 days
Suppressive	400 mg PO bid	250 mg PO bid	500 mg PO qd (<10 outbreaks/year) <i>or</i> 1000 mg PO qd (≥10 outbreaks/yr)

Topical lidocaine jelly 2% is a useful adjunct to oral antiviral drugs in managing severe first episodes in women. It should be applied frequently, and especially before voiding, but for no longer than 24 to 36 hours. There is a theoretical risk of sensitization, but this is very rarely seen in practice. Antifungal or antibacterial agents may be needed to treat secondary infections.

There is no evidence that salt baths, topical antiseptics, lysine, vitamins, or other nonmainstream remedies are more effective than placebo in the treatment or prevention of genital herpes.

Optimum Treatments

First Episodes

After diagnosis, assess the need for further immediate tests if there is clinical suspicion of syphilis, chancroid, primary HIV, or other infection. Tests include darkfield examination, serum for rapid plasma reagin, HIV p24 antigen or serum HIV RNA, or antibody testing.

Use of an oral antiviral for 7 to 10 days should be considered. Symptoms usually resolve in 3 to 4 days. If this is not the case, consider the possibility of secondary infection. Lesions persisting for longer than 14 days should prompt consideration of HIV coinfection, and one should consider repeat serologic testing for syphilis and examination for other genital infections after 2 to 4 weeks. If the initial HSV virologic test results were negative, HSV type-specific serology should be obtained 6 weeks and again 3 months after presentation. HIV testing is recommended for all individuals diagnosed with genital herpes.

Recurrent Episodes

Virologic specimens should be obtained from active lesions if the diagnosis has not yet been confirmed. Consider obtaining type-specific serology in patients with atypical lesions, negative virologic tests, or lesions that cannot be tested for the presence of HSV.

HIV testing should be strongly encouraged for those who have not been recently tested.

Other important considerations include episodic treatment with oral antiviral agents and counseling patients on

treatment options, including continued episodic therapy that may be started at the first signs or symptoms of an outbreak, or suppressive therapy to prevent recurrences.

COUNSELING. First and most importantly, accurate information about all aspects of the disease should be provided. New diagnoses of genital herpes can be emotionally devastating and may make comprehension and retention of information difficult. Important information to cover at the first visit includes the following:

- The availability of effective therapy for primary infection
- The availability of effective therapy for recurrences
- Recurrent episodes tend to be milder than the initial episode
- Transmission of herpes usually occurs from a partner who was not aware of his or her infection or did not believe he or she was infectious when exposure occurred
- Daily suppressive therapy can reduce the risk for transmission by 50%
- Condom use more than 25% of the time can reduce transmission of HSV by 50%

Time should be taken at follow-up visits to address the patient's concerns and to provide appropriate counseling. Patients may be given written information and referred to Internet websites and telephone hotlines.

Prevention

The majority of patients once educated on the mild signs and symptoms of outbreaks will recognize symptomatic outbreaks. The following steps can help prevent the acquisition and transmission of genital herpes:

- Disclosure of HSV status to sexual partners
- Abstinence during outbreaks
- Condoms can reduce transmission, especially during the first 6 to 12 months after initial infection
- Choosing partners with like serologic status
- Daily suppressive therapy has been shown to reduce the risk for HSV transmission to an uninfected partner by about 50%

Avoiding Treatment Errors

Major issues in patients with HSV infections include (1) failure to actively investigate whether other sexually transmitted infections are present in the same individual and (2) failure to counsel infected patients on treatment options. It is also important to understand the need to treat HSV infection more aggressively in immunocompromised individuals.

Future Directions

Preventive and therapeutic vaccines are currently in phase 2 and 3 clinical trials. Clinical efficacy data on these vaccines will be available in 4 years. Even with an effective vaccine, questions concerning the acceptability of a sexually transmitted infection vaccine for the general public and whether the target population should be preteens or young adults will need to be addressed. The development of vaginal microbicides will offer women protection against HSV and a broad array of other sexually transmitted infections.

Varicella-Zoster Infections

Introduction

Varicella-zoster virus (VZV), a large DNA virus, belongs to the family Herpesviridae and, like all herpesviruses, induces lifelong latent infection. VZV causes two clinical syndromes: varicella (chickenpox), a highly contagious childhood rash illness due to primary infection with VZV; and herpes zoster (shingles), usually a dermatomal vesicular rash caused by reactivation of latent VZV infection. Varicella is usually benign in immunocompetent children but causes substantially greater morbidity and mortality in adults, pregnant women, and immunocompromised hosts. Herpes zoster can cause severe and prolonged pain and, like varicella, is sometimes much more severe in compromised hosts. Introduction of the varicella vaccine in the mid-1990s dramatically decreased the incidence of chickenpox in the United States, as well as hospitalizations and deaths due to varicella and its complications among children and adults.

Etiology and Pathogenesis

Primary infection occurs through airborne transmission of infectious droplets from vesicular skin lesions or respiratory secretions resulting in infection of the upper respiratory tract, followed by viral replication in regional lymph nodes, viremia, and subsequent infection of endothelial cells of the skin and the epidermis. The rash of varicella-zoster infection is characterized initially by clear vesicles that contain infectious virus. Vesicles become pustular with migration of polymorphonuclear cells and subsequently either rupture or resorb.

After primary VZV infection, the virus becomes latent in dorsal root ganglia. The factors that promote reactivation and subsequent development of clinical herpes zoster are poorly understood.

Clinical Presentation

Varicella is extremely contagious; the reported attack rate among persons without previous infection exceeds 90%. Before the vaccination era, children aged 5 through 9 years were affected most commonly. About 10% of the U.S. population older than 15 years is susceptible to VZV infection. Illness, characterized by rash, malaise, and fever, appears 8 to 21 days after infection. The rash, varicella's hallmark, begins as a vesicular eruption that occurs in crops of lesions over several days and spreads from the

head to the trunk and finally to the extremities (Fig. 101-1). The skin lesions undergo a characteristic series of changes as vesicles umbilicate and then evolve into pustules and finally crusted papules. Varicella is contagious 1 or 2 days before the onset of rash and until all lesions have formed crusts.

Chickenpox in a previously immunized person (breakthrough varicella) is usually a mild illness, and the rash often differs from typical varicella. Patients with breakthrough infection have fewer lesions, and their rash tends to be papulovesicular or papular instead of vesicular. They can transmit varicella to others but do so less often than individuals with typical varicella.

Varicella is usually a benign illness in immunocompetent children; however, it is generally more severe in older adolescents and adults. In the neonate, it is associated with high mortality risk when maternal disease develops within 5 days before or 2 days after delivery. Disease may be severe in immunocompromised hosts of all ages. Varicella may cause fetal malformations (about 4% of infected mothers) if the mother develops disease, especially in the first trimester.

Complications include secondary skin infections, usually due to *Staphylococcus aureus* or *Streptococcus pyogenes*, which occur as a result of scratching the pruritic lesions. Pneumonia is uncommon in children but complicates about 16% to 20% of adult infections, usually about 3 to 5 days after the onset of illness (see Fig. 101-1). Pneumonia is

Figure 101-1 Varicella Pneumonia.

Hemorrhagic chickenpox

Varicella pneumonia. Nodular infiltrates in both lower lobes, more marked and coalescing on right side

High power: mononuclear infiltrate in interstitium and fibrin lining alveoli

Pulmonary histology, low power. Alveoli filled with fibrin, fluid, and cellular exudate

Multinucleated giant cell with much fluid in alveolus

Pleural hemorrhagic pocks

often associated with dyspnea, cough, and fever, but radiographic evidence of pneumonitis may develop in the absence of respiratory symptoms. Common radiographic findings include interstitial and nodular infiltrates. Morbidity is especially severe in pregnant women with varicella and pneumonia. Central nervous system complications include cerebellar ataxia, aseptic meningitis, encephalitis, Guillain-Barré syndrome, Reye's syndrome, and transverse

myelitis. Myocarditis, hepatitis, nephritis, and arthritis are other complications.

Herpes zoster occurs at all ages, but incidence rises with old age and the waning of cell-mediated immunity. The first symptom is pain, followed within 48 to 72 hours by eruption of a unilateral maculopapular rash in a dermatomal distribution that subsequently becomes vesicular. The thoracic and lumbar dermatomes are most frequently

Figure 101-2 Herpes Zoster with Probable Keratitis.

Herpes zoster

involved. Lesions usually persist for 10 to 15 days, but skin may not become completely normal for several weeks. Involvement of the trigeminal nerve may cause eye involvement (herpes zoster ophthalmicus), a potentially sight-threatening condition (Fig. 101-2). Zoster-associated pain and postherpetic neuralgia are the most troublesome symptoms and may be incapacitating, especially in persons older than 50 years. Pain is especially severe in the areas overlying the site of previous blisters. Risk factors for postherpetic neuralgia include increased age, sensory loss, and severity of pain. Prompt treatment with antiviral agents appears to decrease the risk for postherpetic neuralgia. Central nervous system involvement may present as meningoencephalitis or encephalitis. Herpes zoster is more severe in immunocompromised hosts than in normal hosts. Patients with lymphoma, for example, are at increased risk for cutaneous dissemination and visceral involvement.

Differential Diagnosis

Diagnostic considerations include disseminated herpes simplex virus, Coxsackie virus, echovirus, and atypical measles, but these infections more often cause a morbilliform rash than vesicular lesions. Appearance of impetigo can be similar to varicella, but unroofing of impetigo lesions should reveal gram-positive cocci due to *S. aureus* or *S. pyogenes*.

Diagnostic Approach

History and physical examination are usually sufficient for diagnosis. A characteristic skin rash in multiple stages of development should raise suspicion of varicella, especially

in a person with a history of exposure. A dermatomally distributed vesicular rash should always raise the possibility of herpes zoster. Laboratory testing can help to define the diagnosis in equivocal cases. Vesicular skin lesions are scraped to obtain material for viral culture or performance of direct fluorescent antibody staining. Antibody testing with immune adherence hemagglutination assay, fluorescent antibody to membrane antigen assay, and enzyme-linked immunosorbent assay are occasionally helpful in demonstrating seroconversion or diagnostic rises in titer. Tzanck smears of lesions may reveal characteristic multinucleated giant cells, but sensitivity is only 60%. Such smears do not distinguish herpes simplex virus from VZV. Polymerase chain reaction assays to detect VZV DNA in cerebrospinal fluid are helpful in the diagnosis of central nervous system involvement.

Management and Therapy

Maintenance of good hygiene with bathing is important to decrease the risk for complications in patients with varicella. Fingernails should be cut closely to reduce risk for secondary infection. Dressings and antipruritic drugs can decrease itching. Oral acyclovir (800 mg 4 times daily by mouth for 5 to 7 days) or other similar drugs (i.e., valacyclovir, famciclovir) decrease the duration and number of lesions and reduce fever when given within 24 hours of onset and should be prescribed for adults and adolescents. Children at high risk for complications should also be treated.

In patients with varicella zoster, antiviral therapy with famciclovir (500 mg thrice daily for 7 days), valacyclovir (1 g thrice daily for 7 days), or acyclovir (800 mg 5 times daily for 7 to 10 days) speeds resolution of lesions and pain but is most efficacious when given within 3 days of onset of rash. Valacyclovir results in faster resolution of pain than acyclovir. The addition of prednisone to acyclovir improved pain and other quality-of-life measurements in one study; however, it should be used with caution in patients with diabetes mellitus and others at risk for complications of corticosteroid use. It is unknown whether administration of prednisone with valacyclovir or famciclovir provides additional benefit because these antivirals are more potent than acyclovir. Amitriptyline, desipramine, and gabapentin may be useful in decreasing postherpetic neuralgia.

Avoiding Treatment Errors

The most critical step in avoiding treatment errors is to make an accurate diagnosis as early during the clinical course of varicella-zoster infection as possible. Treatment efficacy is clearly dependent on the early initiation of antiviral therapy. As previously noted, varicella skin lesions are occasionally misdiagnosed as impetigo. This is one example

of an error that could delay the use of antivirals and, in turn, lead to preventable complications, including a greater likelihood of postherpetic neuralgia.

Prevention

Varicella vaccine, a live attenuated virus vaccine, has at least a 95% to 99% efficacy and is approved for use in healthy children at least 12 months old and for susceptible adolescents and adults. All children should be routinely vaccinated between 12 and 18 months, and susceptible children should be vaccinated before their 13th birthday. Varicella-zoster immune globulin (VZIG) can be given after exposure to persons at high risk for complications (e.g., immunocompromised persons, pregnant women, premature infants [born at less than 28 weeks' gestation or birth weight of less than 1000 g]). Varicella immune globulin should be given within 96 hours of exposure. However, VZIG is no longer manufactured in the United States. It may be obtained from Canadian manufacturers but requires administration with informed consent and a research protocol. Although not approved by the U.S. Food and Drug Administration (FDA), antivirals administered at standard doses from postexposure days 8 through 21 have been successful in preventing varicella in immunocompromised persons.

A new vaccine, ZOSTAVAX, was recently approved by the FDA for prevention of VZV among people aged 60 years and older. This vaccine reduced the incidence of both zoster and postherpetic neuralgia in participants in a large clinical trial. Recommendations for use by the Advisory Committee on Immunization Practices are pending.

Future Directions

Introduction and widespread use of the varicella vaccine has changed the epidemiology of varicella infection. Long-term follow-up is essential to definitively determine whether revaccination is necessary and if there are new or different clinical manifestations in people whose waning vaccine immunity allows illness. Varicella may present different clinical manifestations as a result of the vaccine and new types of immunosuppressive therapy. Use of the newly approved zoster vaccine may dramatically decrease the incidence of zoster and postherpetic neuralgia in the future.

This randomized placebo-controlled trial demonstrates that early treatment (within 24 hours of rash onset) of adults with acyclovir decreased the time to healing of cutaneous varicella as well as duration of fever.

Encephalitis

Introduction

The term *encephalitis* refers to inflammation in the brain parenchyma caused by a broad range of infectious and noninfectious etiologies. This chapter primarily focuses on infectious encephalitis. Infectious encephalitis is considered a medical emergency because prompt initiation of treatment for specific pathogens, such as herpes simplex virus (HSV) and Rocky Mountain spotted fever (RMSF), can substantially decrease associated morbidity and mortality. Acute encephalitis, the most common form of fatal sporadic encephalitis in developed countries, is a frightening and potentially devastating manifestation of HSV infection.

Etiology and Pathogenesis

Encephalitis and meningitis share many features including a clinical presentation dominated by fever and headache. The presence of abnormal brain function in the case of pure encephalitis helps to distinguish the two syndromes; however, this distinction may be blurred when patients present with both parenchymal and meningeal involvement. Separating the two entities is important because the etiologies for meningitis and encephalitis vary considerably. The altered consciousness seen with infectious encephalitis reflects diffuse involvement of the cerebral cortex by an infectious pathogen or inflammation produced in response to infection. HSV-1, varicella-zoster virus (VZV), mumps, measles, and enteroviruses are the most common viral causes in immunocompetent hosts. HSV encephalitis has an estimated incidence of between 2 and 4 cases per million individuals per year, and accounts for about 10% to 20% of cases of viral encephalitis. Many arboviruses can cause encephalitis such as Japanese encephalitis and West Nile virus encephalitis. *Listeria monocytogenes* and *Rickettsia rickettsii* (the causative agent of RMSF) are bacterial causes of encephalitis. Important nonviral causes of encephalitis also include African trypanosomiasis in endemic regions and toxoplasmosis in immunocompromised individuals.

Central nervous system (CNS) invasion can occur through hematogenous spread from a primary site such as the respiratory tract (i.e., measles, mumps) or subcutaneous tissues (Eastern and Western equine virus). CNS infection can also result from retrograde transport from

peripheral nerves, as in the case of rabies, or from retrograde transport from skin or mucous membranes into sensory ganglia, as occurs with HSV and VZV infection.

In the case of HSV, the virus enters through mucosal or cutaneous surfaces with initial local, sometimes subclinical, infection, which then leads to infection of autonomic or sensory nerve endings with subsequent transport to the nerve cell bodies in the ganglia. Most HSV encephalitis is caused by HSV-1. In initial infection, HSV replication occurs in the ganglia and surrounding neural tissue before the establishment of latency. In children and some young adults, HSV encephalitis may result from oral or labial infection and neurotropic extension through the olfactory bulb. In many adults, the presence of serologic or historical evidence of HSV-1 infection at the time of HSV encephalitis presentation suggests that the encephalitis is a manifestation of reactivation of latent infection in the ganglion with extension to the CNS. HSV DNA has also been identified with polymerase chain reaction (PCR) in brain tissue from individuals dying of non-neurologic causes; therefore, reactivation of latent infection within the CNS itself may be possible. Thus, HSV infection of the CNS can occur through three routes: (1) immediate CNS invasion through the trigeminal nerve following primary oropharyngeal HSV-1 infection; (2) HSV-1 reactivation followed by CNS invasion; and (3) in situ reactivation of HSV-1 within the CNS.

The temporal lobe is the characteristic site of infection early in the course of HSV encephalitis. This suggests a common mode of entry into the CNS, for example, from reactivation in the trigeminal ganglia and entry into the

brain through the rami meningeals of the trigeminal nerve. In some cases, the HSV-1 variant associated with encephalitis differs from the variant isolated from a patient's oropharynx, suggesting that encephalitis may result from a second HSV infection. The encephalitis is caused by lytic HSV infection of neuronal and astroglial cells with associated necrosis of brain tissue. The infection may extend from the temporal lobe to other areas of the brain.

The differences in the clinical presentation of encephalitis due to various infectious agents may reflect differences in the types of cells infected in the CNS. Infection of neurons can cause focal or generalized seizures. Isolated demyelination, as can be seen by magnetic resonance imaging (MRI), may result from oligodendroglia involvement and cause stroke-like symptoms. Cortical infection or reactive parenchymal swelling can manifest as altered consciousness, and infection of brainstem neurons can cause coma or respiratory failure.

Histopathologic changes vary according to the infectious etiology, host immune response, and the stage of infection but generally show parenchymal damage, reactive gliosis, and the infiltration of inflammatory cells. Meningeal and perivascular mononuclear inflammation predominate in fatal viral encephalitis, although polymorphonuclear cells can be seen. Histologic changes also show degenerating neural cells and phagocytosis of neurons. The characteristic intranuclear inclusions associated with adenovirus, measles, and herpesvirus infections of other tissues are also seen in encephalitis, and Negri bodies are found in the brain tissue with rabies encephalitis. Vasculitis is prominent in encephalitis due to rickettsia.

Viral encephalitis can result from primary viral invasion of the CNS with neuronal involvement, or can be categorized as postinfectious encephalitis. In primary viral infection, neurons are affected, and the pathogen can be recovered. In postinfectious encephalitis, virus cannot be detected or recovered. Histopathologic changes in postinfectious encephalitis show perivascular mononuclear inflammation and perivenous demyelination with sparing of neurons. Histologic findings and the fact that the clinical onset usually begins as the primary infection is resolving or following subclinical illness suggest the syndrome is immune mediated. The clinical distinction between the two disorders is difficult, and some viruses, such as measles, have been associated with both.

Clinical Presentation

Infectious encephalitis is generally an uncommon manifestation of common infections and is most common in young children, adults older than 65 years, and the immunocompromised. Infection with the viruses associated with encephalitis usually does not result in clinically evident disease, with about 1% of St. Louis and West Nile infections causing symptoms of encephalitis. Eastern equine

virus is an exception; infection with this virus frequently produces symptomatic encephalitis in all age groups.

Patients with encephalitis usually present with the acute onset of fever, headache, altered level of consciousness, and brain dysfunction. Altered consciousness can vary from mild lethargy to coma. Abnormal brain function encompasses behavioral and cognitive changes as well as focal neurologic signs and seizures. Clinical manifestations can range from agitation and acute memory disturbances to psychosis and unresponsiveness. Autonomic and hypothalamic disturbances, diabetes insipidus, and the syndrome of inappropriate antidiuretic hormone secretion can also complicate the clinical course. Focal neurologic findings usually develop during the course of encephalitis regardless of the pathogen, and focal and generalized seizures are common. Various other neurologic abnormalities may occur, including hemiparesis, hemianopsia, cranial nerve palsies, abnormal movements, and altered deep tendon reflexes. Meningitis presents similarly with fever, headache, and nuchal rigidity but is generally not associated with abnormal brain function, especially earlier in the disease process, and vomiting and photophobia may also be prominent.

The clinical presentation of encephalitis is usually nonspecific, although certain features can provide clues to specific causes. Parotitis is highly suggestive of mumps, and gastrointestinal symptoms increase the likelihood of enteroviral infection. A parkinsonian tremor has been associated with Japanese encephalitis. Flaccid paralysis in an immunocompromised host with possible mosquito exposure should prompt consideration of West Nile virus. Rabies encephalitis may be preceded by local paresthesias at the site of an animal bite and later evolve to pharyngeal spasms, hydrophobia, and aerophobia (Fig. 102-1). The presence of a rash may lend support to certain diagnoses: rash on the palms and soles with RMSF, the bull's eye lesion of Lyme disease, and the dermatomal, vesicular eruption characteristic of VZV. Focal neurologic findings such as personality change, seizure, hallucinations, and aphasia suggest localization to the temporal lobe and should raise suspicion for HSV encephalitis (Fig. 102-2). Behaviors may be bizarre with HSV encephalitis and include Kluver-Bucy syndrome—visual agnosia, excessive oral tendencies, placidity, altered sexual behavior, and changes in dietary habits. Other presentations include amnesia and hypomanic symptoms such as elevated mood, decreased need for sleep, and hypersexuality. In addition, dysphasia may present as a localizing finding with HSV encephalitis.

Encephalitis related to bacterial and viral pathogens is usually acute in onset; however, Lyme disease, as well as enteroviral, adenoviral, and toxoplasma encephalitis in immunocompromised patients, may present as a subacute process. Subacute presentation of neurologic symptoms with persistent fever is more common with parameningeal infections such as brain abscesses or tuberculous

meningitis. The onset of neurologic symptoms with postinfectious encephalitis is usually acute and occurs 2 to 12 days after symptom onset related to the primary infection.

Differential Diagnosis

There is a broad range of infectious and noninfectious syndromes that can cause encephalitis or present with similar clinical characteristics (Box 102-1). Bacterial meningitides, brain abscesses, and meningoencephalitis (e.g., *Listeria* species) should be excluded and may require empiric therapy until the appropriate diagnostic tests have been completed. Encephalopathy, due to intoxications and malaria, should be considered. Noninfectious causes include intracranial hemorrhage, CNS autoimmune diseases with or without systemic manifestations such as systemic lupus erythematosus, Wegener's granulomatosis, or primary CNS vasculitis. Thyrotoxicosis, neuroleptic malignant syndrome, and exposure to certain toxins or drugs also warrant consideration. Distinguishing encephalitis from meningitis narrows the differential and is critical in the case of HSV. HSV encephalitis can be fatal and cause significant morbidity, but HSV meningitis is usually a self-limited syndrome, typically caused by HSV-2 and associated with the primary episode. Other infectious causes of encephalitis include syphilis, tuberculosis, and opportunist-

tic CNS pathogens such as *Cryptococcus neoformans* or *Toxoplasma gondii* in undiagnosed or advanced HIV infection.

Common causes of viral encephalitis vary worldwide. Rabies is a common cause in India and Mexico; measles is the leading cause in Africa; and Japanese B encephalitis accounts for a large number of cases in China and Southeast Asia. Many viruses can cause encephalitis, and several have clinical features or a seasonal or geographic predilection that suggest their diagnosis (Table 102-1).

As previously noted, HSV encephalitis commonly presents with clinical deficits suggestive of temporal lobe necrosis, including personality changes, dysphasia, and seizures. Other herpesviruses can present similarly, including cytomegalovirus (CMV), VZV, and Epstein-Barr virus (EBV). Additional viral infections include enteroviral and vector-borne viral encephalitides (Eastern equine, St. Louis, and West Nile encephalitis, among others). Less common sporadic viral encephalitides, such as those related directly or indirectly to adenoviruses, influenza, mumps, measles, and acute HIV infection, should be considered (see Table 102-1).

Infectious causes are often suggested by seasonal variation, medical or travel history, or physical, laboratory, or radiologic examinations. HSV encephalitis occurs sporadically throughout the year and in patients of all ages,

Table 102-1 Viral Causes of Encephalitis

Viral Family	Virus	Location
Adenoviridae	Adenovirus	Worldwide
Bunyaviruses	California encephalitis	Midwest and Northeast United States, Southern Canada
	La Crosse	Northern United States
	Rift Valley	Sub-Saharan Africa
	Toscana	Europe
	Coxsackie virus	Worldwide
Enteroviruses	Echovirus	Worldwide
	Hepatitis A	Worldwide
	Poliovirus	—
	Dengue	Central and South America, Caribbean, Southeast Asia, Africa
Flaviviridae	Murray valley	Australia, New Guinea
	Japanese encephalitis virus	East and Southeast Asia, India
	St. Louis encephalitis	South and Central United States, Canada, Caribbean
	West Nile virus	United States, Israel, Mideast
	Cytomegalovirus	Worldwide
	Epstein-Barr virus	Worldwide
	HHV-6 and HHV-7	Worldwide
	Herpes simple virus-1	Worldwide
	Herpes simplex virus-2	Worldwide
	Varicella-zoster virus	Worldwide
Orthomyxoviridae	Influenza A	Worldwide outbreaks, epidemics
Arenaviridae	Lymphocytic choriomeningitis virus	Europe and North and South America
	Junin	Argentina
	Lassa	Western Africa
	Machupo	Bolivia
Paramyxoviridae	Hendra	Australia
	Measles virus	Worldwide
	Mumps	Worldwide
	Nipah	Malaysia, Singapore, Bangladesh
Polyomavirus	JC virus	Worldwide
Rhabdoviridae	Rabies	Worldwide
	Lyssavirus	Australia
	Colorado tick fever	Rocky Mountains of United States
Reoviridae	HIV	Worldwide
Retroviruses	Rubella	Worldwide
Rubivirus	Eastern equine encephalitis	Eastern and Gulf coasts of United States, Caribbean, South America
Togaviruses	Venezuelan equine encephalitis	South and Central America, Florida, Southwest United States
	Western equine	Western United States and Canada

although it may be more common in adolescents and young adults and in individuals older than 50 years. In contrast, viral encephalitides due to arboviruses occur when mosquitoes and ticks are active in respective locales. In temperate regions, mosquito-borne encephalitis tends to peak in late summer, and tick-borne encephalitides occur primarily in late spring and summer. Most arboviruses also have specific geographic distributions (see Table 102-1) related to their animal hosts and vectors. Eastern equine virus occurs predominantly in coastal marshlands of the Atlantic and Gulf coasts of North and South America, whereas St. Louis encephalitis virus infection occurs most commonly in the Midwest and Southern region of the United States. Enterovirus causes encephalitis predominantly in the late summer and fall. Viruses associated with

postinfectious encephalitis include mumps, measles, VZV, EBV, rubella, and influenza.

Travel and outdoor exposure to locales with prevalent tick populations also raise the possibility of nonviral etiologies such as RMSF, Lyme disease, or Colorado tick fever. Lyme disease should be considered with exposure in areas where *Borrelia* species are endemic, such as the Northeastern United States and Europe. Additional animal exposures and geography can further broaden the differential. Nipah virus was first identified following an outbreak of encephalitis among pig farm workers in Malaysia and was subsequently also found in Singapore and Bangladesh. Nipah virus is one of several emerging infections that cause encephalitis and mandates consideration of evolving epidemiologic patterns, particularly with arboviruses. The

West Nile virus was first discovered in North America during an epidemic in 1999 and has since demonstrated substantial geographic expansion attributed to bird migration. Japanese encephalitis was initially focused in China and southeastern Asia but has expanded into India, Pakistan, Russia, the Philippines, and Australia. Other previously unknown pathogens that were responsible for recent outbreaks of encephalitis include hendra virus isolated from horses and humans in Australia, and Australian bat Lyssavirus, which causes a rabies-like disease.

Patients with immune deficiency can also present with subacute or chronic encephalitis due to toxoplasmosis or enteroviruses. Additional causes of encephalitis in individuals who are immunosuppressed due to AIDS or medications include CNS infection with *Histoplasma* species, CMV, JC virus (progressive multifocal leukoencephalopathy), and less commonly *Cryptococcus* species infection, which typically causes meningitis.

HSV-1 encephalitis does not occur more commonly in immune-suppressed patients despite an increased frequency and severity of mucocutaneous HSV-1 infections in this population. Accordingly, it has been postulated that much of the pathophysiology of CNS HSV-1 infection is immune mediated and may explain the subacute presentation and mild histopathologic changes on biopsy specimens that can occur in immunosuppressed patients with HSV encephalitis.

Diagnostic Approach

Diagnostic tests should be guided by medical history, with careful attention to geography, recent travel history, occupation, season, animal and insect exposures, and the immune status of the patient. History should be sought from relatives or other contacts if the patient cannot provide this information because of altered neurologic status. Peripheral blood tests are rarely useful but may show a lymphocytosis common with viral encephalitis. They may also detect malaria or atypical lymphocytes associated with EBV infection. MRI of the brain is the preferred imaging technique because it more sensitive than computed tomography (CT) for the detection of edema and inflammation seen early in encephalitis. Brain imaging by CT or MRI is preferable in patients presenting with mental status changes before lumbar puncture, to evaluate for space-occupying lesions and brain abscesses, and to determine the risk for herniation. Lumbar puncture should be delayed for evidence of elevated intracranial pressure on imaging, for status epilepticus, and immediately after generalized seizure, coagulopathy, or severe thrombocytopenia.

Timely cerebrospinal fluid (CSF) examination is critical and should include opening pressure measurement, cellular analysis, protein, glucose, viral culture, and appropriate PCR and serologic testing, as dictated by history and probable infectious causes. Bacterial and fungal stains and cul-

tures should be obtained given the overlap in clinical presentation between meningitis, meningoencephalitis, and parameningeal infections. Acid-fast bacillus stain and culture should be performed on immunocompromised hosts and considered in immunocompetent hosts at high risk for tuberculous meningitis.

The initial CSF examination may not distinguish aseptic or bacterial meningitis from viral encephalitis. However, the absence of a pleocytosis suggests a noninfectious cause, unless the patient is severely immunosuppressed and unable to mount an inflammatory response. CSF findings characteristic of viral infectious encephalitis include a predominantly mononuclear pleocytosis, ranging from 10 to 2000 cells/mm³, but usually less than 250 cells/mm³. Early in the course, a neutrophil predominance can occur, and a repeat lumbar puncture 8 to 24 hours later is often useful to evaluate for cellular evolution. CSF protein is usually normal or mildly elevated. A significant decrease in CSF glucose is unusual in viral encephalitis, in contrast to a characteristic decrease with tuberculous, bacterial, fungal, and amebic infections. CSF findings of a lymphocytic pleocytosis with a reduced glucose are strongly associated with tuberculous meningoencephalitis. An increased number of red blood cells in the absence of a traumatic tap suggests HSV and hemorrhagic encephalitis, or listerial and primary amebic meningoencephalitis. In contrast, CSF examination with bacterial meningitis characteristically shows a more significant pleocytosis of more than 2000 cells/mm³ with a neutrophil predominance, a protein concentration of more than 200 mg/dL, and hypoglycorrhachia.

Viral culture has been the gold standard for diagnosis of viral encephalitis, but specific PCR for viral DNA amplification technique has advanced diagnostic testing considerably and is currently available for HSV-1, HSV-2, VZV, human herpesvirus-6 and -7, CMV, EBV, enteroviruses, respiratory viruses, HIV, and *Chlamydia pneumoniae* and *Mycobacterium tuberculosis* on CSF. Advantages of this technique include excellent sensitivity and specificity and rapid response times on a small amount of CSF fluid. PCR detection of HSV DNA is the gold standard diagnostic test and has 98% sensitivity and 94% to 100% specificity, and is positive early in the course. Diagnostic yield is highest in the first week of illness and decreases substantially and sequentially in the second and third weeks following symptom onset. Diagnostic workup for encephalitis should generally include PCR for HSV, enteroviruses, and West Nile virus. Additional PCR and serologic testing work will vary according to travel and exposure history and immune status. In some cases, testing for rabies, mumps, EBV, and HIV should be considered. All immunocompromised individuals should have a cryptococcal antigen test and PCR for CMV performed on CSF.

PCR tests have largely replaced serum and CSF antibody tests because they are more rapid and because interpretation of antibody tests can be more difficult. Elevated

viral antibody titers may be nonspecific and reflect polyclonal activation due to infection, previous infection, or reactivation rather than primary infection. However, the detection of specific immunoglobulin M in the CSF does suggest CNS infection. Many viral causes require acute and convalescent serologies for diagnosis, and serum during the acute phase should be tested or saved for later testing, as indicated by the history.

Chest radiography should be obtained in consideration of mycoplasma, legionella, or tuberculosis. MRI of the brain can be useful in diagnosing HSV encephalitis showing abnormalities ranging from localized edema with increased signal on T2-weighted images to large areas with radiographic evidence of frank necrosis and hemorrhage. However, only minimal abnormalities may be seen early in the disease (see Fig. 102-2). MRI of the brain is the preferred imaging method because CT of the brain has only about 50% sensitivity for detecting temporal lobe abnormalities early in the disease. Electroencephalogram is rarely diagnostic except in the case of HSV encephalitis. However, it is sensitive in demonstrating early cerebral involvement and in distinguishing encephalopathy from infectious encephalitis.

Management and Therapy

There are many treatable, nonviral infections that can present similarly and for which diagnosis should be aggressively sought (see Box 102-1). Treatment of bacterial, fungal, and parasitic causes of encephalitis is pathogen specific and will not be covered here. Most viral encephalitis cases remain undiagnosed, but studies have shown VZV and HSV-1 to be commonly involved pathogens. Specific therapy for viral encephalitis is limited. Therefore, supportive care is paramount and may include airway intubation, sedation, and mechanical ventilation when mental status is significantly compromised. The potential for rapid deterioration requires that even patients with minimal alteration in sensorium be carefully observed.

HSV is the most important viral cause of encephalitis to consider because it can be fatal, can cause serious morbidity, and is treatable. The therapy of choice for HSV encephalitis is intravenous acyclovir. Acyclovir administration should not be delayed for diagnostic certainty, but initiated as soon as the diagnosis is entertained and while awaiting results of HSV PCR testing. Acyclovir has poor oral bioavailability and must be given at high doses (10 to 15 mg/kg) intravenously every 8 hours for 14 to 21 days to ensure adequate levels in the CNS and prevent relapse. In the initial comparative study with vidarabine, acyclovir reduced mortality by 50% (from 54% to 28%). Therefore, despite the fact that HSV-1 is very sensitive to inhibition by acyclovir, death or serious sequelae related to HSV encephalitis remain common, especially if therapy is initiated when the patient is near coma or comatose. Even with acyclovir therapy, only 38% of patients with confirmed

HSV encephalitis were considered to be functioning normally 6 months after infection, although only 9% were considered to have moderate debility. Long-term cognitive and memory impairments are not uncommon.

Acyclovir is also indicated for VZV encephalitis at the same doses and duration. If PCR testing for HSV and VZV is negative, acyclovir should, in most cases, be discontinued. Most recommendations include acyclovir for herpes B encephalitis transmitted from infected macaques monkeys given a high fatality rate; however, supportive data are limited. Combination therapy with ganciclovir (5 mg/kg intravenously twice daily) and foscarnet (60 mg/kg every 8 hours or 90 mg/kg every 12 hours) is the preferred treatment for CMV encephalitis. Antiretroviral therapy should be continued or initiated in AIDS patients with CMV encephalitis.

Corticosteroid use for encephalitis remains controversial and is generally advised only for vasculitis due to severe VZV encephalitis or severe and progressive vasogenic edema with a short course (3 to 5 days) of high-dose dexamethasone or methylprednisolone. Supportive and symptomatic management remains crucial, particularly for most viral causes without specific therapy. Brain biopsy is generally considered only if the cause remains unknown and the patient fails to improve, or if surgical decompression is indicated for refractory increased intracranial pressure. Prognosis is dependent on the specific pathogen, the immune status of the host, and timely initiation of appropriate treatment. Isolation precautions are not indicated for community-acquired infective encephalitis, unless rabies or contagious, viral hemorrhagic fever is suspected. Vaccines are available for hepatitis A, influenza, Japanese encephalitis, measles, mumps, polio, and rabies.

Avoiding Treatment Errors

Failure to consider encephalitis and its causes in the differential diagnosis of a patient who presents with fever and headache is a common error that delays diagnosis and initiation of appropriate therapy for treatable causes of encephalitis, such as HSV, *Listeria* species infection, and RMSF. If fever and headache are more prominent than subtle cognitive abnormalities, clinicians may focus more on the diagnosis and treatment of meningitis and may not collect historical clues needed to construct and unravel the differential diagnosis of encephalitis. Broader initial therapy, including acyclovir, doxycycline, ampicillin, or a combination, may avoid sequelae of encephalitis such as persistent neurologic deficits or death.

A delay in performing a lumbar puncture, indicated in almost all patients presenting with fever, headache, nuchal rigidity, or altered mental status, may also impede diagnosis and administration of effective therapy. Not uncommonly, HSV PCR is not performed on the initial CSF sample, which can delay diagnosis and treatment and necessitate repeat lumbar puncture for additional

diagnostic studies. Neither a negative MRI nor CT of the brain can definitively rule out encephalitis because both can be normal early in the disease. Administration of antibiotics before lumbar puncture frequently complicates the interpretation of CSF findings and may make distinguishing between partially treated bacterial meningitis and viral encephalitis of unknown etiology difficult, necessitating a prolonged course of intravenous antibiotics for the former. A careful and thorough history, including travel, occupation, and exposures, is critical in generating a full differential diagnosis because historical information could point to specific etiologies not otherwise considered such as intoxication or tuberculosis.

Future Directions

Advances in PCR testing have provided newer and more rapid diagnostic tests for encephalitis. Currently available PCR tests can be expected to become more widely available, and newer tests for additional etiologies are likely. Multiplex PCR tests in which individual PCR tests are combined into microarrays are a promising new technique for the detection and genotyping of microbes. Microarray-based detection could become a rapid and efficient standard diagnostic technique in the future if the sensitivity improves and the cost is not prohibitive. The past decade has witnessed encephalitis outbreaks due to the expansion of known arboviruses into new geographic distributions and the appearance of encephalitides due to previously unknown pathogens. These trends are likely to continue. New drugs for the treatment of common causes of encephalitis, particularly viral pathogens, are urgently needed. The mortality rate of patients with untreated HSV encephalitis approaches 70%, and most survivors have serious neurologic sequelae. Thus, the wider availability of HSV PCR testing, as well as PCR tests for other etiologies, will allow more rapid diagnosis and initiation of indicated treatment.

Pulmonary Tuberculosis

Introduction

Tuberculosis remains a major scourge of humankind, with an estimated one third of the world's population currently infected. Worldwide, more than 8 million persons develop active tuberculosis each year, leading to an estimated 1.9 million deaths. Worldwide, coinfection with HIV and tuberculosis represents a public health crisis because it is the leading cause of HIV-related morbidity and mortality in developing countries. In the United States, 14,097 (4.8 cases per 100,000 population) were reported in 2005, the lowest rate ever recorded. Overall, an estimated 15 million Americans are infected with *Mycobacterium tuberculosis*. The incidence of tuberculosis in the United States varies independently by age and gender, with higher rates reported among older persons and men. In 2005, disparities in tuberculosis rates persisted among members of racial and ethnic minority populations. In descending order, the highest rates per 100,000 population were reported among Asians (29.6), Native Hawaiians or other Pacific Islanders (16.1), non-Hispanic blacks (11.7), Hispanics (10.3), American Indians or Alaska Natives (8.2), and non-Hispanic whites (1.4). Foreign-born persons accounted for 54.3% of all tuberculosis cases. The percentage of foreign-born persons among all persons with tuberculosis has risen steadily since 1993, when foreign-born persons accounted for 29% of U.S. cases.

Etiology and Pathogenesis

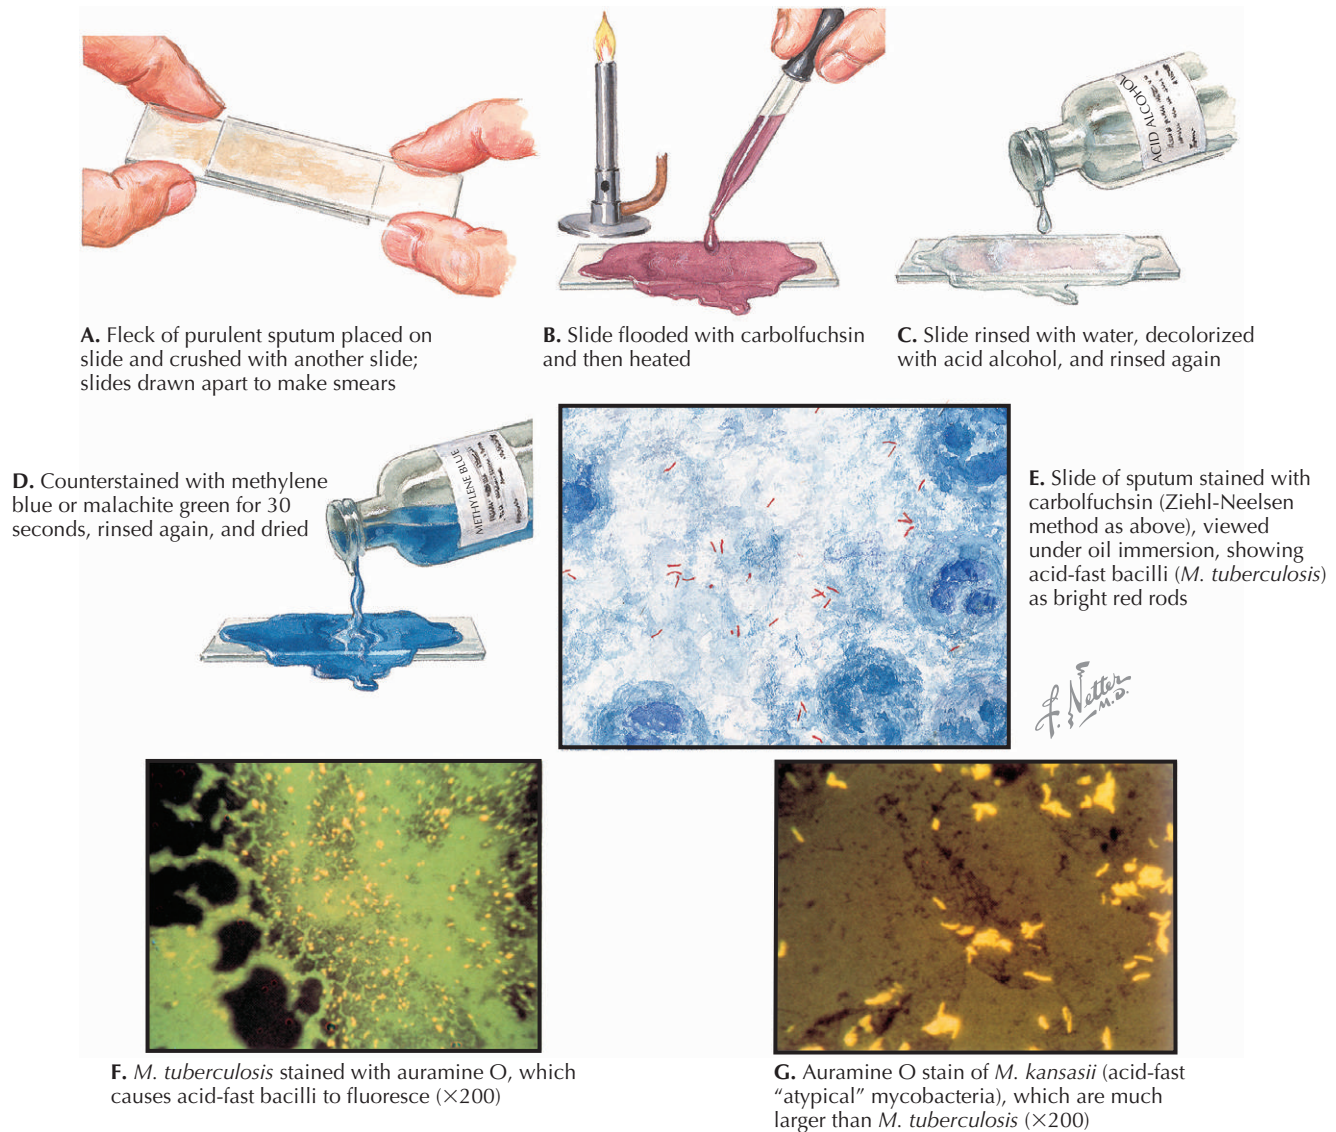

Human tuberculosis is caused by three closely related mycobacteria grouped in the *Mycobacterium tuberculosis* complex: *M. tuberculosis*, *M. bovis*, and *M. africanum*. They are aerobic, non-spore-forming, nonmotile, slightly curved or straight bacilli, 0.2 to 0.6 μm \times 1.0 to 10 μm in size. Their cell walls have a high lipid content that render them impermeable to Gram staining (termed *acid-fastness*). Most laboratories use a fluorochrome stain that allows visualization of the mycobacteria using a fluorescent microscope (Fig. 103-1).

In the United States, *M. tuberculosis* is the only important human pathogen in the *M. tuberculosis* complex. It is found worldwide, and humans are the only known reservoir. *M. bovis*, an important pathogen in developing countries, is most commonly acquired from cattle by ingestion of contaminated milk. The disease produced in humans by *M. bovis* is virtually indistinguishable from that caused by *M. tuberculosis* and is treated similarly. Bacille Calmette-Guérin (BCG), an attenuated strain of *M. bovis*, is used in many parts of the world as a vaccine to prevent tuberculosis. Although there is evidence that BCG vaccine pro-

TECTS against disseminated tuberculosis and meningitis in children, the efficacy of BCG to protect against pulmonary disease has not been proved.

Tuberculosis is spread from person to person through the air by droplet nuclei, particles 1 to 5 μm in diameter that contain *M. tuberculosis* (Fig. 103-2). Droplet nuclei are produced when persons with pulmonary or laryngeal tuberculosis cough, sneeze, speak, or sing. *M. tuberculosis* infection occurs if, after inhalation of infective droplet nuclei, viable bacilli survive the initial host defenses. The organisms grow for 2 to 10 weeks, at which time they elicit a cellular immune response that can be detected by a reaction to the tuberculin skin test (TST). Before development of cellular immunity, tubercle bacilli spread through the lymphatics to the hilar lymph nodes and then through the bloodstream to distant sites. Tuberculous disease (tuberculosis) will develop at some time in about 10% of individuals who acquire tuberculous infection and are not provided preventive therapy.

The interaction between HIV and tuberculosis is synergistic, each increasing the pathogenicity of the other. Unlike many of the pathogens associated with HIV that lead to disease only in the later stages of HIV infection

Figure 103-1 Tuberculosis: Sputum Examination (Stained Smear).

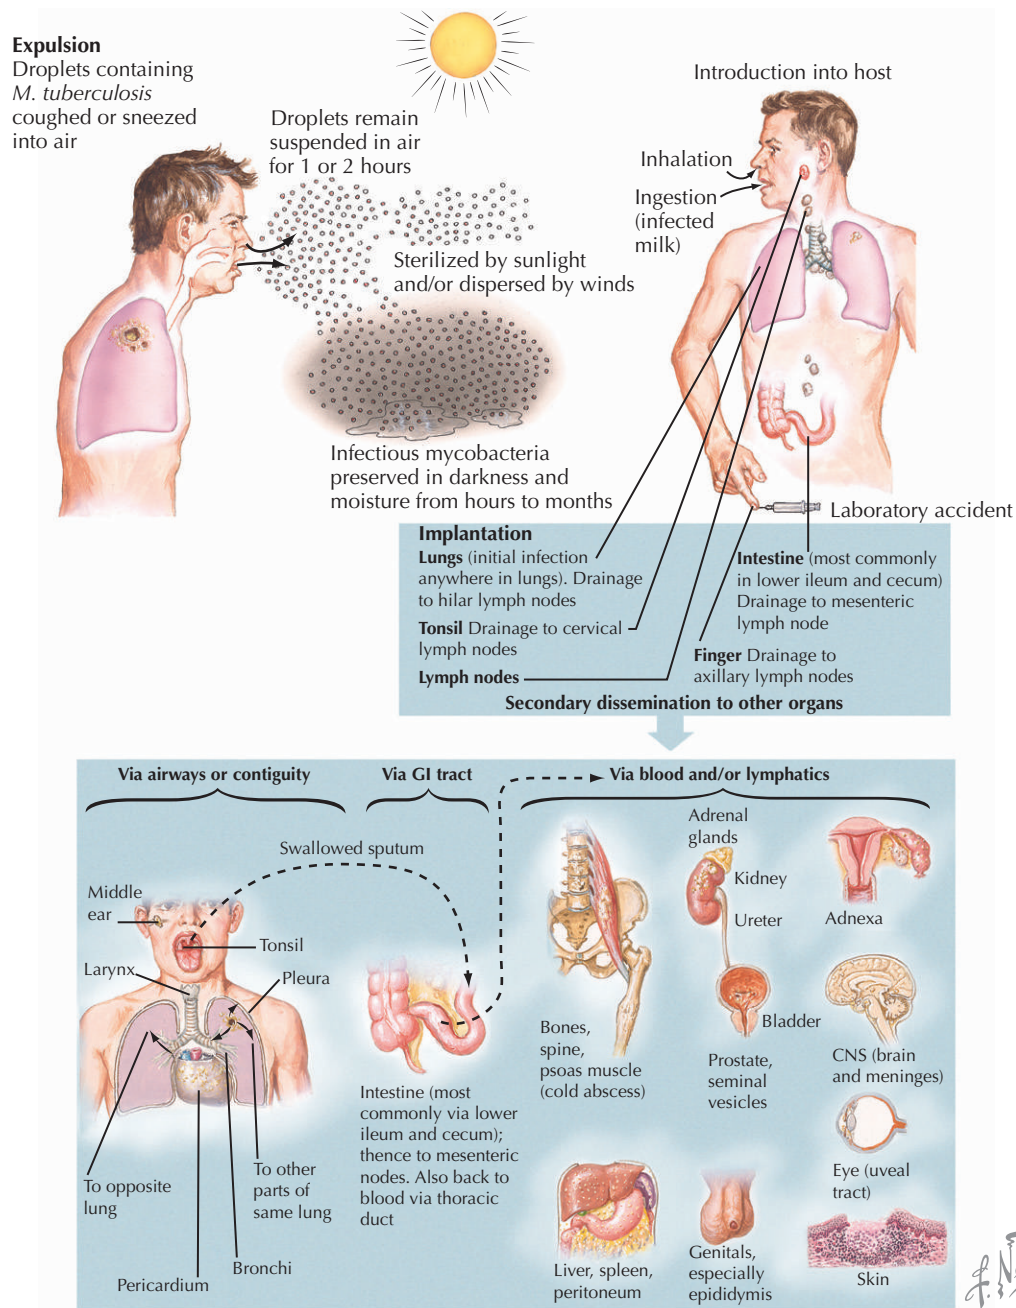

(e.g., *Pneumocystis carinii*, *Toxoplasma* species, cytomegalovirus), *M. tuberculosis* causes disease at any stage of HIV infection.

Clinical Presentation

Primary tuberculosis is generally a self-limited, mild pneumonic illness that often goes undiagnosed. Primary infection may result in granulomas visible on chest radiography. Most pulmonary tuberculosis infections are inapparent radiographically. Thus, the only indication that infection has occurred is a positive TST or whole blood interferon- γ (IFN- γ) assay.

The symptoms of tuberculosis are protean and nonspecific and can be classified as either systemic or organ-spe-

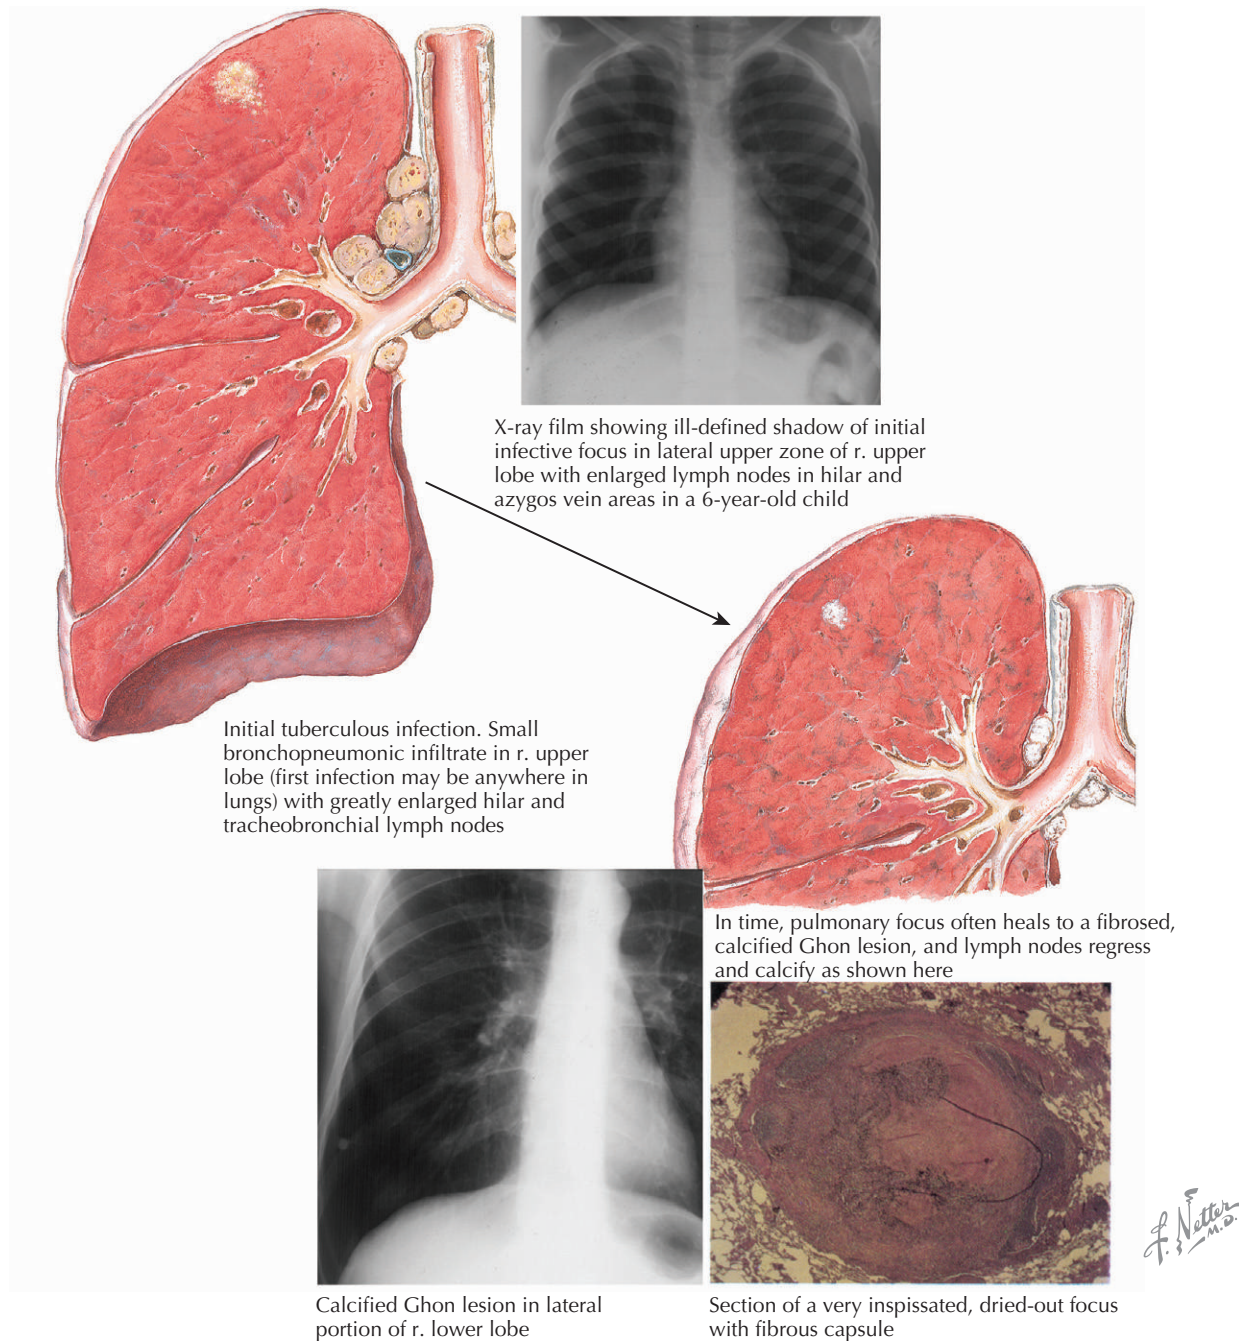

cific. Classic systemic symptoms include fever (present in about 35% to 85%), night sweats, unexplained weight loss, anorexia, and fatigue. Laboratory findings may include an increased peripheral blood leukocyte count (about 10%), anemia (about 10%), and occasionally, an increased monocyte or eosinophil count. The lung is the most common site involved, accounting for 80% of cases reported to the Centers for Disease Control and Prevention (CDC; Fig. 103-3). Organ-specific symptoms in pulmonary tuberculosis include cough, pleuritic chest pain, and hemoptysis. In primary tuberculosis, chest radiographs often show infiltrates in the middle or lower lung zones, with ipsilateral hilar adenopathy (see Fig. 103-3). In reactivation tuberculosis, classic radiographic findings include upper lobe infiltrates, frequently with cavitation. In patients infected with HIV with less than 200 CD4 cells/mm³, the radiographic

Figure 103-2 Dissemination of Tuberculosis.

findings frequently are atypical: cavitation is uncommon; lower lung zone or diffuse infiltrates and mediastinal adenopathy are frequent; and extrapulmonary disease occurs in about half of cases.

Extrapulmonary tuberculosis may involve the pleura, lymphatics, bone or joints, genitourinary system, meninges, peritoneal cavity, or other sites. It often presents a diagnostic challenge with varied symptoms and signs depending on the organ system involved. Signs and symptoms of disseminated tuberculosis are generally nonspe-

cific and include fever, weight loss, night sweats, anorexia, and weakness. A productive cough is common because most patients with disseminated disease also have pulmonary tuberculosis. Physical findings are variable but often include fever, wasting, hepatomegaly, pulmonary findings, lymphadenopathy, and splenomegaly. Small, 1- to 2-mm granulomas are visible on chest radiography in about 85% of patients. These lesions that look like millet seeds have led to disseminated disease being termed *miliary tuberculosis*.

Figure 103-3 Initial (Primary) Tuberculous Complex.

Differential Diagnosis

Patients with pulmonary tuberculosis may present with acute or chronic disease. The differential diagnosis of acute infection includes the common viral and bacterial causes of pneumonia such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Mycoplasma* species, and respiratory viruses. Chronic infection may be confused with noninfectious causes of pulmonary disease, including sarcoidosis, collagen vascular diseases, autoimmune diseases, and cancer. It

may also be confused with other causes of chronic pulmonary infection, especially endemic fungi (blastomycosis, cryptococcosis, histoplasmosis, coccidioidomycosis) and nontuberculous mycobacteria. Guidelines for when to consider pulmonary tuberculosis have been published (Box 103-1).

Tuberculosis must be considered in the diagnosis of fever of unknown origin. Mycobacterial cultures of blood, bone marrow, and liver may sometimes establish the diagnosis. Biopsy specimens of organs with evidence of dys-

Box 103-1 Guidelines for the Evaluation of Pulmonary Tuberculosis

Any patient with a cough ≥ 2 to 3 weeks' duration, with a least one additional symptom, including fever, night sweats, weight loss, or hemoptysis

Any patient at high risk for TB* with an unexplained illness, including respiratory symptoms of ≥ 2 to 3 weeks' duration

Any patient with HIV infection and unexplained cough and fever

Any patient at high risk for TB with a diagnosis of community-acquired pneumonia who has not improved after 7 days of therapy

Any patient at high risk for TB with incidental findings on chest radiograph suggestive of TB even if symptoms are minimal or absent

TB, tuberculosis.

*Patients with one of the following characteristics: recent exposure to a case of infectious TB; history of a positive test result for *Mycobacterium tuberculosis* infection; HIV infection; injection or noninjection drug use; foreign birth and immigration ≤ 5 years from a region in which incidence is high; residents and employees of high-risk congregate settings; membership in a medically underserved, low-income population; or a medical risk factor for TB (i.e., diabetes mellitus, conditions requiring prolonged corticosteroids and other immunosuppressive therapy; chronic renal failure; certain hematologic malignancies and carcinomas, weigh $>10\%$ below ideal body weight, silicosis, gastrectomy, or jejunioileal bypass).

Adapted from Taylor Z, Nolan CM, Blumberg HM; American Thoracic Society; Centers for Disease Control and Prevention; Infectious Diseases Society of America: *Controlling Tuberculosis in the United States. Recommendations from the American Thoracic Society, CDC, and the Infectious Diseases Society of America. MMWR Recomm Rep 54(RR-12):1-81, 2005.*

function or abnormalities on radiographic scans should also include culture testing for mycobacteria.

Consideration of mycobacterial infection is important in chronic organ system disorders including meningitis, peritonitis, epididymitis, pericarditis, pleuritis, and osteomyelitis. The finding of granulomas on biopsy should always raise the suspicion of tuberculosis, although they may also be found in histoplasmosis, coccidioidomycosis, blastomycosis, and sarcoidosis.

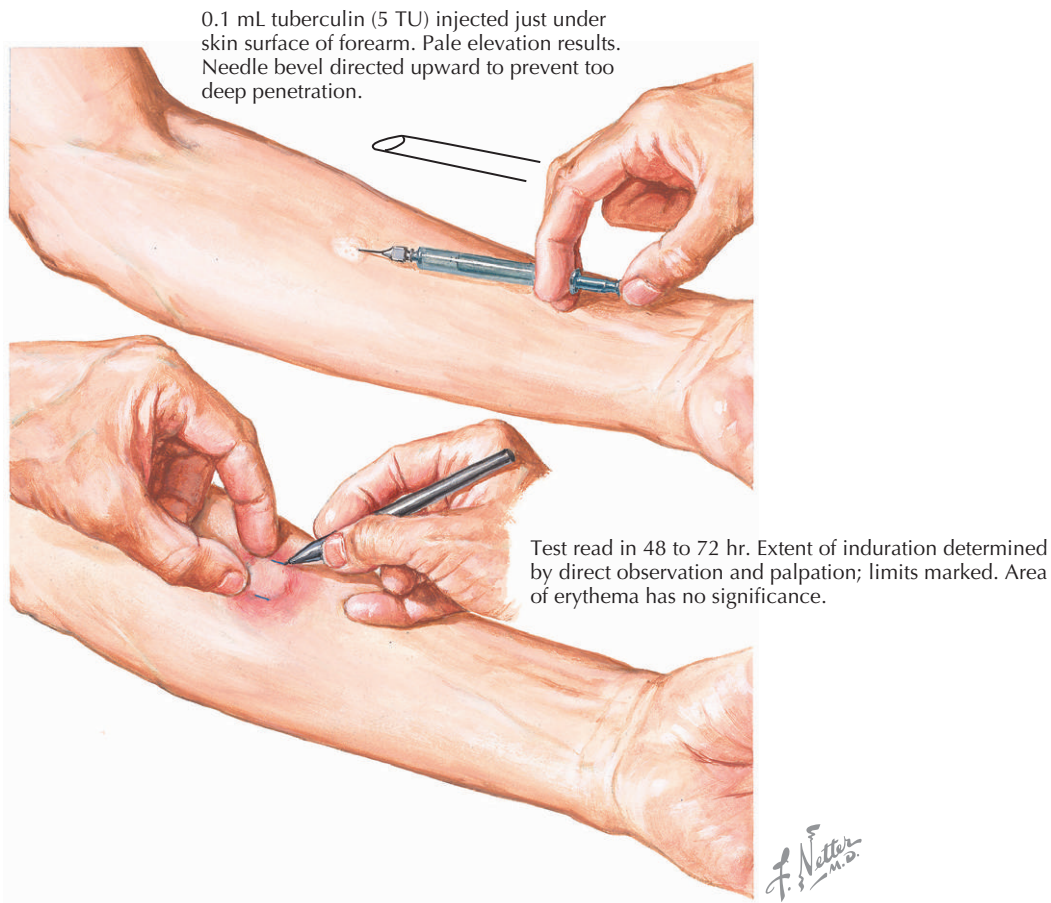

Recently, tuberculosis has been associated with the use of tumor necrosis factor- α (TNF- α) antagonists. These drugs (infliximab, etanercept, adalimumab) are effective in the management of rheumatoid arthritis and active Crohn's disease. They have been used to treat Behçet's disease, psoriasis, uveitis, pyoderma gangrenosum, Still's disease, sarcoidosis, and Sjögren's syndrome. Most cases of tuberculosis have been reported with infliximab, but etanercept and adalimumab may also be associated with an increased risk. Potential recipients of these drugs should be screened with a TST or QuantiFERON tuberculosis Gold test (QFT-G, see later), detailed questionnaire about recent travel and potential tuberculosis exposures, assessment for symptoms such as cough and weight loss, and chest radi-

ography to minimize their risk for acquiring or reactivating tuberculosis. Patients with latent tuberculosis should receive therapy before initiation of therapy with TNF- α antagonists.

Diagnostic Approach

Until recently, latent tuberculosis infection (LTBI) could only be detected by a TST using purified protein derivative (PPD) (Fig. 103-4). This test is subject to both false-positive and false-negative results (Table 103-1) that can be minimized by careful attention to proper placement and interpretation of the test. In most persons, TST sensitivity persists throughout life; however, the size of the skin test may decrease and disappear over time. If PPD is administered to infected persons whose skin tests have waned, an initial test may be small or absent, but a subsequent test (2 to 4 weeks later) may demonstrate an accentuated response. This booster effect should not be misinterpreted as skin test conversion, but rather the second test should be considered as reflecting the individual's true exposure to *M. tuberculosis*. Two-step testing is recommended in people who are likely to undergo repeated tuberculin testing (i.e., health care workers) or for whom immunity is likely to have waned (i.e., elderly people), and who have not had a TST within the previous 12 months. The criteria used for classifying a TST result as positive are based on the size of induration and epidemiologic and clinical characteristics of the patient (Table 103-2). The sensitivity of the TST to detect active tuberculosis is in the range of 75% to 80% but may be lower in some groups such as elderly and HIV-infected persons. The specificity of the TST is about 99% in populations that have no other mycobacterial exposure or BCG vaccination, but decreases to about 95% in populations in which cross-reactivity with other mycobacteria is common (e.g., Southeast United States). Routine testing is recommended only for high-prevalence and high-risk groups (see Table 103-1). Prior receipt of BCG vaccination does not alter the interpretation of TST reactivity. Pregnancy is not a contraindication to TST.

More recently, a blood test, the QFT-G, has become available for diagnosing latent tuberculous infection. The QFT-G test includes a mixture of synthetic peptides representing two *M. tuberculosis* proteins, ESAT-6 and CFP-10. If the patient is infected with *M. tuberculosis*, white blood cells will release IFN- γ in response to contact with these antigens. In the QFT-G test, the patient's blood is incubated with the test antigens for 16 to 24 hours and the amount of IFN- γ is measured. QFT-G can be used in all circumstances in which the TST is currently used, including contact investigations, evaluation of recent immigrants who have had BCG vaccination, and tuberculosis screening of health care workers. Potential advantages of the QFT-G include convenience; avoidance of subjectivity inherent in measurements of cutaneous induration produced by the TST; the need for only one patient visit; and

Figure 103-4 Tuberculin Testing.**Table 103-1** Potential Causes of False-Positive and False-Negative Tuberculin Reactions

Causes of False-Positive Reactions	Causes of False-Negative Reactions
Mistaking erythema for induration Infection with nontuberculous mycobacteria Receipt of BCG vaccine Early reading of skin test with reaction due to immunoglobulins rather than cell-mediated immunity Use of incorrect strength of PPD (i.e., 250 TU)	Anergy due to overwhelming tuberculous infection Recent infection with <i>M. tuberculosis</i> (<10 weeks) Drugs (steroids, immunosuppressive agents) Metabolic derangements (e.g., chronic liver or renal disease)
Poorly standardized antigen	Immune suppressive diseases (e.g., HIV, hematologic malignancies, or lymphoma) Malnourishment Recent receipt of live virus vaccine (e.g., measles) Newborns, elderly population Improper storage or dilution of PPD Inappropriate administration (e.g., too little antigen, or subcutaneous administration) Errors in reading or recording TST

BCG, bacillus of Calmette-Guerin; PPD, purified protein derivative; TST, tuberculin skin test; TU, tuberculin unit.

Am J Respir Crit Care Med* 161(4 Pt 2):S221-S247, 2000. Also adapted from *Screening for tuberculosis and tuberculosis infection in high-risk populations. Recommendations of the Advisory Council for the Elimination of TB. MMWR Recomm Rep* 44(RR-11):19-34, 1995.

the ability to perform repeated testing without boosting the response, as may occur with serial tuberculin testing. However, caution should be used when testing certain populations because of limited data in the use of QFT-G, including immunocompromised persons, patients with extrapulmonary tuberculosis, children, and populations in high-incidence countries. In addition, there are limited data on the long-term reproducibility of this assay, particularly in serial testing situation (e.g., health care workers). Before the QFT-G is conducted, arrangements should be made with a qualified laboratory and courier service, if needed, to ensure prompt and proper processing of blood.

For suspected active tuberculosis, all patients should be evaluated with a TST. A careful history should attempt to elicit the nonspecific symptoms of tuberculosis and organ-specific symptoms, especially of pulmonary disease. Physical examination is of limited utility in the diagnosis but may aid in detecting specific organ infection requiring further investigation. All patients with a positive TST or QFT-G result or symptoms of tuberculosis should have a chest radiograph to aid in the diagnosis of pulmonary tuberculosis and to determine the extent of disease.

A presumptive diagnosis of pulmonary tuberculosis can often be made using the chest radiograph. For suspected cases of pulmonary tuberculosis, mycobacteria may be demonstrated in sputum by acid-fast staining (Ziehl-Neelsen or Kinyoun method) or a fluorochrome procedure using auramine-O or auramine-rhodamine dyes. Smear positivity indicates greater infectiousness. For smear-

positive pulmonary cases, a nucleic acid amplification assay (NAA) can be used to rapidly detect *M. tuberculosis*, with a sensitivity of about 95% and specificity approaching 100%. The U.S. Food and Drug Administration advises against the use of NAA in smear-negative samples because of low sensitivity.

Isolation of *M. tuberculosis* from specimens of sputum and other tissues is essential for confirmation of the identity of the organism and for subsequent drug susceptibility testing, which is recommended for initial isolates for each patient. Cultures also remain the cornerstone for the diagnosis of tuberculosis in smear-negative pulmonary and extrapulmonary cases and, along with sputum smears for acid-fast bacillus, provide the basis for monitoring a patient's response to treatment, for release from isolation, and for diagnosing treatment failure and relapse. Sputum may be obtained every 8 to 12 hours. Induction of sputum with hypertonic saline may increase the yield of obtaining adequate sputum specimens, especially in HIV-infected patients. Detection of mycobacterial growth on conventional Löwenstein-Jensen or Middlebrook 7H10 medium requires 4 to 8 weeks. Assays that detect either the production of carbon dioxide or the consumption of small amounts of oxygen by microorganisms in culture may be used to detect mycobacterial growth in 14 to 21 days. The precise time required for detection of mycobacteria by these metabolic assays is largely dependent on the number of organisms in the inoculum. A computed tomography scan may provide valuable information in assessing whether an abnormal chest radiograph is consistent with tuberculosis.

Table 103-3 Recommended Therapy for Latent Tuberculous Infection

Drug	Duration (mo)	Interval	Rating* (Evidence) [†]	
			HIV Negative	HIV Positive
Isoniazid	9	Daily	A (II)	A (II)
		Twice weekly	B (II)	B (II)
Isoniazid	6	Daily	B (I)	C (I)
		Twice weekly	B (II)	C (I)
Rifampin	4	Daily	B (II)	B (III)

*A, preferred; B, acceptable alternative; C, offer when A and B cannot be given.

[†]I, Randomized clinical trial data; II, data from clinical trials that are not randomized or were conducted in other populations; III, expert opinion. From *Targeted tuberculin testing and treatment of latent tuberculosis infection. A joint statement of the American Thoracic Society (ATS) and the Centers for Disease Control and Prevention (CDC). Am J Respir Crit Care Med* 161(4 Pt 2):S221-S247, 2000.

Aspiration of gastric fluid for culture is often helpful in young children unable to produce sputum. Fiberoptic bronchoscopy is a useful diagnostic test to obtain specimens from the respiratory tract in patients unable to produce sputum.

The diagnosis of extrapulmonary tuberculosis usually requires an invasive procedure to obtain fluid (e.g., cerebrospinal fluid [CSF]) for smear or culture, and biopsy to obtain tissue for culture. A first morning-voided midstream urine specimen should be cultured to establish the diagnosis of genitourinary tuberculosis. Blood for mycobacterial culture should be anticoagulated with heparin and processed by a lysis-centrifugation system or inoculated into broth media designed for mycobacterial blood cultures. The diagnosis of central nervous system tuberculosis is established by culture of the CSF; a minimum of 5 mL of fluid should be submitted to the laboratory in a sterile container for culture. Invasive procedures to obtain specimens from the lung, pericardium, lymph nodes, bones and joints, bowel, salpinges, and epididymis warrant consideration when noninvasive techniques do not provide a diagnosis. Antimicrobial susceptibility testing is essential on all cultures that yield *M. tuberculosis*.

Management and Therapy

Optimum Treatment

All patients with known or suspected tuberculosis should be placed on airborne precautions (>6 to 12 air exchanges per hour, negative pressure, and air directly exhausted to the outside) when receiving care within a health care facility. Health care personnel should don an N95 respirator before entering the room of a patient with potentially communicable tuberculosis. Patients should remain on airborne isolation until they have received at least 2 to 3 weeks of standard multidrug antituberculosis therapy, demonstrated clinical improvement (i.e., reduction in the frequency of cough), and have three consecutive negative sputum smears cultured 8 to 24 hours apart with at least

one sputum being an early morning specimen. Patients with known or suspected multidrug-resistant *M. tuberculosis* should remain isolated until culture results are negative. Close contacts of persons with active pulmonary tuberculosis require evaluation for tuberculosis because active disease is already present in 2% to 3% and latent infection in 5% to 15%.

All persons with a reactive TST (see Table 103-1) or positive QFT-G should have therapy of LTBI recommended (Table 103-3) after excluding active tuberculosis with history, physical examination, chest radiography, and bacteriologic studies (when indicated). Ideally, patients should receive follow-up evaluations at least monthly. Follow-up evaluations should include questioning about adverse drug reactions and a brief physical assessment for signs of hepatitis. Baseline testing of liver function (i.e., alanine transaminase/aspartate transaminase and bilirubin) is recommended only for persons at high risk for liver dysfunction, including patients with HIV infection, persons with a history of chronic liver disease (e.g., hepatitis C), pregnant women, postpartum women within 3 months of delivery, and persons who use alcohol regularly. Active hepatitis and end-stage liver disease are relative contraindications to the use of isoniazid or pyrazinamide. Routine monitoring during treatment of LTBI is indicated for persons whose baseline liver function test results are abnormal and persons at risk for hepatic disease. Such tests should also be performed on persons with signs or symptoms of hepatitis. Isoniazid therapy should be stopped if transaminase levels exceed three times the upper limit of normal if associated with symptoms, and five times the upper limit of normal if the patient is asymptomatic.

Patients with active tuberculosis require therapy with multiple drugs to prevent the development of resistance, enhance tuberculocidal therapy, and properly treat if their strain of *M. tuberculosis* is resistant to one or more drugs. The preferred regimen for patients with fully susceptible bacilli is a 6-month course initially consisting of isoniazid, rifampin, ethambutol (use streptomycin in children too young to be monitored for visual acuity), and pyrazin-

amide, given for 2 months, followed by isoniazid and rifampin for 4 months. If there is evidence of a slow or suboptimal response, therapy should be given for a total of 9 months, or for 4 months after culture results become negative. All patients should be treated using enhanced, directly observed therapy (DOT) to ensure compliance. Extrapulmonary tuberculosis in adults should be managed in a manner similar to that for pulmonary tuberculosis (i.e., 6 months of therapy), except for meningitis for which a 9- to 12-month regimen is recommended. Children who have miliary tuberculosis, bone and joint tuberculosis, or tuberculous meningitis, should receive a minimum of 12 months of therapy. Expert consultation is usually needed when treating tuberculosis in HIV-infected persons because treatment is more difficult because of the possibility of malabsorption of antituberculous medications and because of drug interactions between rifampin and protease inhibitors.

Physicians should be familiar with the administration, adverse reactions, and contraindications of the first-line antituberculous medications. In pulmonary tuberculosis, the response to therapy is monitored by obtaining follow-up sputa for culture. Reevaluation of therapy is necessary if sputum culture results have not become negative after 2 months. In this case, repeat drug susceptibility testing is essential, and DOT therapy should be continued or initiated. Patient education with regard to compliance, symptoms of drug toxicity, and drug interactions is critical to ensure proper therapy.

Treating persons dually infected with HIV and *M. tuberculosis* is challenging because of potential overlapping toxicities, drug interactions, and paradoxical reactions. For example, many antiretrovirals interact with antituberculous medications, especially the rifamycins. In HIV treatment-naïve patients, the timing of initiating highly active antiretroviral therapy (HAART) is complex. Consultation with an infectious disease specialist is recommended. Multidrug resistance (MDR), defined as resistance to at least isoniazid and rifampin, is a growing problem worldwide. In the United States, MDR tuberculosis is more common in persons who are foreign born, who remain culture positive, or whose symptoms do not resolve after 3 months of therapy. All patients with MDR tuberculosis should receive DOT and be managed by persons familiar with use of second-line medications such as aminoglycosides (e.g., streptomycin), polypeptides, fluoroquinolones (e.g., ciprofloxacin), thioamides, cycloserine, and para-aminosalicylic acid. Use of second-line drugs is less effective, more toxic, and costlier than use of first-line isoniazid- and rifampin-based regimens. Recently, extensively drug-resistant (XDR) tuberculosis has emerged as a worldwide problem. The CDC and World Health Organization define XDR tuberculosis as the occurrence of tuberculosis in persons whose *M. tuberculosis* isolates are resistant to isoniazid and rifampin and also to any fluoroquinolone and at least one of three injectable second-line

drugs (i.e., amikacin, kanamycin, or capreomycin). Between 2000 and 2006, about 1% of culture-confirmed cases (N = 922) in the United States were due to MDR TB strains; of these MDR TB strains, about 2% (N = 17) were due to XDR TB strains. Although XDR TB is uncommon in the United States, it is more common in South Korea (15% of all MDR tuberculosis isolates) and the countries of eastern Europe and western Asia (14% of all MDR tuberculosis isolates).

Avoiding Treatment Errors

The most common error in detecting tuberculosis is failure to consider the diagnosis in a patient as it often presents with protean manifestations including low-grade fever, gradual weight loss, cough, night sweats, and fatigue. An appropriate evaluation with a chest radiograph and three sputum collections for smear plus culture will usually allow detection of pulmonary tuberculosis. Diagnosis of extrapulmonary disease is more difficult because it usually requires an invasive procedure. Tissue is the preferred source for material for smears and cultures to detect extrapulmonary tuberculosis rather than fluids (e.g., peritoneal biopsy rather than ascites fluid, pericardial tissue rather than pericardial fluid). A bone marrow aspirate or biopsy is often useful to detect disseminated tuberculosis (laboratory should be notified ahead of time to expect the specimen).

To prevent possible nosocomial transmission, all patients with known or *suspected* tuberculosis should immediately be placed on airborne precautions. Health care personnel should be properly trained in the use of an N95 respirator.

Patients with LTBI should be carefully counseled regarding the need to properly take their medications and to complete the entire course of therapy. Patients with active tuberculosis should ideally be treated with DOT. Failure to properly take medications or complete a full course of antituberculous therapy is the main reason for the development of drug resistance.

Future Directions

The major challenges of tuberculosis are the increasing proportion of multidrug-resistant strains and the prevention and treatment of tuberculosis in HIV-infected persons. Progress against tuberculosis is being made on several fronts. New diagnostic tests are being developed for the rapid detection of *M. tuberculosis* (e.g., polymerase chain reaction) in sputum or tissue samples, and for the rapid identification of drug-resistant strains. New drugs are being studied for the therapy of tuberculosis, including the quinolone moxifloxacin, nitroimidazopyrans (e.g., PA-824), macrolides (e.g., azithromycin, clarithromycin), oxazolidinones (e.g., linezolid, PNU-100480), diamines (e.g., SQ109), and ring-substituted imidazoles. Finally, a major

research effort is being directed toward developing new tuberculosis vaccines. Several candidate vaccines should be ready for human testing within a few years.

Fungal Infections

Introduction

The incidence of medically significant fungal infections has dramatically increased over the past two decades and strongly correlates with the rise in the number of immunocompromised patients. The AIDS epidemic, the expansion of stem cell and solid organ transplantation, and the ever-increasing use of chemotherapy and immunosuppressive agents have placed more hosts at risk for invasive fungal disease and have broadened the range of fungi capable of causing significant disease in humans (Box 104-1). During the past decade, significant advances have occurred in the diagnosis and treatment of these infections as several new antifungal drugs have become available. However, given the complexity of the population of patients who remain at highest risk for these infections (Box 104-2), substantial challenges in, and opportunities for, early diagnosis and management remain. Mortality remains high in certain settings and can be as high as 90% for invasive mold infections in hematopoietic stem cell transplant recipients.

Fungi can exist as yeast or molds (also spelled “moulds”). Yeast-like fungi generally are round, unicellular organisms that reproduce by budding and form flat smooth colonies. Molds are composed of longitudinal tubular structures called hyphae, grow by extension, and have a fuzzy appearance on a growth plate. Although most fungi exist as either yeast or molds, the dimorphic fungi, which include the agents of histoplasmosis, blastomycosis, sporotrichosis, coccidioidomycosis, paracoccidioidomycosis, and chromoblastosis, grow in the host as a yeast but exist in the environment as a mold. Mycoses are infections caused by fungi. With rare exception, mycoses are generally not transmissible from one person to another.

The fungal cell wall is a rigid barrier composed of glucans and chitin. Some fungi, such as *Cryptococcus* species, have a polysaccharide capsule that acts as an added layer of protection and aids in evasion from the immune system. Inside the cell wall is the cytoplasmic membrane that contains ergosterols. Antifungal agents such as azoles and polyene antifungal agents target ergosterols. The new echinocandin class of antifungals targets the production of β -D-glucan in the cell wall (Table 104-1).

Current diagnostic testing includes culture of the affected site, histologic examination of tissue with the use of special staining techniques (Gomori methenamine-silver, periodic acid-Schiff, and calcofluor stain), use of antigen studies (the galactomannan, β -1,3-D-glucan, cryptococcal and histoplasmic antigen assays) and paired acute and convalescent antibody titers. There are limitations to the utility of antibody-based studies. Cross-reactivity and high false-negative rates, particularly in immunocompromised hosts who cannot mount a forceful humoral immune response, can limit the accuracy of this approach. Thus, the current standard for diagnosis of invasive fungal infections relies primarily on clinical suspicion, culture, and histopathologic diagnosis.

HIV-Related Immunodeficiency

Many mycoses are caused by important pathogens in those with immunosuppression caused by HIV, including candidiasis, cryptococcosis, histoplasmosis, and pneumocystosis. Histoplasmosis is discussed in the section on endemic

fungi. Mucocutaneous candidiasis is extremely common in people with AIDS and can be a clue to the diagnosis of immune system dysfunction in the setting of HIV/AIDS. Its presence in a previously healthy patient should prompt an evaluation for an underlying immunologic problem such as malignancy or AIDS. (See “Candidiasis.”)

Cryptococcosis

Cryptococcus neoformans is an encapsulated yeast-like organism that can cause disease in both immunocompetent and immunocompromised hosts but has been an important cause of morbidity and mortality in people with AIDS (Fig. 104-1). *Cryptococcus* is found in soil contaminated with pigeon droppings. Infection occurs after inhalation of the organism with dissemination to other organs through the

Box 104-2 People at Risk for Invasive Fungal Infections
<ul style="list-style-type: none"> Transplant recipients (solid organ and bone marrow transplantations) Patients with hematologic malignancies (leukemias, lymphomas) Injection drug users People with HIV/AIDS and low CD4 counts/advanced immunosuppression Immunosuppressive drug therapy (chemotherapy, corticosteroids, tumor necrosis factor inhibitors, cyclosporine, azathioprine, CellCept, sirolimus, anakinra) Preterm infants (<26 weeks' gestation or <1000 g) Hospitalized patients with: <ul style="list-style-type: none"> ▪ Prolonged length of stay ▪ Intensive care unit ▪ Broad-spectrum antibiotics ▪ High acuity ▪ Diabetes mellitus ▪ Renal failure and hemodialysis ▪ Parenteral nutrition ▪ Cancer and chemotherapy ▪ Severe pancreatitis ▪ Major surgery ▪ Invasive devices (urinary catheters, central venous catheters)

bloodstream. Although the organism can remain in the bloodstream and cause disease in the lungs, urinary tract, skin, joints, and bones, the most common sites of disease are the brain and the meninges. Before the advent of combination antiretroviral therapy, 5% to 10% of people with HIV developed cryptococcal meningitis.

The clinical course can be subacute or acute, with the typical signs and symptoms of meningitis, including fever, nuchal rigidity, photophobia, lethargy, and confusion. Diagnosis can be made by fungal stain and culture of the cerebrospinal fluid (including India ink stain). The cryptococcal antigen assay can also detect the presence of the organism in serum and cerebrospinal fluid. Poor prognostic features include altered mental status at the time of presentation, high opening pressure on lumbar puncture, and a low cerebrospinal fluid white blood cell count, which suggests more advanced immunosuppression. If left untreated, the mortality rate is virtually 100%.

For patients with HIV and meningeal disease, treatment guidelines recommend induction therapy with amphotericin B (or a lipid formulation) at 0.7 to 1 mg/kg/day plus flucytosine (100 mg/kg/day) for 2 weeks followed by a minimum of 10 weeks of oral fluconazole (400 mg/day), followed by lifelong suppression with fluconazole, 200 mg/day. Recent data support discontinuation of maintenance fluconazole in patients with immune reconstitution after the institution of highly active antiretroviral therapy.

Pneumocystosis

Pneumocystis jiroveci is the etiologic agent of pneumocystis pneumonia (PCP). It is an unusual organism that was originally classified as a protozoan but recently was reclassified based on ribosomal ribonucleic acid analysis as a unicellular fungi. It lacks ergosterol in its cellular membrane, however, and is thus unresponsive to treatment with azole and polyene antifungal agents. *Pneumocystis* was recognized as a rare cause of pneumonia in immunocompromised hosts before the AIDS epidemic. There was a dramatic rise in the incidence and mortality related to this pathogen in patients with AIDS in the 1980s and 1990s (Fig. 104-2). Although the advent of highly active anti-retroviral therapy caused a significant decrease in the incidence of PCP in the late 1990s, there are still about 16,000 cases per year in the United States, and it remains the most common AIDS-related opportunistic infection, often occurring in people who are unaware of their HIV diagnosis. There is now increasing recognition of the importance of this pathogen as a cause of pneumonia in developing countries of Africa and Asia in the setting of the AIDS pandemic.

Pneumocystis jiroveci can cause a subacute or acute pneumonia that can deteriorate rapidly to respiratory failure. Chest x-ray findings can include honeycombing (which gave rise to the name pneumocystis), interstitial infiltrates, or minimal abnormalities, but these findings usually are not associated with pleural effusions. The serum lactate dehydrogenase level may be elevated, and generally there is a widened alveolar-arterial oxygen gradient. Diagnosis is made using high clinical index of suspicion, symptoms of dyspnea on exertion, fever, chest pain, and progressive shortness of breath paired with imaging findings and visu-

alization of trophozoites or cysts on special staining of deep (induced) sputum or specimens obtained by bronchoscopy. The organism cannot be cultured. Treatment includes high-dose trimethoprim-sulfamethoxazole (15 mg/kg/day divided in three doses given intravenously or orally) for 21 days followed by chemoprophylaxis; if the partial pressure of oxygen is less than 70 mm Hg or the alveolar-arterial gradient is more than 35 mm Hg, a course of corticosteroids is recommended at the start of therapy to decrease the inflammatory response and subsequent lung damage during treatment.

Candidiasis

Etiology and Pathogenesis

About 154 species of the yeast *Candida* have been described. *Candida* exists as part of the normal human flora of the genitourinary and gastrointestinal tracts and heavily colonizes the skin. It remains the most common cause of fungal infections worldwide and is of particular significance in the hospital setting. Fungal infections make up about 8% of all nosocomial infections, and of these, 80% are attributable to *Candida* species. Historically, *Candida albicans* was the primary candidal pathogen in humans. However, a recent epidemiologic shift has been documented with a rise in the proportion of non-*albicans* species such as *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, and *C. krusei*. This is particularly significant because these species can be resistant to fluconazole, which is commonly used in prevention and as first-line therapy.

Candida of most species form biofilms, which are a matrix-enclosed population that adheres to a surface. These form on catheters and are difficult to eradicate,

Figure 104-1 Cryptococcosis and Torulosis.

allowing persistence in sterile sites through instrumentation such as bladder catheters, abdominal drains, and central venous lines. *Candida* species represent the fourth most common bloodstream isolate, and mortality rates range from 30% to 60%. Candidemia also accounts for about a 10-day increase in hospital length of stay. Candidiasis is more common in patients who have undergone stem cell or solid organ transplantation or prolonged care in an intensive care unit and those who have a history of intravenous drug use, a prolonged course of antibiotics, parenteral nutrition, frequent major surgeries, or AIDS.

Clinical Presentation and Diagnostic Approach

Candida species infection causes a wide spectrum of disease, ranging from vulvovaginitis to oropharyngeal (“thrush”) and esophageal candidiasis, cheilitis, bloodstream infections, endocarditis, surgical abdominal infections, urinary tract infections, and deep-seated organ infection. The type of infection is strongly influenced by the host’s immune status. Vulvovaginal candidiasis is most commonly observed in immunocompetent women, particularly in the setting of antibiotic usage with alterations in the normal flora. Hema-

Figure 104-2 *Pneumocystis carinii* Pneumonia.

togenous disseminated candidal infection is more commonly found after stem cell transplantation and in the setting of prolonged neutropenia. Mucocutaneous candidiasis is commonly seen in individuals with cell-mediated immune dysfunction, such as those with chronic steroid use or AIDS. Invasive candidiasis often presents with non-specific clinical manifestations such as fever and signs and symptoms of sepsis. However, chorioretinitis, nodular skin lesions that can be excised for biopsy, and hepatosplenic abscesses can be specific clues to its diagnosis.

Culture is the mainstay of diagnosis but can take several days, and often treatment must begin empirically. *Candida* that can be grown from a sterile site such as the peritoneum or the bloodstream provides definite evidence of infection. However, positive cultures from pulmonary

specimens and urinary specimens in patients who have a bladder catheter in place may indicate colonization rather than active infection. These cultures must be interpreted in the context of the immune status of the host and other clinical signs and symptoms. The β -1,3-D-glucan assay is under investigation as an antigen-based diagnostic technique to rapidly detect invasive candidiasis and, thus, could be useful in selecting candidates who need aggressive therapy.

Management and Therapy

Candida species are susceptible to all three antifungal classes of drugs, and all are used in different settings to prevent and treat infection. However, certain non-*albicans* species such as *C. glabrata* can be resistant to fluconazole,

and this resistance does, in some cases, cross over to other azoles. *C. krusei* is inherently resistant to fluconazole but remains susceptible to voriconazole. Susceptibility testing has recently become available in many academic and research settings for different candidal species, and these patterns of susceptibility differ by geography and medical setting. For treatment of mucocutaneous disease, topical treatments can be used initially. If extensive thrush or esophagitis is present, fluconazole (100 to 200 mg/day) is initiated for a short course. In those with severe immunosuppression who relapse at the end of therapy, chronic suppression with fluconazole is recommended. In the setting of candidemia, the central venous line must be removed expediently and an evaluation undertaken to exclude endocarditis. For initial treatment, amphotericin B (or a lipid formulation, based on side-effect profile) or an echinocandin offers full susceptibility, although there are in vitro data to suggest decreased activity of *C. parapsilosis* to echinocandins. The clinical importance of these data remains unclear. Once the organism is identified and susceptibility data are complete, the provider can tailor therapy accordingly. Invasive disease from *Candida* species is generally treated for a prolonged course depending on the site involved and the level of immunosuppression of the patient.

Infections in Oncology, Transplantation, and Severely Immunocompromised Hosts

Aspergillus

Aspergilli are filamentous molds that generate conidia, the spore formed at the side or tip of the hyphae. There are multiple different strains of aspergillus, although most infections are due to *Aspergillus fumigatus*, *Aspergillus flavus*, *Aspergillus niger*, and *Aspergillus terreus* (Fig. 104-3). Aspergillus organisms are ubiquitous, and significant numbers are found in soil, dust, and possibly water. The type of infection caused by aspergillus differs based on the immune state of the individual (Table 104-2). Most commonly, individuals acquire infection with aspergillus species by inhalation.

The diagnosis of aspergillosis has been extensively reviewed and a system generated to discern the likelihood of infection. Radiologic findings include nodular lesions, cavities, or the halo sign, which represents edema surrounding a pulmonary nodule. A definite diagnosis of aspergillosis requires culture of the organism from sterile sites or identification of the organism in tissue with a positive culture. Probable aspergillosis requires identification of the organism in tissue in the absence of a positive culture or the identification of the organism in bronchoalveolar lavage sample in the presence of an abnormal radiograph. For transplant recipients who have a higher probability of infection, the criteria for “definite” disease is not generally required to consider therapy. Radiographic evidence in the presence of a culture from bronchoalveolar lavage and the absence of other organisms supports the diagnosis of aspergillosis.

Mortality associated with aspergillosis in the immunocompromised individual is quite high and approaches 60% to 95% in allogeneic stem cell transplant recipients. For this reason, prompt diagnosis is critical. Neutropenia and prolonged use of corticosteroids are significant risk factors for infection. The mainstay of therapy at this time is voriconazole (4 mg/kg intravenously given twice a day preceded by a 6 mg/kg loading dose for two doses) followed by prolonged oral therapy at 200 mg twice a day. There are no current data to indicate whether surgical resection or combination antifungal therapy using an echinocandin and azole or polyene is indicated for invasive or disseminated disease.

Several new noninvasive tests have become available for the diagnosis of aspergillosis. The test most commonly used in the United States is the Platelia galactomannan enzyme-linked immunosorbent assay that detects galactomannan, which is a fungal component present in serum of infected hosts. The galactomannan assay cutoff for positive in the United States is 0.5, and typically two consecutive positive tests improve its specificity. False-positive reactions can occur in patients infected with other molds, in neonates, and in individuals receiving antibiotics generated from fungal products such as piperacillin-tazobactam. False-negative tests are seen in individuals on fungal

Table 104-2 Clinical Manifestations of *Aspergillus* Infections

Type	Immune Status of Host	Clinical Manifestations	Treatment
Allergic bronchopulmonary aspergillosis	Immune competent	Asthma	Steroids, voriconazole
Aspergilloma	Immune competent	Often asymptomatic, cough, malaise, weight loss, hemoptysis	Surgical resection, voriconazole
Invasive pulmonary	Immune compromised	Fever, chest pain, cough, shortness of breath; radiographic findings	Voriconazole
Disseminated invasive	Immune compromised	Organ system dependent	Voriconazole with or without echinocandin
Sino-orbital	Immune competent and immune compromised	Acute form: fever, headache, facial pain; chronic form: headache, congestion	Voriconazole

Gross appearance of an aspergilloma in a chronic lung cavity

Tomogram of an aspergilloma within a cavity in l. upper lobe, demonstrating characteristic radiolucent crescent above fungus ball

Structure of fruiting form of *Aspergillus niger*. Other species of *Aspergillus* vary in configuration, but their general structure is similar

Microscopic structure of an aspergilloma composed of a tangled mass of hyphae within a dilated bronchus. No evidence of tissue invasion

prophylaxis. Other tests that can be used are assays for detecting circulating β -1,3-D-glucan and real-time polymerase chain reaction techniques. The galactomannan assay is helpful in monitoring response to therapy because this test should rapidly normalize in adequately treated patients.

Zygomycetes

Zygomycetes are a group of fungi predominantly found in soil that cause infections primarily in immunocompro-

mised hosts. There are multiple different species of fungi in the zygomycete family (see Box 104-1). Zygomycete infections are typically acquired from aerosol exposure to the fungus in a susceptible host. Thus, the most common sites of zygomycete infection are rhinocerebral and pulmonary, with less common sites of infection being the gastrointestinal tract, skin, kidney, and central nervous system. The most common risk factors for zygomycete infection are diabetes mellitus, neutropenia, allogeneic stem cell and solid organ transplantation, and individuals chronically treated with corticosteroids. Because the organism requires

iron for growth and can utilize chelated iron, treatment with the iron chelation agent deferoxamine is a risk factor for invasive zygomycete infection.

Rhinocerebral zygomycete infection should be suspected in susceptible patients who present with fever, headache, nasal congestion, and nasal discharge. Patients with poorly controlled diabetes mellitus and ketoacidosis are particularly at risk. Typical black eschars due to local tissue invasion and necrosis may be apparent on the nasal mucosa. Direct extension to overlying skin, orbit, cavernous sinus, and central nervous system occur commonly and are often devastating. Pulmonary zygomycete infection is typically found in individuals with neutropenia, stem cell transplantation, or chronic steroid treatment. Presenting signs include fever, cough, and hemoptysis. X-rays demonstrate multiple nodular lesions, and the lesions are often confused with aspergillosis. Gastrointestinal disease involving the stomach or colon often presents as diarrhea with abdominal pain.

Treatment of zygomycete infection requires therapy with amphotericin B or lipid products for a prolonged course. Posaconazole, an oral azole, has been used effectively in the treatment of zygomycete infections; however, neither voriconazole nor the echinocandins are active as treatment. Aggressive surgical débridement is critical for patients with rhinocerebral zygomycete infection. The overall mortality rate for zygomycete infection ranges from 25% to 50% for sinus disease to 80% or greater for pulmonary and cerebral disease.

Endemic Mycoses

Multiple different fungi exist in the soil specific to particular geographic areas and are largely responsible for the primary endemic mycoses in the United States: blastomycosis, histoplasmosis, coccidioidomycosis, and sporotri-

chosis. For most of these organisms, the clinical symptoms and signs depend on the route of acquisition and the immune status of the host.

In the United States, *Blastomyces dermatitidis* is typically found in the Ohio and Mississippi river valleys and the Midwestern states and areas along the Great Lakes and St. Lawrence River. Infection with *B. dermatitidis* has been found in individuals who spend time outdoors either through work or recreation and has been associated with exposure to excavation and water. Infection occurs most commonly due to inhalation of conidia. Thus, the most common clinical presentation of blastomycosis is acute or subacute respiratory infection. Based on surveys from endemic areas in Wisconsin and Minnesota, it is estimated that most infected patients are either asymptomatic or develop a mild flu-like illness. However, an acute process that appears similar to bacterial pneumonia with fever, cough, shortness of breath, and consolidation on chest x-ray can occur. Or, the presentation can consist of subacute respiratory symptoms. Dissemination to the skin, bone, genitourinary tract, central nervous system, and other sites have also been described. The disease is diagnosed by the presence of organisms cultured from an involved area or detected microscopically. X-ray findings for blastomycosis are nonspecific and include lobar and interstitial infiltrates, nodular lesions, and pleural effusions.

Unlike many of the endemic mycoses, immunocompromised patients do not appear to be at greater risk for infection with *B. dermatitidis*. Infection in the immunocompromised host is associated with a higher mortality rate, poorer response rate to therapy, and increased risk for recurrence. Therapeutic approaches for the endemic mycoses are shown in Table 104-3.

In the United States, *Histoplasma capsulatum* is found commonly in the Ohio River and the St. Lawrence River valleys. The organism is found in the droppings of birds

Table 104-3 Therapy for Endemic Mycoses

Mycosis	Acute	Disseminated	Chronic	Immunocompromised*
<i>Blastomyces dermatitidis</i>	Itraconazole, 200 mg/day	Amphotericin B or lipid complex followed by itraconazole		Amphotericin B or lipid derivatives followed by long-term itraconazole
<i>Histoplasma capsulatum</i>	Itraconazole	Amphotericin B followed by azole therapy	Amphotericin B followed by prolonged azole therapy	Amphotericin B followed by prolonged azole therapy
<i>Coccidioides immitis</i>	Either no treatment, itraconazole, or fluconazole	Itraconazole or fluconazole; meningitis: high-dose fluconazole		High-dose prolonged azole therapy (itraconazole, fluconazole) or amphotericin B then azole therapy
<i>Sporothrix schenckii</i>	Fluconazole, itraconazole	Amphotericin B or lipid product	Bone or joint involvement treated with itraconazole	Amphotericin B or lipid product or itraconazole

* For these infections, prolonged (>2 years) or lifelong therapy for the immunocompromised individual is required.

Figure 104-4 Histoplasmosis.

Ulcerating lesion of tongue due to histoplasmosis. Lesion is identical in appearance to carcinoma of tongue

Mycelial or free-living phase of *H. capsulatum* as it exists in nature or in culture

Spores of mycelial phase of *H. capsulatum*. Inhalation of these is source of infection

H. capsulatum in tissue

H. capsulatum in a macrophage. In this yeast or tissue phase, organism is not transmissible from person to person

such as pigeons and bats or is in an aerosolized form in caves. *H. capsulatum* is most commonly acquired by inhalation of the organism. The immune response is critical to control of the infection and requires interaction between CD4⁺ type 1 helper T cells that generate interferon- γ and macrophages that both activate T cells through interleukin-12 and control replication by the production of cytokines and reactive oxygen species. In humans, the organisms are contained in granulomas that are not sterile, leading to a high incidence of reactivation in T-cell-deficient individuals.

The clinical illness caused by *H. capsulatum* varies greatly depending on the immune status of the host and the expo-

sure (Fig. 104-4). Most individuals exposed to *H. capsulatum* are either asymptomatic or develop a flu-like illness with fever, chills, headache, cough, and chest discomfort. An overwhelming exposure can lead to severe pneumonia with adult respiratory distress syndrome. A very small percentage of infected individuals develop chronic histoplasmosis, which has multiple varied manifestations. Chronic disseminated histoplasmosis is characterized by weight loss and fever and is often confused with mycobacterial infections such as tuberculosis. Subacute disseminated histoplasmosis is characterized by hepatosplenomegaly, peripheral blood count abnormalities, fever, and oral lesions. Acute disseminated histoplasmosis is seen in

immunocompromised individuals and presents as a fulminant infection with a sepsis syndrome. Chronic disseminated histoplasmosis without therapy is almost always fatal. The diagnosis of histoplasmosis is made by identifying the yeast form in fluids or tissues. Antibody-based testing is helpful in the diagnosis of acute infections based on a fourfold rise in titers or based on the urinary histoplasmic antigen assay.

Infection with *Coccidioides immitis* is found predominantly in the United States in the Lower Sonoran Life Zone, which is found in the desert areas of Arizona, California, Nevada, New Mexico, and Texas. Outside of the United States, the organism is found in Mexico and in Central and South America. As in blastomycosis and histoplasmosis, infection is typically due to inhalation of the organism. Most patients infected with *C. immitis* are asymptomatic. Those who become sick after exposure most commonly develop a flu-like respiratory illness characterized by fever, chills, nonproductive cough, pleuritic chest pain, and fatigue. Acute infections typically resolve over 2 to 3 weeks; however, a small percentage of infected patients develop chronic infection. Chronic coccidioidomycosis can manifest as both a persistent pulmonary process characterized by the formation of cavities and as extrapulmonary manifestations including involvement of the meninges, skin and soft tissue, bone, and joints. Chronic coccidioidomycosis is typically fatal without prolonged specific therapy. Therapy is not typically required for immunocompetent patients who present with acute infection. However, any immunocompromised individual requires therapy for coccidioidomycosis (see Table 104-3).

Sporothrix schenckii is a fungus found in soil. Like the other fungi listed above, *S. schenckii* exists as a mycelium and yeast. Unlike the other organisms, *S. schenckii* causes infection throughout the world and is generally acquired by direct contact with soil or contaminated plants that cause puncture wounds. Clinically, patients with sporotrichosis present with local findings at the site of inoculation. The lesions are typically violaceous or red skin nodules that tend to ulcerate. Over time, direct extension of the organism to joints or bone occurs in some individuals. Disseminated sporotrichosis is typically found only in immunocompromised individuals. The diagnosis of sporotrichosis is made by culturing the organism from the site of infection. Antibody testing is available but not commonly used. The mainstay of treatment for skin or localized soft tissue sporotrichosis is azole therapy using either itraconazole (200 mg/day) or fluconazole (400 to 800 mg/

day). Direct extension of sporotrichosis to bone or joint is typically treated with itraconazole.

Parasitic Infections

Introduction

Enteric parasitic infections remain an important cause of morbidity in developing countries. With the constant influx of immigrants, the growing number of travelers to developing countries, and immunosuppression related to HIV, transplantation, and chemotherapy, knowledge of parasitic diseases is of increasing importance. Parasitic diseases can be largely divided into two categories: those due to helminths (of which nematodes are a major category), and those due to protozoa.

Nematodes: Roundworms

Nematodes are categorized according to where the adult form of the worm resides. Intestinal nematodes are the most prevalent. Although intestinal nematode infections occur worldwide, most cases occur in tropical or subtropical countries and disproportionately afflict children. Poor sanitation plays a major role because maturation of eggs within the environment must occur to maintain the worm life cycle and human infections. Symptoms are highly dependent on the number of infectious organisms, the so-called worm burden. Infections involving a low worm burden (light infections) are generally asymptomatic, whereas those with a high worm burden (heavy infections) result in more severe symptoms and complications. Eosinophilia generally occurs with the tissue migration phase of the immature worm and may be absent when the adult worm resides in the intestine. Coinfections in individuals with intestinal worms are common.

Enterobiasis (Pinworm)

Etiology and Pathogenesis

Pinworm infection is caused by *Enterobius vermicularis* (Fig. 105-1). When infectious eggs are ingested, larvae mature within the intestine, and adult female worms lay eggs on the perianal skin. Immature eggs must mature in the environment to become infectious. Because the maturation of *Enterobius* eggs occurs within hours, reinfection of the child and infection of family members and close contacts is common.

Clinical Presentation

Nocturnal pruritus ani is the predominant symptom, particularly among children. Pruritus vulvae and genitourinary symptoms may occur in girls.

Differential Diagnosis

Other nematode infections or vaginal candidiasis can present similarly.

Diagnostic Approach

The cellophane tape test is the best diagnostic method. Cellophane tape pressed on the perianal skin in the morning will reveal eggs and possibly female worms. Fecal smears for ova and parasites are frequently negative and less useful in diagnosis.

Management and Therapy

Optimum treatment is a single dose of mebendazole, 100 mg; pyrantel pamoate, 11 mg/kg; or albendazole, 400 mg. Clothing and bedding should be washed to eradicate infectious eggs in the environment. The entire family should be treated simultaneously, and retreatment of all family members should occur within a 2-week period.

Trichuriasis (Whipworm)

Etiology and Pathogenesis

Whipworm infection is caused by *Trichuris trichiura*. This infection is also maintained through a direct life cycle.

Figure 105-1 Parasitic Diseases: Enterobiasis.

However, *Trichuris* eggs require weeks to months to mature; therefore, autoinfection (repeated infection of oneself) generally does not occur.

Clinical Presentation

Most infections are asymptomatic. Heavy infections in malnourished infants may result in diarrhea and rectal prolapse.

Differential Diagnosis

Other nematode infections should be considered.

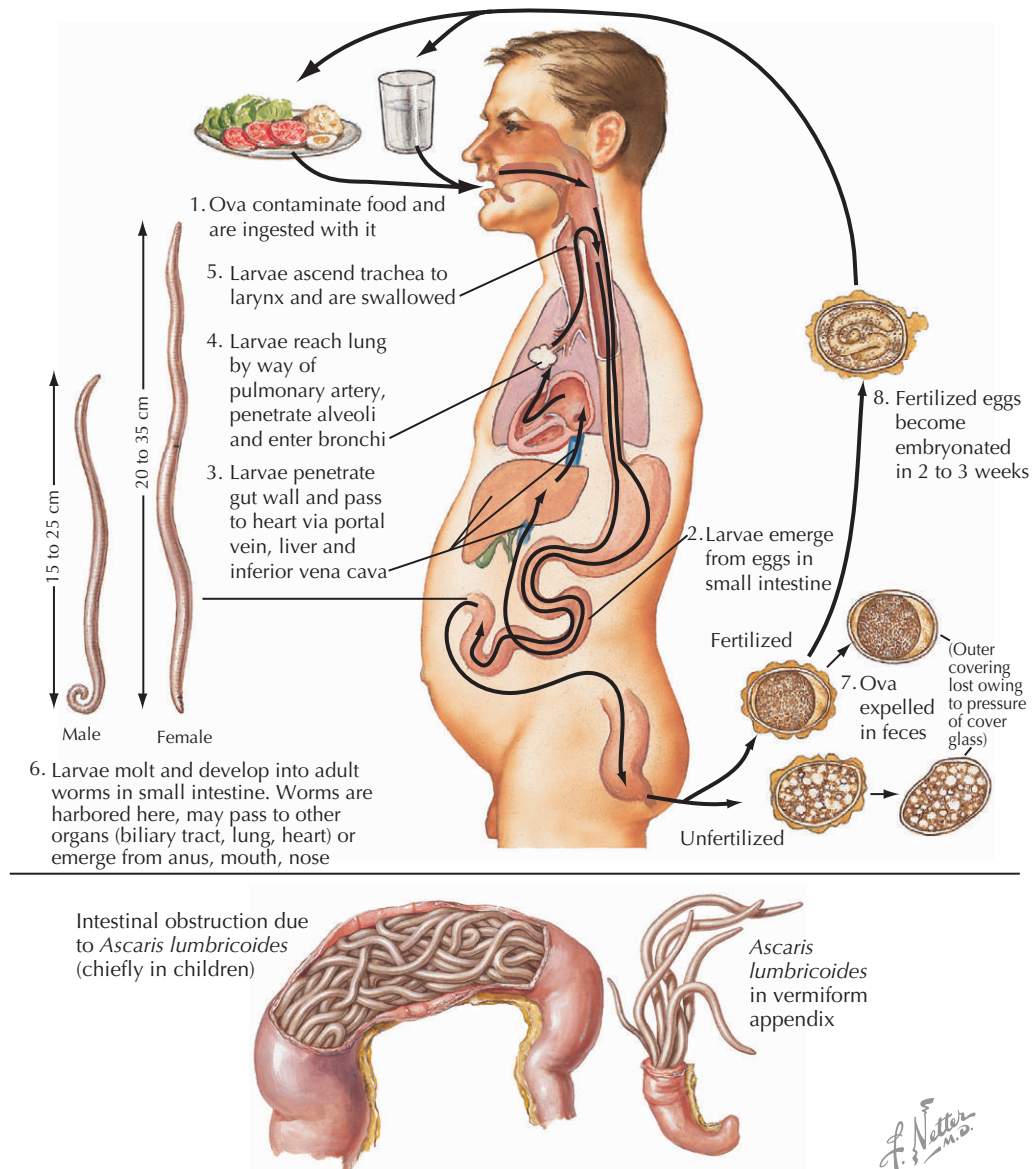

Diagnostic Approach

A fecal smear for ova and parasites is the preferred diagnostic method.

Management and Therapy

Optimum treatment is either mebendazole, 100 mg twice daily for 3 days; mebendazole, 500 mg in a single dose; albendazole, 400 mg once daily for 3 days; or ivermectin, 200 µg/kg once daily for 3 days.

*F. Netter
M.D.*

Figure 105-2 Parasitic Diseases: Ascariasis.

Ascariasis

Etiology and Pathogenesis

Ascaris lumbricoides infection occurs through a complex life cycle (Fig. 105-2). After ingestion of infectious eggs, the immature larvae migrate through the lungs before reaching the adult stage in the intestine.

Clinical Presentation

Pulmonary symptoms, such as cough, dyspnea, and wheezing with infiltrates and eosinophilia may occur during the lung migration phase. Low levels of infection are largely asymptomatic, whereas high worm burdens may cause gastrointestinal symptoms of abdominal pain, nausea, and small bowel obstruction. Rarely, ascarids may migrate into

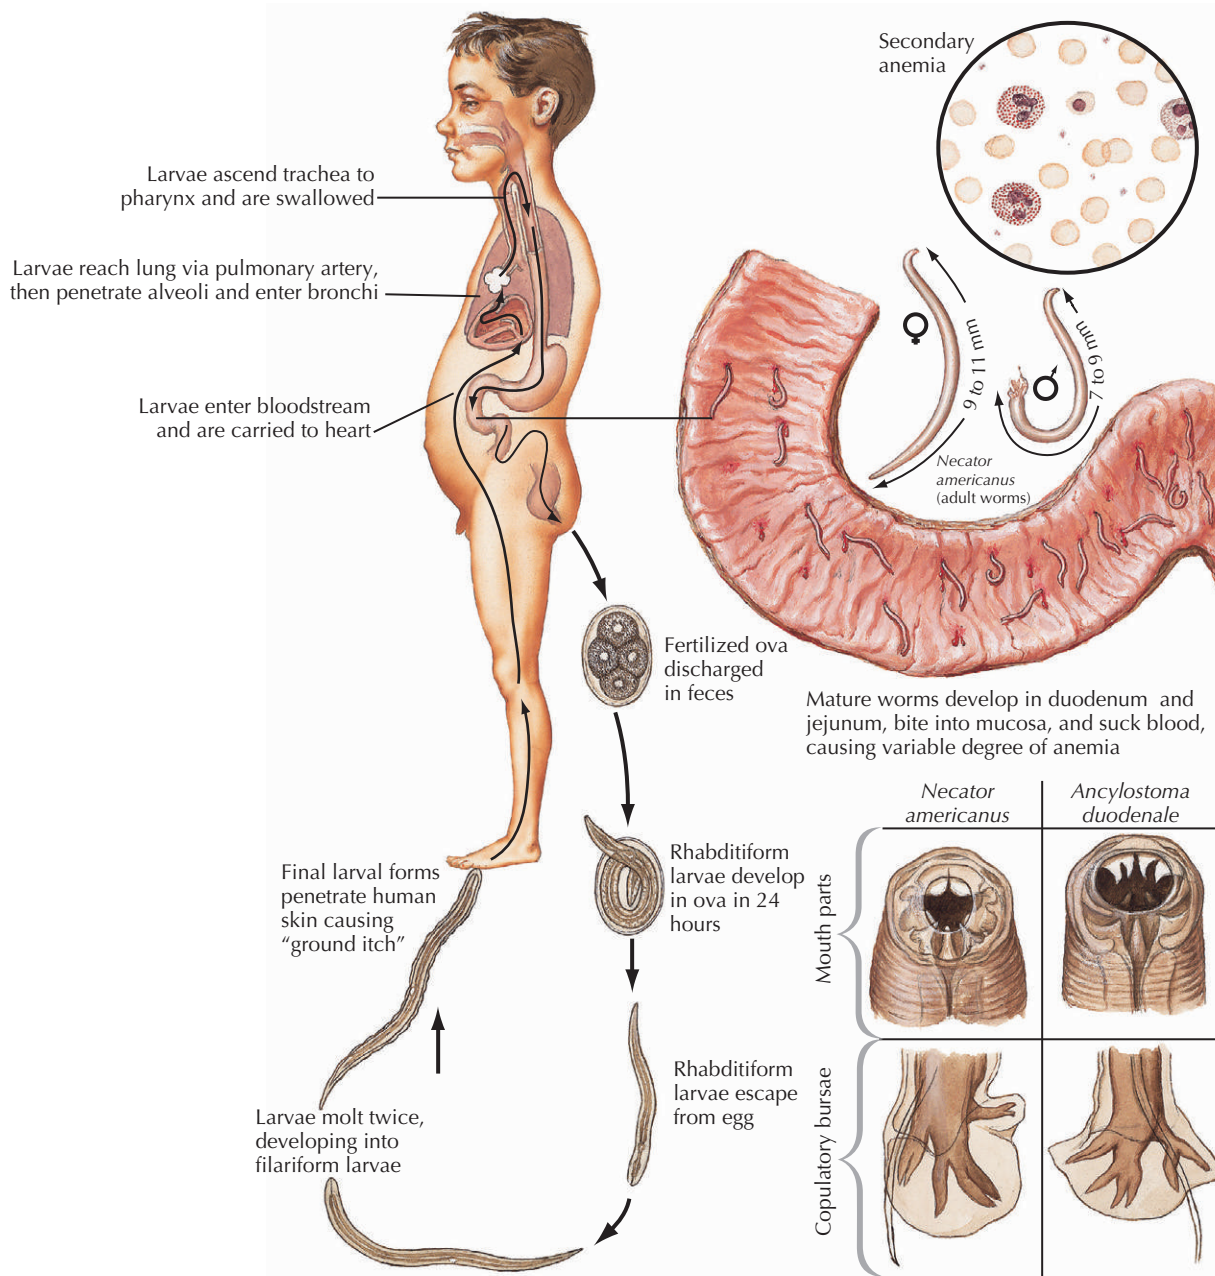

the biliary tract or pancreatic duct, causing symptoms consistent with biliary colic or pancreatitis. Occasionally, patients present with fecal passage of a large adult worm.

Differential Diagnosis

During the migration phase, pulmonary disorders such as asthma, eosinophilic pneumonia, and interstitial lung diseases may be considered. Peptic ulcer disease, biliary disease, or pancreatitis may be related to abdominal symptoms. Other nematode infections may also be considered.

Diagnostic Approach

A fecal smear for ova and parasites is generally positive because of the high egg output of this parasite.

Figure 105-3 Parasitic Diseases: Necatoriasis and Ancylostomiasis.

Management and Therapy

Optimum treatment is either mebendazole, 100 mg twice daily for 3 days; mebendazole, 500 mg in a single dose; albendazole, 400 mg in a single dose; pyrantel pamoate, 11 mg/kg in a single dose; or nitazoxanide, 500 mg twice daily for 3 days. After treatment, patients may experience the migration of adult worms from the nose or mouth, and reassurance may be required.

Hookworm Infections

Etiology and Pathogenesis

Hookworm infections are caused by either *Necator americanus* or *Ancylostoma duodenale* (Fig. 105-3). The hookworm life cycle begins with the percutaneous penetration of the infectious filariform larvae, usually through bare feet. The larvae migrate from the skin to the lung and eventually transit to the small intestine, where the adult worm resides

and releases eggs into the feces. The eggs must embryonate into rhabditiform larvae, then to filariform larvae before they are infectious again. The repetitive release and reattachment of the adult worm to intestinal mucosa may result in low-grade bleeding and anemia.

Clinical Presentation

A pruritic maculopapular rash may result after the penetration of the filariform larvae. Migration of the larvae through the lung is associated with cough, wheezing, pulmonary infiltrates, and eosinophilia. Abdominal symptoms include abdominal pain, diarrhea, and nausea and vomiting. Symptoms of iron-deficiency anemia such as fatigue, dyspnea, or pica may develop with chronic infection. Hypoproteinemia and growth retardation occur in children who have chronic infection.

Differential Diagnosis

During the migration phase, pulmonary disorders such as asthma, eosinophilic pneumonia, and interstitial lung diseases may be considered. Abdominal symptoms similar to those due to hookworm can result from peptic ulcer disease, biliary disease, or pancreatitis. Given the finding of iron-deficiency anemia in some cases, alternative causes of gastrointestinal blood loss (carcinoma, diverticular disease, peptic ulcer disease) should also be considered.

Diagnostic Approach

A fecal smear for ova and parasites is diagnostic.

Management and Therapy

Optimum treatment is either mebendazole, 100 mg twice daily for 3 days; mebendazole, 500 mg in a single dose; albendazole, 400 mg in a single dose; or pyrantel pamoate, 11 mg/kg once daily for 3 days. Iron supplementation may be necessary to correct the iron-deficiency anemia.

Currently, there is investigation into a hookworm vaccine. Until this is available, sanitation and ensuring the use of footwear are the key to prevention of this infection.

Strongyloidiasis

Etiology and Pathogenesis

Strongyloides stercoralis penetrates intact skin, transits the lung, and then resides in the small intestine as mature organisms. It is capable of maintaining an autoinfective cycle whereby rhabditiform larvae transform into the infectious filariform larvae within the host, allowing reinfection and persistence of the cycle for years. Autoinfection in an immunocompromised host can result in life-threatening disseminated illness known as *hyperinfection*. Those infected with human T-cell leukemia virus-1 are at increased risk for hyperinfection. In the southern United States, strongyloidiasis occurs at an estimated prevalence of 0.4% to 4%.

Clinical Presentation

Larva currens, a recurrent serpiginous urticarial rash usually around the buttocks, is suggestive of autoinfection. During the pulmonary transit phase, infected individuals may experience cough, wheezing, and pulmonary infiltrates. Abdominal symptoms include pain, diarrhea, nausea, and vomiting. Malabsorption and weight loss occur with heavier infections. Hyperinfection results in ileus, pneumonia, meningitis, polymicrobial gram-negative bacteremia, and multiorgan failure.

Eosinophilia, usually present, may be absent in hyperinfection.

Differential Diagnosis

During the migration phase, pulmonary disorders such as asthma, eosinophilic pneumonia, and interstitial lung diseases should be considered as alternative diagnoses. Peptic ulcer disease, biliary disease, or pancreatitis may be considered related to abdominal symptoms. Other nematode infections should also be considered.

Diagnostic Approach

A fecal smear is often negative, and multiple stool specimens using concentration techniques may be required for diagnosis. Alternatively, duodenal aspirate specimens from endoscopy or a string test can be used to make this diagnosis when necessary. In hyperinfection, sputum examination may reveal larvae. Patients from endemic areas planning immunosuppressive treatment such as chemotherapy or organ transplantation should have enzyme-linked immunosorbent assay (ELISA) serologic testing before initiating therapy, and individuals found to be infected should be treated appropriately.

Management and Therapy

Optimum therapy is ivermectin, 200 µg/kg/day for 1 to 2 days, which is highly efficacious and nontoxic for uncomplicated disease. Albendazole, 400 mg twice daily for 3 days, or thiabendazole, 25 mg/kg twice daily for 2 days, is also effective but has fallen from favor given the efficacy of ivermectin. For disseminated disease, treat with ivermectin, 200 µg/kg/day for 7 to 10 days.

Cestodes (Tapeworm)

Etiology and Pathogenesis

Tapeworm infection occurs in humans when uncooked or undercooked infected meat is ingested (Fig. 105-4). The infection transmitted depends on the meat consumed: beef, *Taenia saginata*; pork, *Taenia solium*; and fish, *Diphyllobothrium latum*.

Clinical Presentation

Infection is often asymptomatic, or individuals may sense the movement of the proglottids through the anus.

Figure 105-4 Parasitic Diseases: Taeniasis Solium (Cysticercosis Cellulosae).

Infection with *D. latum* may result in megaloblastic anemia secondary to vitamin B₁₂ deficiency.

Differential Diagnosis

Infection with other nematodes, particularly pinworm, should be considered.

Diagnostic Approach

Fecal demonstration of proglottids or eggs is diagnostic.

Management and Therapy

Optimum treatment is praziquantel, 10 mg/kg in a single dose, or niclosamide, 2 g in a single dose.

Cysticercosis

Etiology and Pathogenesis

The tapeworm *T. solium* has the potential to cause cysticercosis (see Fig. 105-4). When the egg of *T. solium* is ingested either directly through fecal contamination or through autoinfestation by reverse peristalsis, the larval form of the disease, cysticercus cellulosae, develops, and tissue cysts (cysticerci) may often develop in subcutaneous tissues, muscle, and brain.

Clinical Presentation

Subcutaneous nodules may be palpable. Neurologic symptoms vary widely according to the location and number of

cysts, stage of the infection, and the host response. Asymptomatic disease is common, particularly in the first years after infection. Seizure is the most common presenting symptom; headache, increased intracranial pressure, altered mental status, and focal neurologic findings occur less frequently.

Differential Diagnosis

Skin nodules may also occur with onchocerciasis. Primary epilepsy and infectious diseases of the central nervous system (toxoplasmosis, meningitis, tuberculosis, brain abscess) may be considered depending on the neurologic presentation.

Diagnostic Approach

Computed tomography (CT) scan and magnetic resonance imaging (MRI) are the primary methods to diagnose neurocysticercosis. MRI is more sensitive in the diagnosis of extraparenchymal cysts and inflammatory reactions to cysts. The enzyme-linked immunotransfer blot assay (serum titer) is highly specific for *T. solium* and highly sensitive in patients with multiple active cysts.

Management and Therapy

Treatment with antiparasitic agents should be individualized according to the location and activity of the cysts. Albendazole, 400 mg twice daily for 8 to 30 days with concomitant corticosteroids, may be effective if therapy is indicated. Praziquantel, 50 mg/kg daily for 15 days combined with corticosteroids, may also be effective. Consultation with an infectious disease physician is recommended.

Antiepileptic medication may be required even after successful treatment.

Intestinal Protozoa

Although several species of protozoa may be found in the human intestinal tract, many are regarded as nonpathogenic commensals. *Giardia lamblia* and *Entamoeba histolytica* cause most enteric protozoal diseases among immunocompetent individuals in the United States. *Cryptosporidium*, *Cyclospora*, *Microsporidia*, and *Isospora* species are important enteric protozoal diseases in patients with AIDS and are discussed elsewhere.

Giardiasis

Etiology and Pathogenesis

Giardia lamblia, the most common intestinal parasite worldwide, is a frequent cause of diarrhea and malabsorption. It is typically acquired through the ingestion of contaminated food and water or by person-to-person contact. Synonyms for *G. lamblia* include *G. intestinalis* and *G. duodenalis* (Fig. 105-5).

Giardiasis occurs in sporadic, epidemic, and endemic forms. Sporadic infections are seen with international travel, rural camping, or person-to-person contact. Outbreaks have been reported with community water systems and in institutions with close contact and the potential for fecal-oral contamination, such as day care centers. Giardiasis is endemic in the developing world. Studies based on stool specimens suggest that the prevalence is 2% to 5% in the developed world, compared with 20% to 30% in the developing world. Infection occurs year-round, with a small peak in the spring in the United States.

G. lamblia has two stages in its life cycle: cysts, the infectious form; and trophozoites, the replicating form. The cyst form is inert and environmentally resistant, viable for months outside the host. Water treatment, by filtration or boiling, prevents *G. lamblia* infections. Addition of iodine or chlorine to drinking water also inactivates cysts under appropriate concentrations and exposure duration. The trophozoite is the motile form, which is adherent to the small bowel mucosa. Replication occurs by binary fission within the intestine, with a doubling time of about 12 hours. Encystation occurs in the ileum, possibly triggered by exposure to bile, followed by cyst excretion in feces.

Clinical Presentation

Protracted diarrhea is a central feature of giardiasis. Typically, stools are loose and foul smelling and may contain mucus but not blood. Anorexia, nausea, abdominal cramping, bloating, and weight loss are common symptoms. Fever occurs in about 10% of patients. Patients chronically infected with *Giardia* often have malabsorption and weight loss.

Determinants of disease severity remain an enigma. Infected patients are either asymptomatic (60%), have acute infection (40%), or have a chronic infection (including 40% of those with acute infections). About 10% of asymptomatic patients have stool cysts and can transmit the disease. The infectious inoculum may be as low as 10 to 25 cysts. The incubation period is 1 to 2 weeks on average, with a range of 1 day to 6 weeks.

Differential Diagnosis

The primary focus in the evaluation of acute diarrhea is infectious agents. Important bacterial infections that should be included in the differential diagnosis are *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* species, *Escherichia coli*, and *Clostridium difficile*. Other potential parasitic infections should also be included, particularly *Entamoeba histolytica* and *Cryptosporidium* species. Viral enteritides are also common and include rotavirus and the Norwalk agent. Dietary indiscretion, recent medication changes, and new-onset chronic diarrhea should also be considered.

Chronic diarrhea has a broad differential diagnosis with a variety of classification schemes. Other infectious diseases may be considered, particularly for the returning international traveler. The differential diagnosis includes

Figure 105-5 Giardiasis.

the inflammatory diarrheas (e.g., Crohn's disease), mal-digestion (e.g., pancreatic insufficiency), and malabsorption (e.g., bacterial overgrowth). Other considerations include systemic disease, lymphoma, medication side effects, and the rare tumor-related secretory diarrheas (e.g., gastrinoma, carcinoid tumor).

Diagnostic Approach

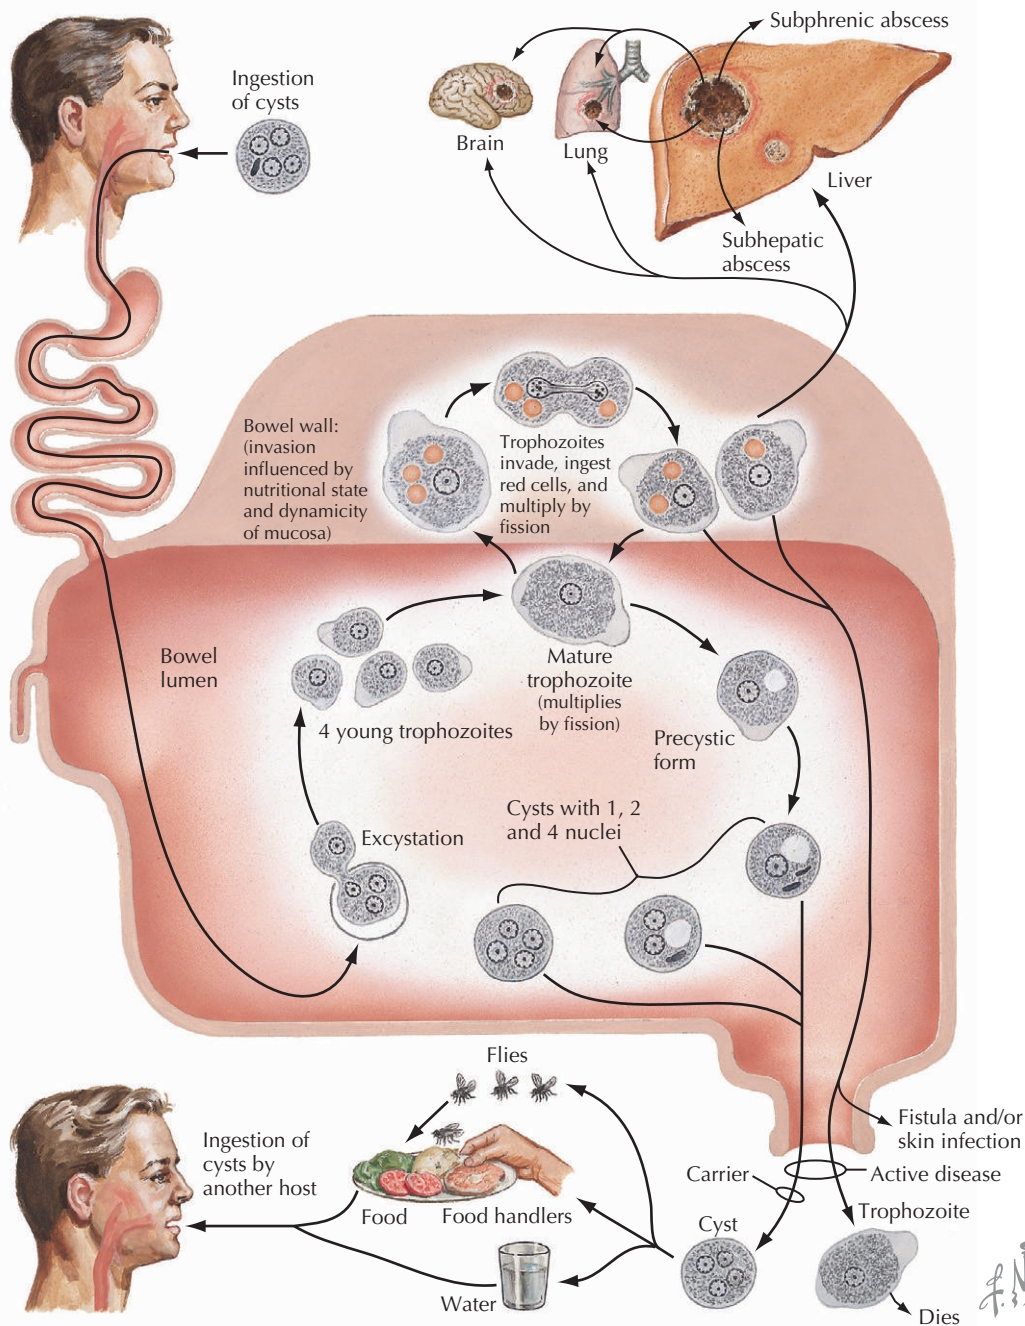

Examination of fecal specimens is the primary means for diagnosis. Cyst passage in stool is sporadic, and three samples are recommended as sensitivity increases from

60% to 90% with examination of one to three specimens. Many laboratories use *Giardia* antigen assays, using either immunofluorescent or ELISA technology, which typically have single specimen sensitivities greater than 90%.

Management and Therapy

Treatment is recommended for symptomatic patients and, in institutional settings, for asymptomatic patients to prevent the spread of disease. Metronidazole, 250 mg orally three times daily for 5 days; tinidazole, 2 g stat dose; and nitazoxanide, 500 mg twice daily for 3 days, are all

Figure 105-6 Amebiasis.

effective treatments. Treatment of giardiasis in pregnancy is difficult, and there are no consistent recommendations.

The prevention of *Giardia* outbreaks in community water systems depends on adequate sedimentation, filtration, and possibly a higher chlorine concentration within the treated water. For individuals who have been camping or for international travelers, boiling (at least 10 minutes), filtration (pore size less than or equal to 2 mm), or halogens (chlorine, iodine) are recommended. Within day care centers and other institutions, handwashing is important. Breast-feeding is recommended because maternal immu-

noglobulin A has been shown to be effective in preventing infection in infants.

Amebiasis

Etiology and Pathogenesis

Entamoeba histolytica infection is spread by fecal-oral contamination with infectious cysts (Fig. 105-6). Symptoms develop if the cysts become trophozoites capable of invading the colonic mucosa. *E. histolytica* cysts are morphologically indistinguishable from the nonpathogenic *Entamoeba dispar*.

Clinical Presentation

Most infected individuals with *Entamoeba* cysts in the stool are asymptomatic because most are actually infected with *E. dispar*. Symptomatic disease occurs in only 10% of *E. histolytica* cyst carriers. Among symptomatic patients, diarrhea with blood and mucus, and abdominal pain developing over 1 to 2 weeks are the predominant complaints. Rarely, patients present with a localized painful abdominal mass secondary to ameboma formation. Chronic amebic colitis presents with recurrent episodes of bloody diarrhea over years and may be confused with inflammatory bowel disease. Extraintestinal manifestations include abscess formation of the liver, lung, brain, or pericardium, with liver abscess the most common. Most patients with amebic liver abscess present with fever, right upper quadrant pain, and tenderness of the liver; others may present solely with fever.

Differential Diagnosis

Bacterial dysentery, giardiasis, inflammatory bowel disease, bacterial liver abscess, and biliary disease should all be considered in the differential diagnosis, depending on the presentation of the patient.

Diagnostic Approach

The finding of *Entamoeba* cysts and hematophagous trophozoites in a fresh stool wet mount is diagnostic of *E. histolytica*. In asymptomatic cyst passers, *E. histolytica* may be differentiated from *E. dispar* by the presence of positive amebic serology. Liver ultrasound, CT, and MRI are useful in the diagnosis of liver abscess. Biopsy of colonic tissue revealing trophozoites is diagnostic of amebic colitis.

Management and Therapy

Asymptomatic *E. dispar* cyst carriers do not require treatment. Asymptomatic *E. histolytica* cyst carriers should be treated with either iodoquinol, 650 mg thrice daily for 20 days, or paromomycin, 12 mg/kg orally thrice daily for 7

days. Amebic colitis is treated with metronidazole, 750 mg thrice daily for 10 days, or tinidazole, 2 g once daily for 3 days, followed with treatment with iodoquinol or paromomycin. Extraintestinal amebic disease is treated with metronidazole, 750 mg thrice daily for 10 days, or tinidazole, 2 g once daily for 5 days, followed with treatment with iodoquinol or paromomycin.

Future Directions

Efforts toward improving waste sanitation, food handling processes, animal husbandry processes, and ensuring quality control of water purification can virtually eliminate these enteric infections. Focused treatment of high-risk individuals, such as children in developing countries, in conjunction with improved sanitation remains a challenge and merits high priority as a global health initiative.

Malaria

Introduction

Malaria is a common and important infectious disease globally. An estimated 300 to 500 million cases of malaria occur worldwide each year, with more than 1 million deaths, primarily in Africa, Asia, and South and Central America (Fig. 106-1). Although once common in parts of the United States, most of the about 1300 cases reported in the United States each year are travelers to endemic regions. Cases have been reported from all 50 states, with most cases from New York City, California, and Maryland. More than half of the imported cases of malaria to the United States are *Plasmodium falciparum*, the most severe form of malaria.

Etiology and Pathogenesis

Malaria is caused by one of four species: *Plasmodium falciparum*, *Plasmodium vivax*, *Plasmodium ovale*, or *Plasmodium malariae*. The species are morphologically distinct, providing the basis for specific diagnosis.

The life cycles of the four species are similar (Fig. 106-2), but with important differences. Infection of humans begins with the inoculation of sporozoites from the salivary glands of an infected female *Anopheles* mosquito. The sporozoites rapidly invade hepatocytes and are largely cleared from the blood within 30 minutes of inoculation. In the liver, the parasite undergoes asexual multiplication to form hepatic or tissue schizonts. After a variable period of development, merozoites emerge from the liver cells into the bloodstream. The duration of the liver stage is typically 1 to 3 weeks, but is longer, 2 to 4 weeks, for *P. malariae*.

A critical difference between species is the existence of persistent liver forms, or hypnozoites, in *P. ovale* and *P. vivax* infections. In these species, hypnozoites form and can remain dormant for months or years before becoming active and causing relapse. Neither *P. falciparum* nor *P. malariae* have persistent liver forms. However, persistent, low-grade infections in the blood with *P. falciparum* or *P. malariae* may cause recrudescence of clinical disease.

The merozoites released from the liver attach to and invade erythrocytes. In the erythrocyte, ring forms with a small nucleus and a ring of pale cytoplasm develop. The parasite then develops into a trophozoite and finally into

an erythrocytic schizont. Rupture of the schizont releases merozoites into the bloodstream, leading to another cycle of asexual development in fresh erythrocytes.

The parasite also undergoes a sexual cycle, which requires both humans and mosquitoes. In the erythrocyte, some merozoites develop into male and female gametocytes. These gametocytes are taken up during a blood meal by the female *Anopheles* mosquito. In the mosquito stomach, gametes form. Macrogametes are fertilized by microgametes forming zygotes, which then develop into ookinetes. The ookinetes invade the gut wall, form oocysts, and sporozoites develop within the oocysts. The sporozoites migrate to the salivary gland of the mosquito and await inoculation into the human host.

The cycle within the human host is affected by several host and parasite factors. *P. malariae* invades mature erythrocytes. *P. vivax* and *P. ovale* invade young erythrocytes. *P. falciparum* is capable of invading erythrocytes of any age. Thus, parasitemia is limited in *P. malariae*, *P. vivax*, and *P. ovale* infections but can reach extremely high levels in *P. falciparum* infections.

Persons with high levels of hemoglobin F and hemoglobin S have increased resistance to falciparum malaria due to reduced survival of the parasite in the erythrocytes. Persons with the heterozygous state of hemoglobin AS have a survival advantage and experience less severe falciparum malaria. Persons with glucose-6-phosphate dehydrogenase deficiency also appear to have increased resistance to falciparum malaria.

Persons lacking the Duffy group antigens on erythrocytes are resistant to infection with *P. vivax*. This trait,

Figure 106-1 Geographic Distribution of Malaria.

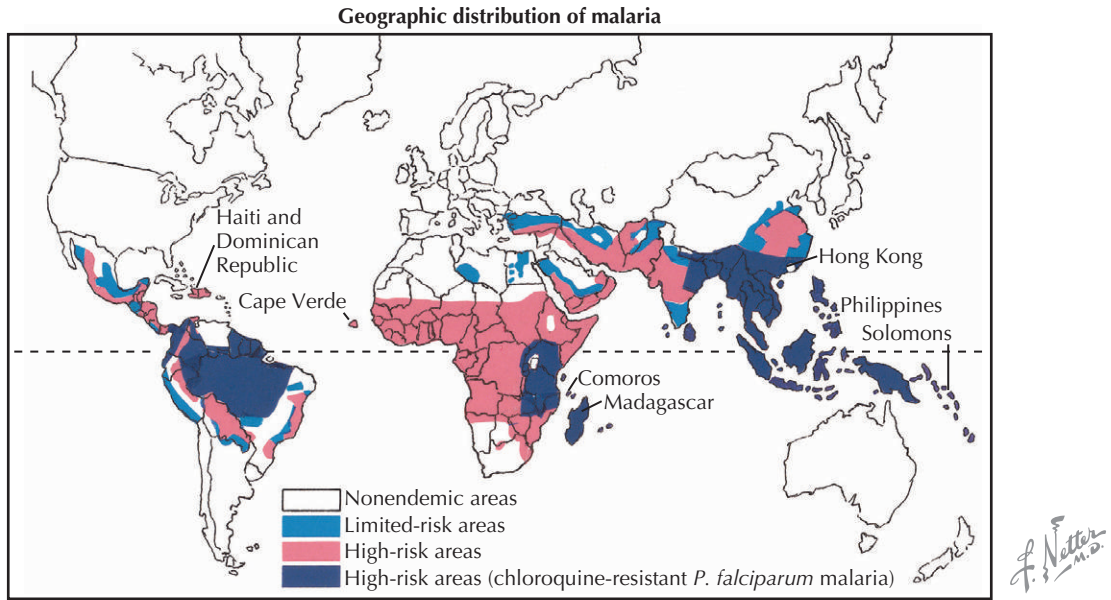

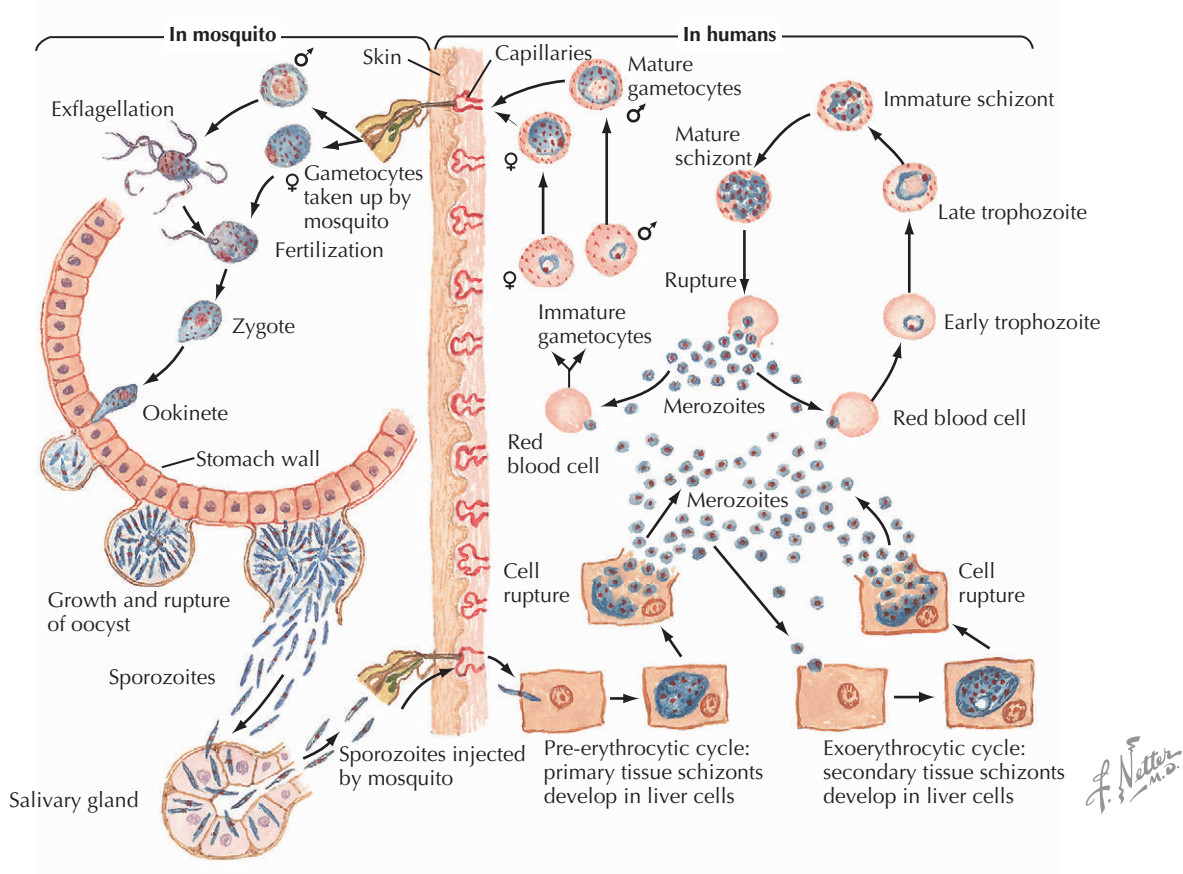

Figure 106-2 Life Cycle of Malaria Parasites (*Plasmodium vivax*).

common throughout much of Africa, accounts for the low incidence of vivax malaria in Africa.

The symptoms, signs, and complications of malaria are due to the intraerythrocytic cycle. Fever occurs with schizont rupture. Anemia is common in all forms of malaria and is due primarily to destruction and phagocytosis of infected erythrocytes.

Falciparum malaria may be severe with life-threatening complications including cerebral malaria, acute renal failure, pulmonary edema and adult respiratory distress syndrome (ARDS), hyponatremia, and hypoglycemia. Cerebral malaria is caused, at least in part, by increased adherence of infected erythrocytes to capillary endothelial cells in the brain. Acute renal failure may result from volume depletion or acute tubular necrosis in the context of hyperparasitemia, intravascular hemolysis, and hemoglobinuria. Pulmonary edema may result from fluid administration. Pulmonary edema with an ARDS-like picture is more common, presumably because of increased capillary leakage secondary to cytokine production. Hyponatremia occurs secondary to inappropriate secretion of antidiuretic hormone. Hypoglycemia may be due to impaired hepatic gluconeogenesis. It is important to note that administration of quinine or quinidine may exacerbate hypoglycemia. Splenic rupture occurs with rapid rise in parasitemia. It is the primary cause of mortality in persons with *P. vivax* and *P. ovale* malaria.

Clinical Presentation

Many patients with malaria experience a prodrome with headache, decreased appetite, malaise, myalgias, and in some cases, low-grade fever. The prodrome may last 2 to 3 days but may be longer in persons with partial immunity or incomplete suppression due to prophylaxis.

Fever is the classic manifestation of malaria. The onset of a paroxysm of fever begins with abrupt onset of chills, often with teeth chattering and shivering. The subsequent fever, as high as 40° C to 41° C in falciparum malaria, typically lasts 2 to 4 hours and is followed by diaphoresis. The duration of the entire paroxysm is 8 to 12 hours. Between paroxysms, the patient may feel well.

The paroxysms of fever and chills are intermittent and may have periodicity (Fig. 106-3). Paroxysms associated with *P. vivax* and *P. ovale* infections occur every 48 hours, whereas with *P. malariae*, the interval interceding between episodes is 72 hours. The paroxysms of fever with these species are more common during the daylight hours. Fever is often irregular during the first few days of the illness. Periodicity is often absent in falciparum malaria but may occur with an interval of about 48 hours. Malaria cannot be excluded on the basis of the lack of periodicity.

Other symptoms, in addition to fever, include headache, backache, and myalgias. Nausea and vomiting commonly occur during the febrile paroxysm. Diarrhea may be present. Lightheadedness and postural hypotension may

result from volume depletion. Confusion and delirium may also occur during the paroxysm of fever.

Physical findings in patients with malaria include fever, tachycardia, and orthostatic hypotension. Splenomegaly is typical, and tender hepatomegaly is often present. Jaundice and crackles in the lungs may be present.

Cerebral malaria is the most important and severe complication of falciparum malaria. Typically, it occurs after several days of illness, but it may also occur early in the course. Common initial manifestations include confusion and hallucinations, but coma is required for a true diagnosis of cerebral malaria. Physical examination may be nonfocal or have focal findings including disconjugate gaze, increased muscle tone, hemiparesis, and meningismus.

Splenic rupture may occur spontaneously or in association with minor trauma. Abdominal pain, possibly with radiation to the left shoulder, is typical. Hypotension and tachycardia result from the hemorrhage and rapid fall in blood volume. Rapid surgical intervention is essential.

A normocytic, normochromic anemia is typical, usually with evidence of hemolysis. Thrombocytopenia is also common. Hyponatremia, elevated blood urea nitrogen, bilirubinemia, and mildly elevated liver transaminase levels are also seen. Elevation of the serum creatinine level suggests acute renal failure due to hypovolemia or acute tubular necrosis.

The clinical presentation of malaria in adults from endemic regions is usually milder, manifested primarily by fever, headache, and gastrointestinal symptoms. This mild form of the illness is most often due to the acquisition of partial immunity. Immunity is not permanent and may wane after a prolonged period without exposure. In fact, natives to endemic regions represent one of the most common groups of travelers with imported malaria in the United States. Use of prophylaxis is uncommon among persons who have previously lived in malarious regions and are returning after a stay abroad.

Malaria during pregnancy is often more severe than in other adults. Mortality is increased, and the infection is associated with stillbirth, premature delivery, and low birth weight. Anemia is worse in malaria during pregnancy. Hypoglycemia is common in malaria during pregnancy, and as in other infected individuals, may be exacerbated by treatment with quinine or quinidine.

Differential Diagnosis

The clinical manifestations of malaria are nonspecific and may be present in a variety of other febrile illnesses. Common infections in the United States, such as influenza, bacteremia, viral gastroenteritis, viral hepatitis, viral encephalitis, and viral or bacterial meningitis, may present similarly. Febrile illnesses associated with travel that must be considered in the differential diagnosis include typhoid fever, relapsing fevers, yellow fever, leptospirosis, brucellosis, and traveler's diarrhea. Noninfectious causes of fever

Figure 106-3 Malaria: Clinical Course and Diagnosis.

may also be considered, such as drug-induced fever with hemolysis.

Diagnostic Approach

Malaria must be considered in any person with fever and a history of travel to an endemic area. A carefully elicited travel history will assist in making the diagnosis and eliminating several of the other possible infectious causes of malaria. The travel history will provide insight into the likely species of *Plasmodium* and guide treatment choices. *P. falciparum* occurs throughout the malarious regions of the world but predominates in Africa, Haiti, and New Guinea. It is common in India, Southeast Asia, Oceania, and South America. *P. ovale* occurs primarily in Africa. *P. vivax* occurs in Central and South America, western Asia, and North Africa. *P. vivax* is rarely found in sub-Saharan Africa. *P. malariae* is widespread throughout the malarious regions of the world.

Throughout the world, including the United States, the primary diagnostic method is the use of blood films (Fig. 106-4). Thick films are prepared by placing a fresh drop of blood, preferably from a finger stick, on a microscope slide. After drying, the cells are lysed with distilled water,

and the slide is stained with Giemsa or Wright-Giemsa stain. Thin films are prepared in the same manner as slides for examination of erythrocyte morphology. Preparation of thin films may be made from tubes of blood with anticoagulant, although the anticoagulant may distort parasite morphology. Thick films are more sensitive than thin films, but thin films are necessary for species identification. Speciation is critical for determining the appropriate therapy.

Thick and thin films may be falsely negative. Collection of specimens repeatedly is essential to ensure that the diagnosis is made. These specimens should be made at varying times of day to increase the likelihood of detecting the parasite. An experienced laboratory technologist should review the smears.

Maintenance of the microscopes and the quality of microscopy in resource-poor settings can lead to difficulty in accurately diagnosing malaria. Because of this, alternative methods of diagnosis have been developed. Several rapid diagnostic tests based on antigen capture techniques are now in use throughout the world. These methods are highly sensitive and specific for falciparum malaria and may eventually contribute immensely to improving malaria diagnosis.

Figure 106-4 Malaria: Clinical Course and Diagnosis.

Management and Therapy

The treatment decisions for malaria depend on the species and the severity of the illness (Fig. 106-5). Decisions concerning therapy have become much more complex over the past decade because of the increase in drug-resistant malaria. Guidelines for therapy of malaria are available from both the Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO). Malaria is a nationally reportable disease and should be reported to the state health department. The CDC also provides a 24-hour hotline for enquiries about malaria (770-488-7788 or 770-488-7100).

Optimum Treatment

Severe falciparum malaria requires parenteral therapy with quinine, quinidine, or an artemisinin derivative. Because intravenous quinine and artemisinin compounds are not routinely available in the United States, quinidine is the drug of choice. The CDC currently recommends that parenteral quinidine is paired with an oral agent: doxycycline, tetracycline, or clindamycin. In cases with high parasitemia (greater than 10% of erythrocytes infected), exchange transfusion can be considered as an adjunct to quinidine. However, there have been no comparative trials for the use of exchange transfusion, and the WHO does not make any recommendation for its use.

In uncomplicated falciparum malaria, treatment is guided by the location of acquisition of the infection. In most of the areas with endemic malaria, chloroquine resistance is common. However, *P. falciparum* in Central America, Haiti, the Dominican Republic, and the Middle East remains sensitive to chloroquine. In the past decade,

resistance to pyrimethamine-sulfadoxine has also become more widespread. For this reason, many countries around the world are attempting to introduce artemisinin combination therapy (ACT) for treatment of malaria. ACT is highly effective but will be limited for some time owing to the high costs and availability of the drugs. Artemisinin derivatives are not currently available in the United States.

Persons with travel history to areas where falciparum malaria is sensitive to chloroquine should be treated with chloroquine. If the species of malaria is unknown or travel occurred to regions with chloroquine-resistant *P. falciparum*, treatment should consist of oral quinine sulfate paired with one of the following drugs: doxycycline, tetracycline, or clindamycin. The CDC also recommends the use of atovaquone and proguanil in these patients. If neither of these options is available, the CDC recommends mefloquine as a third-line agent.

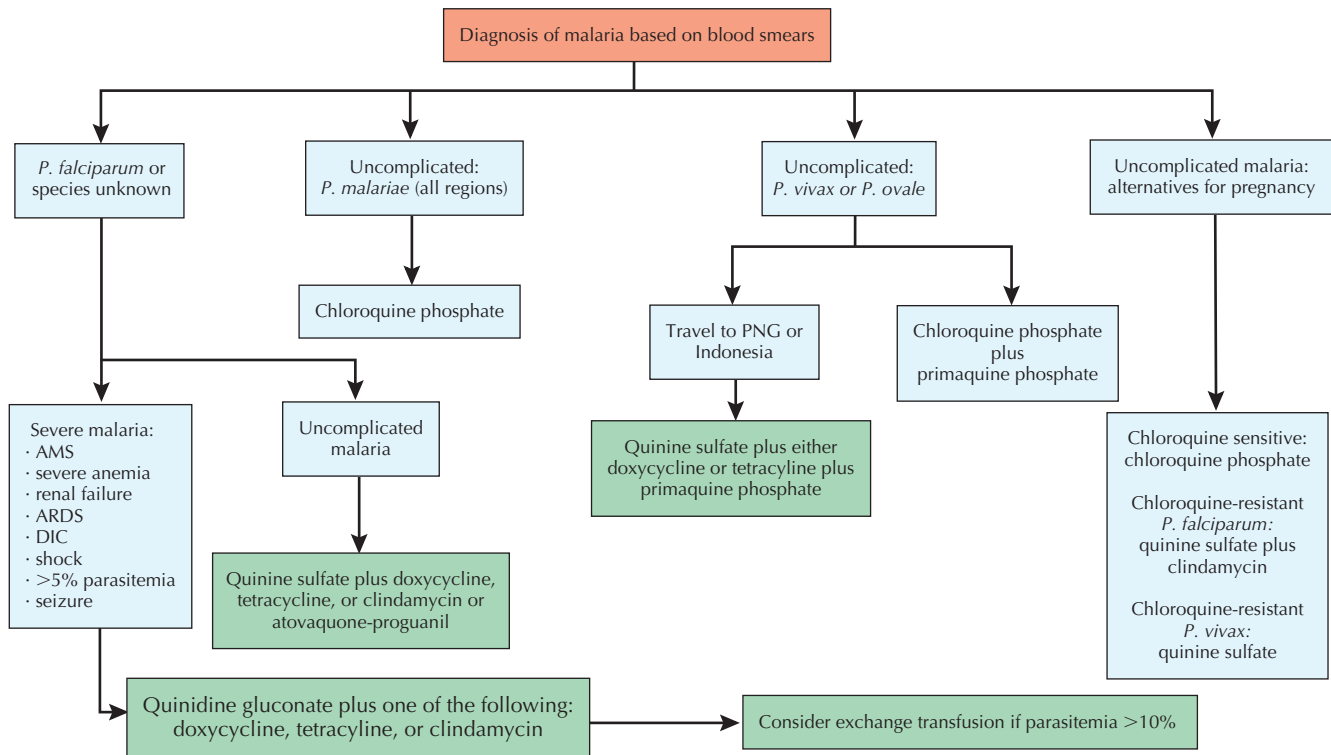

In infections due to *P. vivax*, *P. ovale*, and *P. malariae*, chloroquine is the drug of choice. Chloroquine does not treat the liver forms of *P. vivax* and *P. ovale*. Persons with infections by *P. vivax* and *P. ovale* must also receive primaquine to prevent relapse.

Cases of chloroquine-resistant *P. vivax* have been reported in Indonesia and Papua New Guinea. Treatment of persons with *P. vivax* acquired in these regions should consist of oral quinine sulfate with doxycycline or tetracycline and primaquine or mefloquine.

Avoiding Treatment Errors

A common treatment error is failure to use the correct antimalarial drug regimen. Before treatment, the species

Figure 106-5 Algorithm of Current Centers for Disease Control and Prevention Treatment Guidelines. AMS, altered mental status; ARDS, adult respiratory distress syndrome; DIC, disseminated intravascular coagulation; PNG, Papua New Guinea.

Dosages:

Quinidine gluconate: 6.25 mg base/kg loading dose IV over 1-2 hr, then 0.0125 mg base/kg/min continuous infusion over at least 24 hr.

Chloroquine phosphate: 600 mg base PO loading dose, followed by 300 mg base PO at 6, 24, and 48 hr.

Quinine sulfate: 542 mg base PO tid for 3 to 7 days (7 days if infection from SE Asia or pregnant).

Doxycycline: 100 mg PO bid for 7 days.

Tetracycline: 250 mg PO qid for 7 days.

Clindamycin: 20 mg base/kg/day PO divided tid for 7 days.

Atovaquone-proguanil: 4 adult tabs PO qd for 3 days.

Primaquine phosphate: 30 mg base PO qd for 14 days.

and the region of acquisition must be identified for appropriate treatment. Furthermore, treatment of liver forms is essential for eradication of *P. vivax* and *P. ovale*.

The treatment of malaria is complicated primarily by medication side effects. Quinidine gluconate can cause hypotension, hypoglycemia, and widening of the QRS complex or lengthening of the QT interval. Cardiac complications may warrant temporary discontinuation of the drug or slowing of the intravenous infusion. Consultation with a cardiologist or a physician with experience treating malaria is recommended.

Prophylaxis

Chemoprophylaxis is a critical component of prevention of malaria for travelers to endemic regions. The choice of agent should be dictated by the location to which the patient travels. Recommendations are available by the CDC at their website. Chloroquine is effective for travel

to areas with chloroquine-sensitive *P. falciparum* and the other species of *Plasmodium*. Mefloquine, atovaquone-proguanil or doxycycline are all acceptable for chemoprophylaxis for most other areas. However, the areas along the Thai-Cambodian and Thai-Burmese borders have malaria resistant to mefloquine, and this drug should be avoided in those areas. In addition to chemoprophylaxis, personal protective measures such as insect repellent, treated bed nets, and long clothing are important in the prevention of malaria.

Future Directions

Malaria is likely to remain a problem worldwide for the foreseeable future. In the past decade, the malaria situation in sub-Saharan African has deteriorated owing to multiple factors including climate instability, global warming, civil disturbances, HIV, drug resistance, and insecticide resis-

tance. Consequently, several new initiatives for malaria control have been established, such as the Roll Back Malaria Partnership and the Gates Foundation. Other new resources include free online journals for dissemination of information on all areas of research, including vector control, drug resistance, and health policy.

Infectious Diseases in Travelers

Introduction

In 2004, there were about 700 million visits across international borders, an increase of about 75% over the course of 15 years. The health risks of international travelers are significant: 1% to 5% of travelers seek medical attention, 0.01% to 0.1% require medical evacuation, and 1 in 100,000 dies. This chapter reviews the medical hazards faced by travelers, methods for reducing the risks associated with travel, and evaluation of fever in the traveler returning from developing countries. The focus is on prevention and management of infectious diseases.

Prevention of Travel-Associated Illnesses

Health care providers should counsel travelers to less-developed countries on travel-related risks and methods to prevent illness. An accurate risk assessment requires information regarding the patient's medical condition (i.e., age, immunization history, underlying medical disorders, pregnancy status, allergies, and host defense abnormalities) and exact travel itinerary (i.e., locations to be visited, including exact length of stay, urban versus rural locales, and level of accommodations and activities such as freshwater exposure, contact with animals, and sexual relations). Special efforts should be made to identify and counsel travelers who are at high risk, such as those traveling to physically unsafe locations, persons planning a prolonged stay, those traveling off the usual tourist routes, persons providing medical care, and immunocompromised persons. Current information regarding prevention of travel-associated diseases is available on the website maintained by the Centers for Disease Control and Prevention.

General risk counseling includes advice on how to avoid the following:

- Accidents, trauma, and injuries
- Transportation-related injuries
- Altitude illness
- Heat-, humidity-, and sun-related illnesses
- Water-related illnesses

Special emphasis should be placed on the most common infectious diseases encountered by international travelers, including the following:

- Traveler's diarrhea (TD)
- Respiratory tract infections
- Arthropod-borne illnesses (especially malaria, dengue, yellow fever, and Japanese B encephalitis)
- Sexually transmitted diseases (especially HIV)
- Blood-borne illnesses (especially hepatitis B and HIV)
- Animal bites (especially rabies) and envenomations

All patients should have their immunization status reviewed, and if deficiencies are noted in universally recommended vaccines (e.g., measles, mumps, rubella, varicella, diphtheria, tetanus), the vaccinations should be provided. Travelers should be offered vaccines available to prevent travel-associated illnesses based on an individual risk assessment. Physicians prescribing vaccines must be familiar with indications, contraindications, and administration guidelines. Although immunoglobulin can be used to protect against hepatitis A, the hepatitis A vaccine is preferred provided there is time for immunity to develop before travel.

Etiology and Pathogenesis

Causes of Fever after Travel to Tropical Countries

Only limited data are available regarding the causes of fever in travelers returning from developing countries. A

recent series of patients evaluated in Australia from 1998 to 2004 reported the following frequency of diagnoses: malaria 27%, gastroenteritis 12%, upper respiratory tract infections 8%, dengue fever 7%, typhoid or paratyphoid fever 4%, pneumonia 4%, influenza A or B 4%, viral syndrome 4%, rickettsial disease 3%, urinary tract infection 3%, skin infection 2%, helminth infection 2%, and hepatitis A 1%. Only 7% of patients in this series had a febrile illness without a confirmed diagnosis. The same study evaluated infectious illnesses in immigrants and refugees. This group more typically has illnesses indigenous to their country of origin. The diagnoses reported were tuberculosis 50%, schistosomiasis 13%, helminth infections 10%, chronic hepatitis 9%, leprosy 6%, malaria 3%, gastroenteritis 2%, upper respiratory tract infections 2%, HIV 2%, eosinophilia 2%, amebiasis 1%, and other 9%. Thus, it is important to recognize the unique spectrum of diseases that most commonly present in short-term travelers who return to their country of origin with a fever, and that these are dramatically different from those of immigrants.

Researchers from 30 international sites that are specialized travel or tropical medicine clinics on six continents reported data on 17,353 ill returned travelers from 1996 through 2004. Reasons for travel included tourism 59%, business 14%, visit to friend or relative 15%, missionary or volunteer work 8%, and research or education 4%. Selected syndromes experienced by the travelers included systemic febrile illness 22.6%, acute diarrhea 22.2%, dermatologic disorder 17.0%, chronic diarrhea 11.3%, respiratory disorder 7.7%, genitourinary disorder 3.5%, adverse drug or vaccine reaction 1.2% and death 0.1%. Of the patients with a systemic febrile illness, the following specific disorders were diagnosed: malaria 35.2%, dengue fever 10.4%, mononucleosis 3.2%, rickettsial infection 3.1%, and typhoid or paratyphoid fever 2.9%. Among patients with acute diarrhea, the following disorders were diagnosed: giardiasis 17.3%, amebiasis 12.0%, campylobacteriosis 8.5%, shigellosis 4.1%, and paratyphoid fever 11.0%.

Diagnostic Approach

Fever in Returning Travelers

In evaluating fever in the returning traveler, checking the vital signs to assess whether the patient is medically stable is a crucial first step. If cardiorespiratory distress is present, initial therapy should be targeted toward stabilizing the patient. Next, one should assess whether the patient has a potentially communicable disease and determine the need for isolation and personal protective equipment. All patients should be evaluated using standard precautions, including the use of gloves when in contact with all body secretions or excretions (except sweat). Surgical masks should be worn if it is suspected that the patient has a droplet-transmitted (e.g., meningococemia) or airborne-

transmitted (e.g., varicella) disease. An N-95 respirator should be worn if pulmonary tuberculosis, avian influenza, or a viral hemorrhagic fever is suspected.

Clinicians may find use of an algorithm helpful in establishing the differential diagnosis in returning travelers with fever. First, it is important to assess the patient for the presence of hemorrhagic manifestations given the potential severity of the likely pathogens. If hemorrhagic manifestations are present, viral hemorrhagic fevers (e.g., Ebola, Lassa, Marburg, Congo-Crimean, yellow fever), meningococemia, gram-negative sepsis, and rickettsial infections should all be considered. If viral hemorrhagic fever is possible based on history, clinical presentation, and incubation period, one should proceed immediately with appropriate isolation precautions, expert consultation, and consideration of ribavirin therapy. Second, consider the diagnosis of malaria. If infection with *Plasmodium falciparum* is possible and the patient is acutely ill with signs of severe malaria, empiric therapy should be initiated. If the patient is not acutely ill, it is advisable that serial thick and thin blood smears be obtained and the decision how to treat be based on laboratory results (see Chapter 106). One should then perform a complete history and physical examination and obtain preliminary laboratory tests. If localized findings are present, pursue the appropriate differential diagnosis (Table 107-1). If no localizing findings are present enteric fever, dengue, rickettsial infections, leptospirosis, schistosomiasis, brucellosis, and noninfectious causes of disease should be considered.

Key historical questions include exact itinerary, immunization history, and prophylaxis. Physical examination should focus on a thorough dermatologic examination; inspection of the eyes for scleral icterus, conjunctival suffusion, or conjunctival petechiae; assessment for lymphadenopathy, splenomegaly, and hepatomegaly; auscultation of lungs for evidence of pneumonia; and neurologic evaluation for altered mental status. Altered mental status in a returned traveler represents a medical emergency. Initial laboratory examination includes a complete blood cell count; serum chemistries; liver function tests; urinalysis; cultures of blood, stool, and urine; and chest radiography. Additional tests are obtained as directed by the results of the history, physical examination, and preliminary laboratory results.

Caveats for the evaluation of fever in the returning traveler are as follows:

- The patient should be thoroughly evaluated for all causes of febrile illnesses, both travel- and non-travel-related (e.g., pneumonia, urinary tract infections) infections. Remember that fever after travel may be unrelated to exposures during travel.
- The most common tropical infections are malaria, respiratory tract infections, infectious gastroenteritis, dengue, typhoid and paratyphoid fever, viral hepatitis, and rickettsial infection.

Table 107-1 Possible Physical Findings in Selected Tropical Infections

Physical Finding	Infection or Disease
Rash	Acute HIV seroconversion disease, brucellosis, Ebola virus, cytomegalovirus, dengue fever, Epstein-Barr virus, gonorrhea, measles, syphilis, typhoid, typhus
Eschar	Anthrax, <i>Borrelia</i> species infection, Congo-Crimean fever, South African tick-bite fever, scrub typhus, tick typhus
Jaundice	Brucellosis, cytomegalovirus, leptospirosis, malaria, Q fever, relapsing fever, rickettsial diseases, viral hepatitis (A, B, C, D, E), yellow fever
Lymphadenopathy	Acute HIV seroconversion disease, brucellosis, cat-scratch disease, dengue fever, Lassa fever, leptospirosis, plague, secondary syphilis, tularemia, visceral leishmaniasis
Hepatomegaly	Amebiasis, leptospirosis, malaria, typhoid, viral hepatitis
Splenomegaly	Acute American trypanosomiasis, African trypanosomiasis, brucellosis, cytomegalovirus, dengue fever, Epstein-Barr virus, malaria, leptospirosis, Q fever, relapsing fever, trypanosomiasis, typhoid, tularemia, visceral leishmaniasis
Hemorrhagic fever	Congo-Crimean fever, dengue hemorrhagic fever, Ebola virus, epidemic louse-borne typhus, Hantaviruses, Lassa fever, Marburg virus, meningococcemia, Rift Valley fever, yellow fever
Neurologic findings	Arboviruses (including dengue, Japanese encephalitis), brucellosis, malaria, leptospirosis, meningococcemia, Q fever, rickettsial infections, typhoid fever

- Malaria is potentially fatal and may progress rapidly; it should be excluded as rapidly as possible in all travelers with a history of fever and epidemiologic exposure, even if the patient is afebrile when seen.
- Useful diagnostic points include travel history, travel itinerary, immunization and prophylaxis history, an assessment of incubation period (Box 107-1), and specific exposure history.

Clinical Presentation and Management of Traveler's Diarrhea and Typhoid Fever

Traveler's Diarrhea

Clinical Presentation

Traveler's diarrhea (TD) is characterized by a twofold or greater increase in the frequency of unformed bowel movements. Symptoms often include abdominal cramps, nausea, vomiting (about 15%), bloating, urgency, fever, and malaise. Episodes usually begin abruptly and are generally self-limited. The most important determinant of risk is the destination of the traveler; high-risk destinations include Latin America, Africa, the Middle East, and Asia. TD is almost always acquired through ingestion of fecally contaminated food or water. TD typically causes four to five loose or watery stools per day. The average duration of diarrhea is 3 to 4 days, but about 10% of cases persist longer than 1 week. Fever or bloody stools occur in 2% to 10% of cases. A causative pathogen is demonstrated in 50% to 75% of patients with diarrhea that lasts less than 2 weeks. The most common bacterial causes of TD are enterotoxigenic *Escherichia coli*, *Salmonella* species, *Shigella* species, *Campylobacter jejuni*, and *Vibrio parahaemolyticus*. Viral etiologies include rotavirus and norovirus. Although less common, parasitic enteric pathogens, including *Giardia*

Box 107-1 Differential Diagnosis of Fever in the Returning Traveler*

Short Incubation (<7 days)

- Arboviral infection (including dengue fever)
- Anthrax
- Enteric bacterial infections
- Influenza A and B
- Malaria
- Paratyphoid
- Plague
- Relapsing fever (*Borrelia* species)
- Typhus (louse-borne, flea-borne)
- Viral hemorrhagic fever (Ebola, Lassa, Marburg)

Medium Incubation (8-21 days)

- Anthrax
- Amebic liver abscess
- Brucellosis
- Hepatitis A, C, and E
- Leptospirosis
- Malaria
- Measles
- Q fever
- Scrub typhus
- Trypanosomiasis, American
- Trypanosomiasis, African
- Typhoid fever
- Typhus
- Viral hemorrhagic fever (Ebola, Lassa, Marburg)

Long Incubation (>21 days)

- Amebic liver abscess
- Brucellosis
- Filariasis
- Hepatitis A, B, and C
- HIV
- Malaria
- Melioidosis
- Schistosomiasis (Katayama fever)
- Tuberculosis
- Visceral leishmaniasis

*Lists are not exhaustive

Figure 107-1 Amebiasis.

Sigmoidoscopic view: acute amebic colitis; pinpoint ulcers; minute submucous abscesses and hemorrhagic effusions

Segment of large bowel: amebic colitis of moderate degree; small ulcers with raised, undermined edges

Severe amebic colitis—now rarely seen: large ulcerated areas resulting from confluence of smaller ulcers; ulcers have ragged, undermined edges; intervening mucosa congested

Amebic ulcers with beginning submucous tunnel formation

Numerous amebae in submucosa at edge of ulcer

species, *Entamoeba histolytica* (Fig. 107-1), *Cryptosporidium parvum*, and *Cyclospora cayatanensis*, may cause TD.

Management and Therapy

Prevention of TD rests on three approaches: counseling regarding food and beverage consumption, use of non-antimicrobial medications, and use of prophylactic antibiotics. Bismuth subsalicylate decreases the incidence of diarrhea by about 60% but may result in temporary blackening of the tongue and stools, occasional nausea and constipation, and rarely, tinnitus. Bismuth subsalicylate

should be avoided in infants and young children, persons with aspirin allergies, and persons taking anticoagulants, probenecid, or methotrexate. Several antibiotics (trimethoprim-sulfamethoxazole, doxycycline, trimethoprim alone, and fluoroquinolones) decrease the incidence of TD by 50% to 95%. However, their efficacy depends on local antibiotic resistance patterns. Antimicrobial prophylaxis is not recommended because of potential side effects. Prophylaxis is reasonable in travelers who are immunosuppressed, although no data directly support this practice.

Initial treatment of TD includes fluid replacement (oral or intravenous), bismuth subsalicylate, and antimotility agents (e.g., tincture of opium, diphenoxylate, loperamide). Antimotility agents should be avoided in persons with fever or bloody stools. In addition, antimotility agents should be discontinued if symptoms persist longer than 48 hours. Antibiotic therapy with a fluoroquinolone should be considered in patients with prolonged TD, severe TD, bloody stools, or fever. However, resistance to fluoroquinolones is a growing problem among *Campylobacter* species. When resistance is a problem, therapy with azithromycin should be considered. The diagnostic evaluation should include stool culture, stool for ova and parasites, and assessment for rotavirus and norovirus.

Typhoid Fever

Clinical Presentation

Typhoid fever is an acute, life-threatening febrile illness caused by *Salmonella typhi*. Clinical manifestations include fever, headache, malaise, anorexia, splenomegaly, and a relative bradycardia. Infection may result in mild symptoms. A clinical syndrome quite similar to typhoid fever can result from infection with other *Salmonella* species (paratyphoid disease) (Figs. 107-2 and 107-3).

Management and Therapy

Preventive measures include careful selection of food and drink and immunization. Immunization is recommended for travelers to high-risk destinations (e.g., Indian subcontinent and developing countries in Asia, Africa, and Central and South America).

Typhoid fever should be considered in any returned traveler with high fever and systemic disease. The diagnosis is confirmed by cultures of stool and blood. Treatment should be initiated with intravenous antibiotics, usually a third-generation cephalosporin or a quinolone. Because *S. typhi* may demonstrate antimicrobial resistance, susceptibility tests should be performed on all isolates.

Avoiding Treatment Errors

It is important to screen returning travelers for potential infectious disease exposures because postexposure prophylaxis or early treatment may be available. Screening questions should include contact with fresh water (schistosomiasis), sexual contacts (HIV, STDs), malaria prophylaxis and prevention, vaccinations, and animals bites or scratches (rabies). It is critical that returning febrile travelers be thoroughly evaluated for all causes of their illness, both travel-related and non-travel-related causes. Patients with a clinically febrile significant illness should be evaluated for malaria by thick and thin smears regardless of a history of malarial prophylaxis. Patients with

hemorrhagic manifestations should be evaluated for viral hemorrhagic fevers (e.g., Ebola, Lassa, Yellow fever), meningococemia, rickettsial infections, and gram-negative sepsis. It is crucial to institute proper precautions (i.e., isolation and use of personal protective equipment) as soon as any person-to-person disease (e.g., meningococemia, viral hemorrhagic fever) is possible. Clinically ill patients without localizing findings should also be evaluated for enteric fever, dengue, rickettsial infections, leptospirosis, and viral hepatitis.

A common mistake in evaluating returned travelers with fever who have been home for several days is failure to consider common infections acquired in the United States such as Rocky Mountain spotted fever, viral encephalitis, pneumonia, urinary tract infections, and intra-abdominal infections.

In severely ill patients, diagnostic tests should be rapidly performed. Critically ill patients may require empiric therapy directed against possible infectious agents.

Future Directions

The events of September 11, 2001 have raised the specter of bioterrorism. Although the ultimate impact remains to be seen, physicians must remain ever vigilant of this new threat. Because many of the potential agents of bioterrorism (with the exception of smallpox) represent potential infections in travelers, clinicians providing care to travelers should be familiar with these agents, including anthrax, plague, Q fever, tularemia, and botulism. In addition, physicians must be aware of potentially new and emerging diseases such as severe acute respiratory syndrome and avian influenza.

The most active research area that will affect travelers to developing countries is the worldwide effort to develop safe and effective vaccines for pandemic diseases, including HIV, malaria, and tuberculosis. It is hoped that such vaccines will become available within the next 10 years.

Acquired Immune Deficiency Syndrome (AIDS)

Introduction

Infection with HIV causes a continuum of diseases, from the acute (primary) HIV infection to prolonged periods of asymptomatic infection to AIDS. The diagnosis of AIDS implies that there has been significant damage to the immune system and is a surveillance case definition established by the Centers for Disease Control and Prevention (CDC) as part of the classification of the clinical status of HIV-infected patients.

To date, two types of HIV, HIV-1 and HIV-2, have been identified as the causative agents of AIDS. There are several subtypes (clades) of HIV-1 with varying distributions throughout the world, whereas HIV-2 is more prevalent in Western Africa. The pandemic of HIV continues to be a serious international problem. As of 2005, there were about 38.6 million people worldwide living with HIV/AIDS, with 2.8 million deaths in 2005 and 4 million people newly infected with HIV.

Etiology and Pathogenesis

HIV predominantly infects T cells bearing the CD4 surface protein and other cells associated with the immune system. HIV exhibits a cytopathic effect on most infected cells, but it can also establish a latent state in cells with a very long half-life, which makes eradication difficult if not impossible. Most patients with HIV experience a slow, progressive decline in the CD4+ T-cell count—the rate of which varies with plasma viral load—and become increasingly at risk for opportunistic infections and certain types of malignancies.

HIV is transmitted by blood and other blood-derived products, through sexual contact, and from infected mothers to infants during the intrapartum and perinatal periods or through breast-feeding. There is no evidence to suggest that HIV is transmitted by casual social contact.

Clinical Presentation

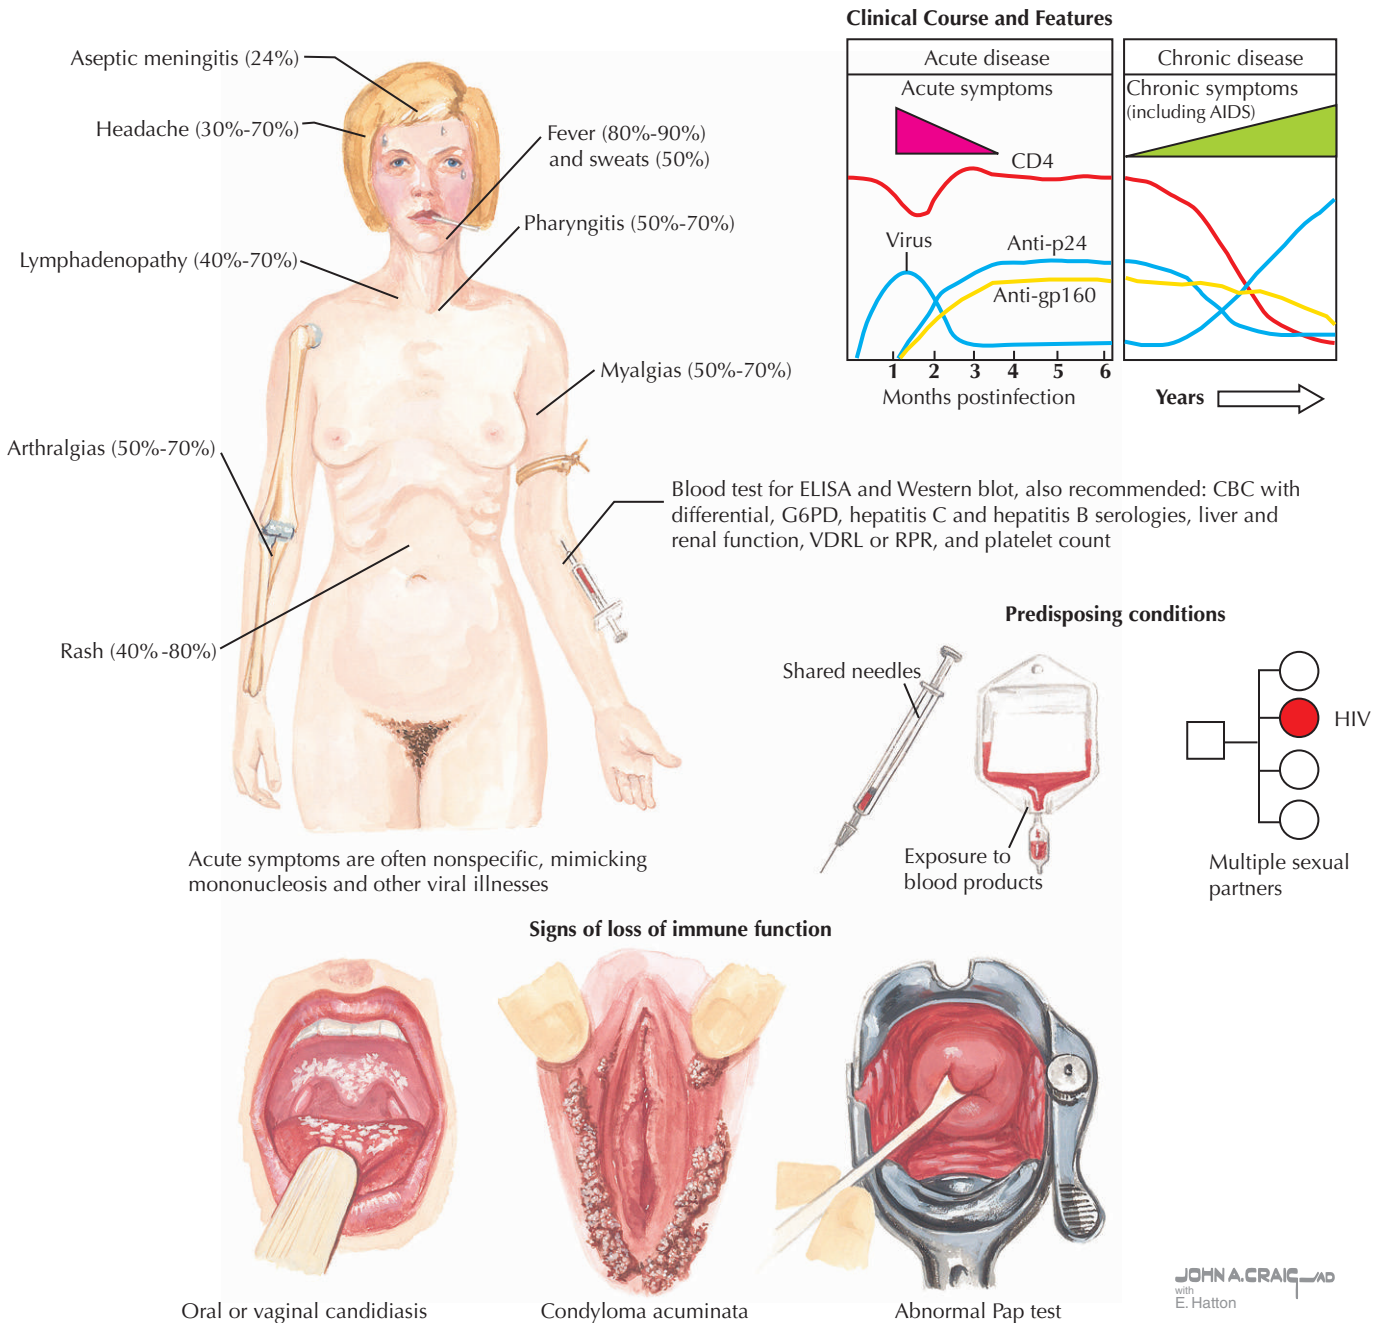

From 40% to 90% of patients with primary HIV infection present with symptomatic illness, including fever, fatigue,

a rash (typically maculopapular), headaches, lymphadenopathy, pharyngitis, nausea, vomiting, and diarrhea. These symptoms usually last for less than 2 weeks (Fig. 108-1).

After these symptoms of acute illness abate, patients infected with HIV can remain asymptomatic for up to several years. Once the CD4+ cell count decreases to 200 to 500 cells/mL, certain infections may develop, including varicella zoster, oral hairy leukoplakia, molluscum contagiosum, oral thrush, reactivation of tuberculosis, increased frequency and severity of pneumococcal pneumonia, herpes simplex infections, and esophageal or vaginal candidiasis (Figs. 108-2, 108-3, and 108-4). These patients are also at higher risk for malignancies, including Kaposi's sarcoma and lymphoma, and may experience unexplained weight loss, sinusitis, diarrhea, and fatigue. Screening for HIV is always indicated in patients who present with these conditions. After the CD4+ T-cell count decreases to less than 200 cells/mL, patients are at greater risk for opportunistic infections (OIs) and certain malignancies. They can present with a number of symptoms, including fever, headache, weakness, cough, shortness of breath, nausea,

ELISA, enzyme-linked immunosorbent assay; CBC, complete blood count; G6PD, glucose-6-phosphate dehydrogenase; VDRL, venereal disease research laboratory; RPR, rapid plasma reagin test.

vomiting, and diarrhea. A careful history and physical examination are essential, and a high index of suspicion for HIV should be maintained because of the varied clinical presentation in HIV disease.

Differential Diagnosis

The presentation of primary HIV infection can mimic other viral diseases, including infectious mononucleosis due to Epstein-Barr virus or cytomegalovirus (CMV),

rubella, herpes simplex infection, and secondary syphilis. Patients with rare congenital immune deficiencies may present with opportunistic infections. However, the serologic tests for HIV generally allow a definitive diagnosis in those patients who are infected.

Diagnostic Approach

Early diagnosis of HIV is crucial. Currently, the CDC recommends that all persons between the ages of 13 and

Figure 108-2 Hairy Leukoplakia of the Tongue.

64 years be tested for HIV. In the absence of universal testing, the diagnosis of HIV infection requires a careful history to identify potential high-risk behavior and a physical examination to seek clinical evidence of opportunistic infections and malignancies.

Laboratory confirmation of chronic HIV infection requires detection of antibodies against HIV-derived proteins by enzyme-linked immunosorbent assay (ELISA) followed by a confirmatory Western blot. There are also U.S. Food and Drug Administration (FDA)-approved rapid ELISA tests that may be performed on whole blood, plasma, saliva, or urine.

At this time, the use of the HIV ribonucleic acid (RNA) polymerase chain reaction (PCR) test is not approved by the FDA for diagnosis of primary HIV infection, but it is routinely used by many clinicians. Patients with acute HIV usually have negative ELISA and Western blot test results.

The quantification of HIV RNA levels (viral load) and the CD4+ T-cell counts are used to assess prognosis and to monitor the effectiveness of antiretroviral therapy.

The diagnosis of AIDS is confirmed by diagnosis of opportunistic infections or a CD4 count less than 200 cells/mL in the presence of documented HIV infection. The 1993 revised CDC classification for AIDS in HIV-infected adults is shown in Box 108-1.

Management and Therapy

Therapy for HIV Infection

General Principles

There is no known cure for HIV infection. The current principle of therapy is the use of three or more antiretro-

Box 108-1 Conditions Included in the 1993 AIDS* Surveillance Case Definition

- Candidiasis of bronchi, trachea, lungs, or esophagus
- Cervical cancer, invasive
- Coccidioidomycosis, disseminated or extrapulmonary
- Cryptococcosis, extrapulmonary
- Cryptosporidiosis, chronic intestinal (>1 month duration)
- Cytomegalovirus disease (other than liver, spleen, or nodes; including cytomegalovirus retinitis with loss of vision)
- Encephalopathy, HIV related
- Herpes simplex: chronic ulcers (>1 month duration) or bronchitis, pneumonitis, or esophagitis
- Histoplasmosis, disseminated or extrapulmonary
- Isosporiasis, chronic intestinal (>1 month duration)
- Kaposi's sarcoma
- Leukoencephalopathy, progressive multifocal
- Lymphoma, Burkitt's (or equivalent form), immunoblastic (or equivalent form), or primary of brain
- *Mycobacterium avium* complex or *M. kansasii*, disseminated or extrapulmonary
- *Mycobacterium tuberculosis*, pulmonary or extrapulmonary
- *Mycobacterium*, other species or unidentified species, disseminated or extrapulmonary
- *Pneumocystis carinii*
- Pneumonia, recurrent
- *Salmonella* septicemia, recurrent
- Toxoplasmosis of brain
- Wasting syndrome due to HIV

*Patients infected with HIV and who have a CD4+ T-cell count <200 or CD4+ percent <14% are classified as having AIDS.

Adapted from 1993 Revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Recomm Rep* 41(RR-17):1-19, 1992.

viral agents to maintain an undetectable viral load and thus allow some regeneration of the immune system. This approach prevents progression of HIV disease and significantly improves survival. Moreover, the concurrent use of multiple antiretroviral agents reduces the risk for early emergence of HIV that may be resistant to one or more agents.

Currently, there are four FDA-approved classes of antiretroviral agents: the nucleoside reverse transcriptase inhibitors (NRTIs), the non-nucleoside reverse transcriptase inhibitors (NNRTIs), the protease inhibitors (PIs), and the fusion inhibitors (Table 108-1). With the exception of the fusion inhibitors, almost all of these agents can cause nausea, vomiting, and diarrhea to varying degrees.

When to Start Treatment?

The most recent guidelines issued by the U.S. Department of Health and Human Services suggest that antiretroviral therapy be offered when the CD4+ T-cell count decreases below 350 cells/mL or with the occurrence of an AIDS-defining illness. In addition, all pregnant women, regardless of CD4+ count, should be offered antiretroviral treatment to reduce perinatal transmission and improve

maternal health. The initiation of antiretroviral therapy is a major therapeutic decision that requires a mutual commitment between the patient and the physician to long-term, full adherence to therapy regardless of CD4 count. Poor antiretroviral adherence is associated with the rapid development of resistant virus and can limit future therapeutic options. Mental illness (especially depression) and addiction are potential barriers to full adherence that should be screened for and treated before initiation of HIV therapy.

Optimum Treatment

The choice of antiretroviral agents should consider multiple factors, including previous exposure to antiretroviral drugs (and thus a chance to harbor resistant strains of HIV), the status of the patient's immune system, the presence of coinfections, the patient's ability to adhere to drug treatment, the potential side effects, and drug-drug interactions. All newly diagnosed patients should have a genotype for resistance.

Currently, patients are usually started on at least two NRTIs, in combination with a PI or one of the NNRTIs (Table 108-2). Alternative regimens are available in the references. Combination tablets with two or more antiretroviral agents are available and should help simplify medication management and increase compliance. In many instances, low-dose ritonavir (100 to 200 mg orally once or twice daily) may be used to enhance the pharmacokinetic profile of other PIs.

Avoiding Treatment Errors

Antiretroviral treatment errors can range from drug-drug interactions to the inappropriate use of single drug regimens. In general, at least three antiretroviral agents should be administered at the appropriate dose and frequency. Antiretrovirals without overlapping side-effect profiles should be selected based on established guidelines or HIV resistance testing. Fusion inhibitors are not routinely used in treatment-naïve patients and should be reserved for treatment-experienced patients. Some drug combinations, such as zidovudine and stavudine, are to be avoided due to competitive antagonism. Drug interactions are common with PI- and NNRTI-containing regimens that may alter the efficacy and safety of concomitant medications as well as the antiretroviral regimen. Abacavir should never be restarted if a hypersensitivity reaction is suspected.

Particular attention must be paid to selecting appropriate regimens in pregnant patients and in patients with comorbidities such as tuberculosis, hepatitis B (HBV), and hepatitis C.

Patients coinfecting with HIV and HBV should be evaluated for the need to treat the HBV. Three of the NRTIs are also active against HBV (emtricitabine, lamivudine, and tenofovir). In the coinfecting patient, two different drugs active against HBV should be included as part of the three-drug regimen to prevent development of resistant

Table 108-1 Summary of Antiretroviral Agents

Drug	Usual Dosage	Major Side Effects (Besides Nausea, Vomiting, and Diarrhea)
Nucleoside and Nucleotide Reverse Transcriptase Inhibitors (NRTIs)		
Zidovudine (AZT)	300 mg by mouth twice a day	Anemia, granulocytopenia, headaches, myopathy
Lamivudine (3TC)	150 mg by mouth twice a day, <i>or</i> 300 mg every day	Pancreatitis (in pediatric trials), headaches, fat wasting, hepatitis B flares upon discontinuation
Abacavir (ABC)	300 mg by mouth twice a day, <i>or</i> 600 mg every day	Hypersensitivity reaction (including fever, respiratory symptoms, gastrointestinal upset, rash— <i>do not rechallenge</i> , headache
Didanosine (ddI)	<ul style="list-style-type: none"> ■ >60 kg: 400 mg enteric coated by mouth every day ■ <60 kg: 250 mg enteric coated by mouth every day 	Pancreatitis, peripheral neuropathy lactic acidosis
Stavudine (d4T)	<ul style="list-style-type: none"> ■ >60 kg: 40 mg by mouth twice a day ■ <60 kg: 30 mg by mouth twice a day 	Pancreatitis, peripheral neuropathy, lactic acidosis, fat wasting, dyslipidemia
Tenofovir (TDF)	300 mg by mouth every day	Asthenia, headaches, renal failure, osteopenia, hepatitis B flares upon discontinuation
Emtricitabine (FTC)	200 mg by mouth every day	Rash, photosensitivity, headache, hepatitis B flares upon discontinuation
Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)		
Nevirapine (NVP)	200 mg by mouth every day ×2 weeks, then 200 mg by mouth twice a day	Hepatotoxicity, rash (including Steven-Johnson syndrome)
Delavirdine (DLV)	400 mg by mouth 3 times a day	Skin rash, headaches
Efavirenz (EFV)	600 mg by mouth every evening	Dizziness, insomnia, somnolence, abnormal dreams, rash (including Steven-Johnson syndrome) teratogenic, hepatotoxicity
Protease Inhibitors (PIs)		
Amprenavir (APV)	<ul style="list-style-type: none"> ■ >50 kg: 1200 mg by mouth twice a day ■ <50 kg: 20 mg/kg twice a day 	Rash
Indinavir (IDV)	800 mg by mouth every 8 hours, <i>or</i> 800 mg by mouth + ritonavir 100 mg every 12 hr	Nephrolithiasis, insomnia, rash
Nelfinavir (NFV)	1250 mg by mouth twice a day, <i>or</i> 750 mg by mouth 3 times a day	Rash, diarrhea
Ritonavir (RTV)	<ul style="list-style-type: none"> ■ Not to be used boosted with ritonavir Mainly used for protease inhibitor boosting at low doses (100-200 mg every day to twice a day)	Bitter aftertaste, perioral paresthesias, dyslipidemias, hepatotoxicity
Saquinavir (SQV)	1000 mg by mouth + ritonavir 100 mg twice a day	Gastrointestinal disturbances
Lopinavir/Ritonavir (LPV/r)	400/100 mg (2 tablets) by mouth twice a day	Dyslipidemia, hepatotoxicity
Fosamprenavir (FPV)	1400 mg by mouth twice a day, <i>or</i> 1400 mg by mouth every day with ritonavir 200 mg by mouth every day, <i>or</i> 700 mg + ritonavir 100 mg by mouth twice a day	Rash, dyslipidemia, hepatotoxicity
Darunavir (DNR)	600 mg by mouth + ritonavir 100 mg by mouth twice a day	Rash
Tipranavir (TPV)	<ul style="list-style-type: none"> ■ Ritonavir boosting always required 500 mg + ritonavir 200 mg twice a day	Rash, hepatotoxicity, intracranial hemorrhage (use caution with anticoagulants, surgery, central nervous system lesions)
Atazanavir (ATV)	400 mg by mouth every day, <i>or</i> 300 mg by mouth + ritonavir 100 mg by mouth every day	Jaundice, asymptomatic hyperbilirubinemia, peripheral paresthesias, PR interval prolongation
Fusion Inhibitors (FIs)		
Enfuvirtide (T-20)	90 mg subcutaneous twice a day	Injection site/skin reaction

Table 108-2 Initial Antiretroviral Regimens Recommended by DHHS

	Non-nucleoside Reverse Transcriptase Inhibitor Based	Protease Inhibitor Based
Preferred	Efavirenz + (lamivudine or emtricitabine) + (zidovudine or tenofovir DF)*	Lopinavir/ritonavir + (lamivudine or emtricitabine) + zidovudine
Number of pills	2-3	6-7

* Except in pregnant women or women with high pregnancy potential. DHHS, Department of Health and Human Services.

HBV strains. Discontinuation of HBV regimens can result in a severe hepatitis flare, and liver function tests should be monitored for several months after discontinuation.

Side Effects

Side effects associated with specific antiretroviral agents are listed in Table 108-1. More importantly, class-specific side effects have recently been noted. NRTIs have been implicated in mitochondrial dysfunction and rare but potentially life-threatening lactic acidosis and liver failure. Use of PIs and a subset of NRTIs has been associated with lipodystrophy with peripheral fat wasting and central fat accumulation and with hyperlipidemia in up to 50% of patients after 1 year of therapy. In a subset of these affected patients, type 2 diabetes mellitus has also been noted. Treatment of these metabolic side effects is similar to that of non-HIV-infected patients; however, special attention may be needed regarding drug interactions and concomitant side effects between these agents (i.e., statins) and antiretroviral agents.

An immune reconstitution syndrome is being increasingly recognized 1 to 8 weeks after initiation of highly active antiretroviral therapy (HAART). It presents as a paradoxical worsening of a patient's clinical, radiologic, or laboratory status (despite an improvement in viral load and CD4 count) and is due to restoration of immune responses to specific OIs or malignancies. Risk factors include a low baseline CD4+ count (<50 cells/mL) and a brisk virologic and immunologic response to HAART. Treatment is usually to continue HAART and OI treatment, with the occasional introduction of NSAIDs or steroids.

Follow-up

Ideally, HIV-viral load assays and CD4+ T-cell counts are obtained before therapy and 4 weeks and 8 to 12 weeks after initiation of treatment, and thereafter followed at 3- to 4-month intervals. If the treatment is effective, the viral load should decrease to less than 50 copies/mL within 4 to 6 months. Patients should be closely monitored for potential side effects of therapy. Consider performing the following laboratory studies at each clinic visit: serum chemistries, liver function tests, amylase, lipase, complete blood cell count with differential, viral load, and CD4+ T-cell count.

Prevention and Management of HIV-Associated Infections

The following baseline labs should be obtained before therapy: hepatitis A immunoglobulin G (IgG), hepatitis B surface antigen and antibody and hepatitis C IgG; CMV IgG; toxoplasma IgG; and rapid plasma reagin test (RPR). A tuberculin skin test should be done. A baseline Papanicolaou test should be performed, repeated at 6 months and annually thereafter with aggressive management of abnormal results.

The Pneumovax, HBV, and influenza vaccines are recommended for all HIV-infected patients. Hepatitis A vaccine is recommended in susceptible persons (those with negative anti-HAV antibody).

Based on the CD4 count, the following algorithm may be used in initiating prophylaxis for serious opportunistic infections in HIV-infected patients:

- CD4 count less than 200 cells/mL: obtain baseline ophthalmologic examination, start *Pneumocystis jirovecii* pneumonia (PCP) prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX), 1 double-strength tablet daily (preferred regimen); or dapsone, 100 mg orally once daily (check baseline glucose-6-phosphatase dehydrogenase); or atovaquone, 1500 mg daily.
- CD4 count less than 100 cells/mL: if toxoplasma IgG positive, start either TMP/SMX double-strength daily or dapsone, 50 mg daily, and pyrimethamine, 50 mg once weekly, with folinic acid, 25 mg once weekly.
- CD4 count less than 50 cells/mL: ophthalmologist examination every 3 months, prophylaxis against *Mycobacterium avium* complex (MAC) with azithromycin, 1200 mg weekly, or clarithromycin, 500 mg orally twice daily.

In evaluating HIV-positive patients, particularly those with a CD4 count of less than 200 cells/mL and the following clinical complaints, consider:

- Respiratory symptoms: bacterial pneumonia, PCP, tuberculosis, and histoplasmosis. Obtain chest x-ray, arterial blood gas, sputum culture, early referral for bronchoscopy if clinically warranted.

- Headache: computed tomography or magnetic resonance imaging, lumbar puncture. The differential diagnosis includes toxoplasmosis (if toxoplasma IgG positive and CD4 cell count <100 cells/mL), central nervous system lymphoma, meningitis (bacterial, cryptococcal, syphilis, tuberculosis).
- Diarrhea: *Salmonella*, *Giardia*, *Shigella*, *Campylobacter*, and *Yersinia* species. Obtain stool culture and ova/parasite screen; consider *Cryptosporidia*, *Isospora*, and *Microsporidia* species, *Mycobacterium-avium* complex, CMV, and *Clostridium difficile*.
- Rash: always consider drug-induced rash, most commonly from antiretroviral agents and TMP-SMX.

For specific treatments for these and other HIV-associated opportunistic infections, early referral to specialists is essential.

Prevention of Infection and Transmission

Physicians should emphasize preventive education to all patients, especially those who are sexually active or engage in high-risk behavior such as intravenous drug or crack cocaine use. Offer HIV testing (which requires patient consent) with pretest and post-test counseling to patients who request such tests and also to those at increased risk for HIV and other sexually transmitted diseases. Diagnosis of acute HIV infection requires an increased level of suspicion and testing must be done with HIV RNA PCR because HIV antibody testing has a window period following initial infection and will not be positive for several weeks to months. Patients with acute HIV infection generally have very high viral loads and the greatest risk for transmitting the virus is in this period.

HIV-infected patients should be carefully counseled to avoid transmission of HIV by practicing safer sexual behaviors and informing past and future partners of their HIV status, never sharing needles, and informing those involved in their care of their HIV status.

Future Directions

Management of HIV infection continues to change rapidly, as new potential therapeutic agents are being introduced

and studied in clinical trials. Two new classes of antiretroviral medications, CCR5 receptor entry inhibitors (Maraviroc), and integrase inhibitors (Raltegravir), were approved for use in 2007. They are approved for use in treatment-experienced patients with resistant virus and are being studied in antiretroviral-naïve patients.

Analysis of viral genotype for mutations that confer resistance against specific antiretroviral agents is also available and should facilitate the selection of optimum therapeutic combinations in treatment-naïve and treatment-experienced patients. Numerous strategies to generate a vaccine against HIV are also being tested.

Nongonococcal Urethritis

Introduction

Urethritis, inflammation of the urethra, is a syndrome classically characterized by a urethral discharge and dysuria, but urethritis may also be asymptomatic. Urethritis is most accurately defined as the presence of an increased number of polymorphonuclear leukocytes (PMNs) from the anterior urethra. It is sexually acquired, primarily, and has many infectious etiologies. In general, the disease can be classified as either gonococcal or nongonococcal urethritis (NGU). The presence of gram-negative intracellular diplococci (GNID) on urethral smear correlates highly with gonorrhea infection. NGU is diagnosed when inflammation is present without GNID. Mucopurulent cervicitis (MPC) is the female equivalent. Noninfectious etiologies include chemical and physical irritants. As with most sexually transmitted infections, NGU is most prevalent in the 19- to 24-year age group, a time when changing sexual relationships are common. A minor disorder in most cases, MPC is clinically important for three reasons: (1) the potential for complications, particularly pelvic inflammatory disease (PID) associated with decreased fertility in female partners when *Chlamydia trachomatis* is the underlying pathogen; (2) its damaging influence on interpersonal relationships, especially when the condition is not adequately understood; and (3) prolonged anxiety when symptoms, although mild, are slow to resolve or when there are recurrences.

Etiology and Pathogenesis

C. trachomatis is the most common known causative organism and can be isolated from the urethra in 15% to 55% of men with NGU. Unlike most bacteria, this organism is dependent on the energy-producing metabolic activities of the host cells and thus is an obligate intracellular parasite. The prevalence of NGU caused by *C. trachomatis* infection varies by age, with lower prevalence in older age groups. Complications of NGU caused by *C. trachomatis* infection include prostatitis, epididymitis, and Reiter's syndrome.

Often, the causes of NGU are not elucidated, but recently defined pathogens include *Ureaplasma urealyticum*, *Mycoplasma genitalium*, *Trichomonas vaginalis*, *Candida* species, adenovirus, and *Neisseria meningitidis* (Fig. 109-1). Genital herpes simplex virus (HSV) can cause urethritis in about 30% of men with primary genital infection, but it is seen in a much lower percentage of men with recurrent genital HSV infection. Often, *Ureaplasma urealyticum* is isolated from the urethra of men with NGU, and differential antibiotic studies support the view that it sometimes has a pathogenic role. However, this organism is often isolated from the urethra in healthy men, and there is no simple way of identifying those cases in which it is patho-

genic. Between 20% and 30% of men with NGU have no detectable organisms. Recent observations have found an association of NGU with bacterial vaginosis and oral sex. Asymptomatic urethritis, without a visible discharge but with evidence of increased PMNs on smear, may have a different etiology from symptomatic disease. *C. trachomatis* is detected less frequently in this situation.

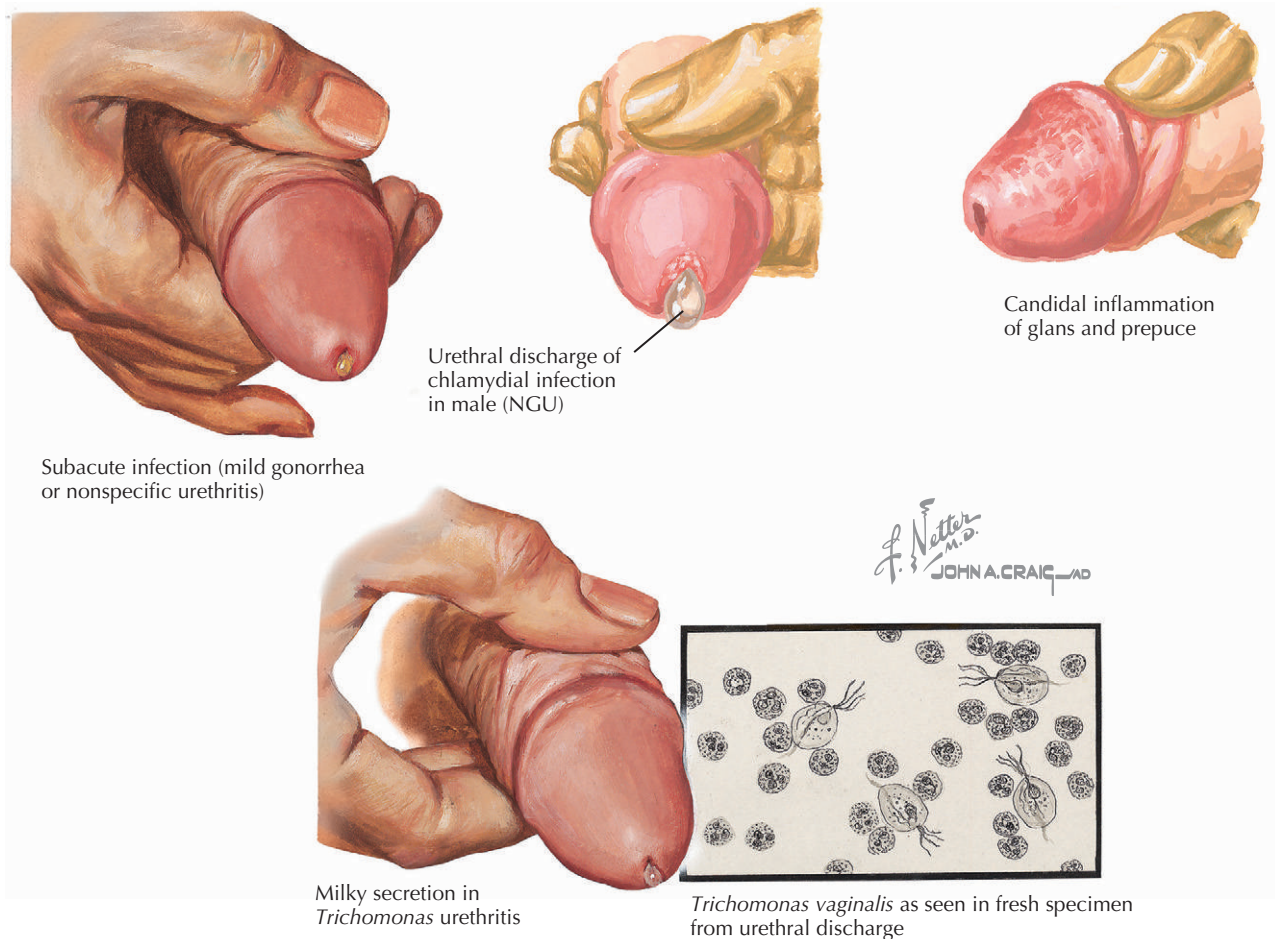

Noninfectious etiologies include chemical irritants (e.g., spermicides, bath products), physical irritants, urethral stricture, foreign bodies, bacterial urinary tract infections, repeated vigorous urethral stripping, and heavy crystalluria or calculous gravel in the urine.

Clinical Presentation

In the typical patient, symptoms include dysuria, urethral discharge (mucoid or purulent), and penile irritation. Urethral discharge, which may be present on examination or on a urethral smear in a significant number of asymptomatic individuals, is a sign of NGU (see Fig. 109-1).

The patient first notices symptoms from several days to several weeks after infection; 2 or 3 weeks is a common incubation period. Urethral inflammation will often give

Figure 109-1 Urethritis.
NGU, nongonococcal urethritis.

rise to a discharge and dysuria, and the patient may experience urinary frequency. When the posterior urethra is involved, symptoms are usually mild and may be intermittent or transient, lasting only 1 to 2 days. The absence of symptoms does not exclude the diagnosis of NGU. There is a high incidence of asymptomatic infection of the urethra with *C. trachomatis*.

Spotty balanitis caused by candidal overgrowth in uncircumcised men is the most common complication of NGU. Men presenting with balanitis should always be checked for NGU, even when there are no symptoms. Hyperglycemia should be excluded because diabetes mellitus sometimes presents with candidal balanitis. Other complications include epididymitis, orchitis, acquired reactive arthritis, and Reiter's syndrome.

Epididymitis occurs less commonly. Swelling and tenderness begins in the lower pole. The groove between the epididymis and the testis is accentuated at first but then becomes obscured as the condition progresses. Occasionally, patients complain of blood-stained semen due to seminal vesiculitis. Reiter's disease is a rare complication that presents 10 to 30 days after the sexual contact. Patients

may have an acute arthritis affecting one or more large peripheral joints. Conjunctivitis may also be present.

Diagnostic Approach

The diagnosis is confirmed by the demonstration of PMNs in the anterior urethra and by the absence of gram-negative diplococci on Gram stain with a negative culture or test result for *Neisseria gonorrhoeae*. Excessive PMNs can be confirmed by a Gram-stained urethral smear with more than 2 PMNs per high-power microscopic field ($\times 1000$), or a Gram-stained preparation from a first-pass urine specimen containing more than 9 PMNs per high-power microscopic field ($\times 1000$). Leukocyte esterase activity on first-pass urine correlates with the presence of urethritis but lacks sufficient sensitivity to be considered a reliable diagnostic test for NGU. The quality of the smear is dependent on how the specimen is collected.

Five or more PMNs per high-power field ($\times 1000$) is generally accepted as the criterion for urethritis. The absence of PMNs in a single urethral smear does not exclude the diagnosis, particularly if the patient urinated

before the examination. There is no conclusive recommendation on the optimal time between micturition and specimen collection, but 2 to 4 hours is preferred, with a minimum of 30 minutes. Urethral specimens should be obtained using a 5-mm plastic loop or cotton-tipped swab. There is no information suggesting the superiority of either method, although the loop appears to be less physically and psychologically traumatic to the male patient.

Symptomatic patients without evidence of inflammation should be tested for an etiologic diagnosis. In most clinical settings, this includes testing for *N. gonorrhoeae* and *C. trachomatis*. Re-examination the following morning, having the patient not urinate overnight, may increase the diagnostic yield of the Gram stain. Empiric treatment is in order for those individuals with an observable purulent discharge, those at high risk for infection (e.g., patients in a sexually transmitted disease clinic, adolescent males in a juvenile detention center), or individuals unlikely to return for re-evaluation. The minimum time between exposure and the development of a detectable inflammatory response, by urethral smear or microscopic study of a urine sample, is not known, but it is reasonable to allow 1 week after a risk contact before accepting a negative result as conclusive. The two-glass test, because of its low sensitivity and specificity, is not recommended to diagnose NGU or to differentiate it from urinary tract infection.

Management and Therapy

Optimum Treatment

The diagnosis should be established by demonstrating that urethral inflammation is present and by excluding gonorrhea; all patients should have testing for *N. gonorrhoeae*. *C. trachomatis* testing, although preferable, may be deferred in men with inflammation on urethral smear when resources are limited. Urethral smears without evidence of significant PMNs should be tested for *C. trachomatis* in symptomatic men. The provider should take a detailed sexual history to identify all sexual partners requiring assessment and treatment and should treat sexual partners considered to be at risk even if there are no signs of infection. Chlamydial cervicitis or PID can develop suddenly and without warning in a female partner. It is better to treat unnecessarily if exposure to infection has occurred, rather than risk this complication. A full course of antibiotics should be completed even when the symptoms resolve within a few days. Alcohol in moderation will not affect the outcome. Sexual activity should be avoided until the inflammation has resolved.

Treatment should be administered at the time of diagnosis with medications that are highly effective against chlamydia (cure rate for *C. trachomatis* of more than 95%), are easy to use (preferably single-dose therapy, but not more than twice-daily therapy), have a low incidence of side effects, and minimally interfere with lifestyle. The

preferred medication regimens are azithromycin, 1 g orally in a single dose, or doxycycline, 100 mg orally twice daily for 7 days. Alternative regimens include erythromycin, 500 mg orally 4 times daily for 7 days; erythromycin ethylsuccinate, 800 mg orally four times daily for 7 days; ofloxacin, 300 mg twice daily or 400 mg orally once daily for 7 days; or levofloxacin, 500 mg once daily for 7 days.

Trimethoprim-sulfamethoxazole (cotrimoxazole) is active against chlamydia but is not effective in the treatment of NGU and is, thus, *not* recommended.

Patient Follow-up

Patients should be instructed to abstain from sex for 7 days after initiation of therapy. Re-evaluation is not necessary unless signs or symptoms persist or recur after completion of therapy.

Recurrent or Persistent Nongonococcal Urethritis

In recurrent or persistent NGU, the urethral inflammation is usually mild and will resolve over several days with appropriate antibiotic therapy. Persistence occurs in 20% to 60% of men treated for acute NGU; however, resolution may take several weeks. Occasionally, relapse occurs, even in the absence of reinfection. Relapse is most common in the first 3 months after the initial episode. The pathologic basis of these relapses is not understood and is probably multifactorial. Persistence of signs and symptoms beyond 3 months should prompt the clinician to consider chronic prostatitis or chronic pelvic pain syndrome.

When relapse occurs in the context of a stable relationship, it is important to exclude the possibility of reinfection by confirming that the sexual partner has completed an appropriate course of antibiotics. Careful explanation is also necessary because relapse sometimes leads to the erroneous conclusion that there has been a sexual contact outside of the relationship.

Female partners of men with persistent or recurrent NGU do not appear to be at increased risk for the development of PID, provided they received appropriate therapy as a contact.

Minor sensations of urethral irritation may persist for some time after resolution of NGU, and the patient will often feel that the infection is still present. It is important to document definite urethral inflammation before prescribing another course of antibiotics.

After confirming persistent inflammation on urethral smear, alternative antibiotic therapy should be considered. If the patient has not adhered to initial therapy, consider switching to single-dose therapy. Azithromycin or doxycycline failure may be due to resistant *U. urealyticum* or to *T. vaginalis*. If the patient is symptomatic, was compliant with the initial regimen, and has not had sexual contact with an untreated partner, consider therapy with erythro-

mycin, 500 mg orally 4 times daily for 7 days, plus a single oral dose of metronidazole, 2 g, or tinidazole, 2 g orally in a single dose. Some isolates of *U. urealyticum* are resistant to erythromycin but may respond to ofloxacin, 300 mg every 12 hours orally for 7 days. Persistent NGU following two courses of therapy requires other diagnostic considerations (i.e., cystitis and prostatitis) and urologic evaluation to rule out foreign bodies, strictures, and periurethral abscess. *M. genitalium* may cause persistent NGU and requires a 6-week course of erythromycin. If no cause for persistent NGU can be found, a 6-week course of empiric doxycycline or erythromycin is rational.

Sexual contacts and partners, including all partners and sexual contacts of symptomatic men 2 weeks before the onset of symptoms and those of asymptomatic men 6 months before diagnosis, should be evaluated and offered empiric therapy. The treatment regimen should be consistent with that used for the partner and, at a minimum, be effective for uncomplicated chlamydia infection. Female contacts of men with chlamydial urethritis should be treated regardless of the results of chlamydia testing. Concurrent treatment is preferred and may result in improved clinical response in men with chlamydia-negative NGU.

Referral to a specialist clinic is advisable if there is reluctance to give a detailed sexual history. Treatment of all partners who may be at risk, if symptoms persist after two courses of antibiotics or if complications develop, should be arranged.

Avoiding Treatment Errors

Whenever possible, single-dose, directly observed therapy for NGU is the best way to ensure adherence to treatment. The main cause of recurrent symptoms following treatment is reinfection from an untreated partner. NGU, like all bacterial sexually transmitted infections, requires referral for screening and treatment of partners. For patients in whom reinfection is not deemed the probable cause for persistent or recurrent infection, clinicians must consider antimicrobial resistance or the possibility of infection with pathogens not covered by the initial choice of therapy.

Future Directions

The use of urine-based nucleic acid amplification tests (NAATs) for the diagnosis of gonococcal and chlamydial urethral infections may warrant reclassification of urethritis into three categories: gonococcal, chlamydial, and nongonococcal-nonchlamydial urethritis. Diagnostic screening and testing for *C. trachomatis* will be strongly recommended for males as the cost of NAAT continues to decrease because chlamydia infection has significant public health

implications. Other developments include clarification of the role of *M. genitalium* in NGU and the development of screening algorithms for men at increased risk for recurrent NGU.

Gonorrhea

Introduction

Gonorrhea is a sexually transmitted disease (STD) known since biblical times, for more than 2000 years, characterized by superficial or deep infection of mucosal surfaces, especially the genital mucosa, by the organism *Neisseria gonorrhoeae* (the gonococcus). Untreated infection often results in deeper complications, including salpingitis or epididymitis, and occasionally bacteremia and arthritis, meningitis, or endocarditis. Although antibiotic resistance is more common than in earlier decades, treatment is still highly efficacious. The primary problem is in case detection. Because some infections may have few symptoms, infected persons can be missed without attention to risk factors in a patient's history and knowledge of the epidemiology pertinent to gonorrhea. Excellent new noninvasive diagnostic tests are readily available in the United States.

Most cases of gonorrhea are sexually transmitted. Infection in neonates may be from the mother's birth canal. Infection of prepubescent children should be assumed to be the result of sexual abuse. Infection is most common in adolescents and young adults, with peak prevalence in women aged 15 to 19 and men aged 21 to 25 years. Prevalence is much higher in the United States among African Americans, which probably reflects a complex mixture of socioeconomic, behavioral, health care seeking, and health care access factors. Rates of infection are particularly high in many rural southeastern states and in certain large cities. In some inner cities, prevalence may approach 5%, but this is now uncommon. In general, risk is increased among the young and unmarried, and among those having a new sex partner or multiple sex partners or a sex partner with multiple partners. The prevalence of infection has declined in the past decade but is increasing in certain groups, including young men who have sex with men, among whom rectal gonococcus is increasing in some locales. Condoms probably are quite effective in prevention of transmission by genital sex. The risk for infection after unprotected genital sex with an infected partner is about 30% for men and 70% to 80% for women. Antibiotic-resistant strains are becoming more common, but distribution is uneven; multiple resistances including resistance to ciprofloxacin are found, particularly in isolates from persons from southeast Asia or parts of Africa.

Etiology and Pathogenesis

The gonococcus is a gram-negative diplococcus that grows only in humans and does not survive long outside of the body. It attaches to epithelial surfaces by several adherence ligands that interact with specific receptors. Attachment is followed by local invasion and sometimes by penetration of deeper tissues and bacteremia. Although much is known about molecular pathogenesis, there is no current vaccine candidate; earlier attempts to develop a vaccine based on the pilus adherence ligand failed. Strains may be typed on the basis of reactions with a panel of monoclonal antibodies against the porin (major outer membrane) protein (serotyping), or on the basis of DNA sequence differences

in the *por* gene (genotyping), but these are only available in research laboratories.

Clinical Presentation

In men, purulent urethritis with dysuria and small amounts of yellow or greenish mucoid discharge develops, especially in the early morning before urination, within 2 to 7 days of exposure (Fig. 110-1). In 5% to 10% of men, a persistent low-grade or asymptomatic infection of the urethra may develop. These men do not present for health care and may transmit infection to their sexual partners. Epididymitis in men younger than 35 years is usually due to either gonococcal or genital chlamydia infection.

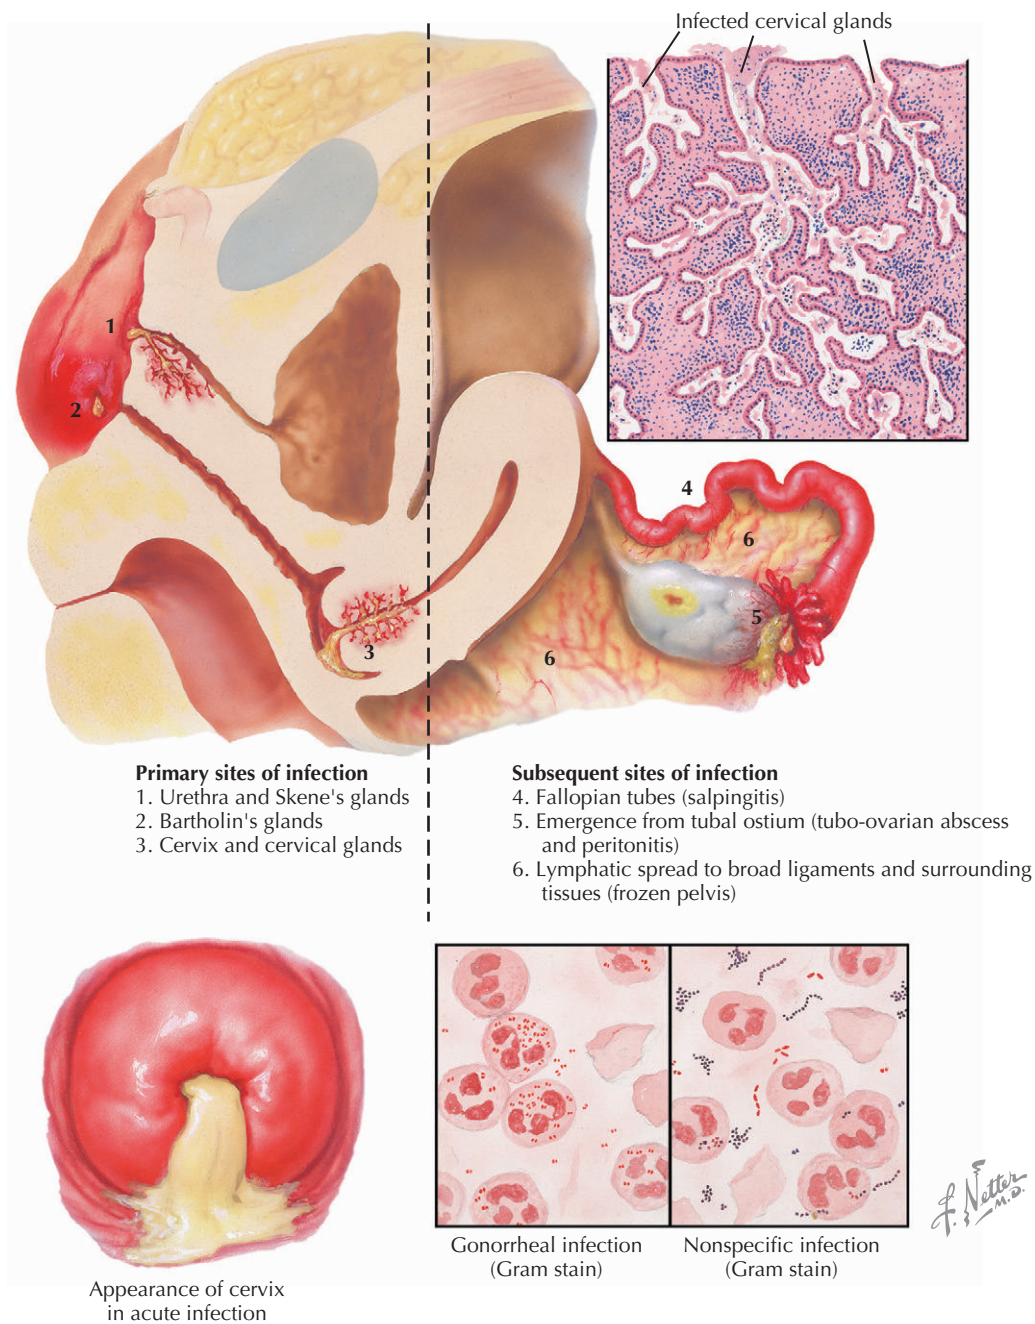

Figure 110-1 Urethritis in Men.

Asymptomatic or oligosymptomatic cervical infection may develop in 50% of women; others have increased vaginal discharge or dysuria (Fig. 110-2). Physical examination often reveals mucopurulent cervical discharge. Low-grade infection of the endometrium is relatively common. About 10% to 15% of untreated genital infections in women are followed by salpingitis, with adnexal pain, and sometimes with fever and leukocytosis. Risk for salpingitis is increased in very young women (15 to 16 years) and in those who have had it previously. The severity of illness is variable, ranging from mild to acute; some patients may be treated as outpatients, whereas others require hospitalization. Physical examination may reveal cervical motion tenderness and adnexal tenderness or fullness. Salpingitis may

be followed by tubal scarring and infertility, or increased risk for ectopic pregnancy (see Fig. 110-2).

Infection of the pharynx is found in up to 20% of patients with genital gonorrhea, but there usually are no symptoms. Rectal gonorrhea is found in up to 40% of women with cervical gonorrhea, also without symptoms and, presumably, reflecting spread of infection from the contiguous genital site. In contrast, rectal gonorrhea in men who have sex with men is often quite symptomatic with pain, discharge, and tenesmus.

Bacteremia develops in about 1% of patients, particularly in those infected by strains that are highly resistant to human serum complement. Persons with homozygous deficiency of late complement components are susceptible

Figure 110-2 Gonorrhea in Women.

to recurrent gonococcal or meningococcal bacteremias; about 5% of patients with the disseminated gonococcal infection (DGI) syndrome are lacking one of the late complement components C5 through C9. A CH50 test will detect such individuals, although it is best done after the acute infection has subsided. DGI presents in several forms, but patients usually are not acutely or severely ill, in contrast to meningococcal bacteremia. About half of patients with DGI do not have fever. Many have a typical rash distributed over the periphery, especially the hands,

with a small number (fewer than 30) of pustular or hemorrhagic tender lesions. This may be accompanied by polyarticular arthralgias or monoarticular arthritis, typically involving major joints; rash may be absent in patients with arthritis. DGI frequently follows asymptomatic genital or pharyngeal infection.

Typically, infection in neonates presents as purulent conjunctivitis, which was a major cause of blindness but is now rare. Infection in young females most often presents as vulvovaginitis.

Differential Diagnosis

Gonococcal urethritis must be differentiated from *Chlamydia trachomatis* urethritis and from other causes of urethritis including *Mycoplasma genitalis* and, occasionally, herpes simplex virus or *Trichomonas vaginalis* (see Fig. 110-1). Gonococcal urethritis tends to have a more profuse and purulent discharge, but this is not helpful in individual patients. The differential diagnosis for epididymitis includes chlamydia epididymitis and testicular torsion. Gonococcal cervicitis with mucopurulent discharge must be differentiated from chlamydia cervicitis, which may produce an indistinguishable clinical picture. Many diseases, including ectopic pregnancy and appendicitis, may mimic salpingitis. The DGI syndrome may mimic Reiter's syndrome, bacterial endocarditis, and other types of acute arthritis.

Diagnostic Approach

The diagnosis of gonorrhea depends on awareness of patient risk factors, including a sexual history. Urethral discharge or mucopurulent cervicitis suggests gonococcal or chlamydial infection. In women, it is important to differentiate vaginal discharge and vaginitis from cervicitis; gonococci do not cause vaginitis except in prepubescent girls.

In men with purulent urethral discharge, a Gram stain showing intracellular gram-negative diplococci (see Fig. 110-2) is both highly sensitive and specific, and cultures or other tests are not usually necessary. In infected men without frank discharge, Gram stain is no more than 60% sensitive, and diagnosis is best achieved either by culture of a urethral swab or fresh urine sediment, or by use of a nucleic acid amplification test (NAAT) (polymerase chain reaction; transcription-mediated amplification; or DNA strand displacement assay). NAATs on urine or self-obtained vaginal swabs are more than 98% sensitive and 98% specific, and are as sensitive as cultures, but cost may be a limiting factor for some patients or practices. NAATs may be utilized for screening for both gonorrhea and chlamydia infection, and one combined test (Aptima Combo II) has a reported positive predictive value of greater than 95% in a population with prevalence of only 0.5% gonorrhea. Cultures are still required for pharyngeal or rectal infections because NAATs are not approved for such specimens. Despite their convenience, the NAATs do not preserve an isolate for testing susceptibility to antimicrobials, and they do not easily allow strain typing, which may be useful in medical-legal cases. Cultures should be plated on selective chocolate agar media containing antibiotics to inhibit the normal flora or placed in transport media for prompt transfer to the laboratory. There are no serologic tests for gonorrhea.

Women ordinarily require either cervical culture or a NAAT test of urine or vaginal introitus. Gram stains of

cervical discharge are only 50% sensitive and not sufficiently specific for accurate diagnosis in most clinics. In patients with possible salpingitis, it may be helpful to seek consultation and to perform vaginal ultrasound to examine the anatomy of the fallopian tubes. Computed tomography of the pelvis and laparoscopy may be needed. Pregnancy tests should be obtained, and if culture materials are available from the fallopian tubes, they should be sent for testing for anaerobic and aerobic bacteria.

If DGI is suspected, culture specimens should be obtained from blood, genital, pharyngeal, and rectal sites, and NAAT performed on urine. Culture specimen results from infected joints are positive in only about one third of patients, and skin lesion culture results are rarely positive. Obtain a total serum hemolytic complement, especially in patients with recurrent DGI.

Sexual partners of patients with any type of gonorrhea should be seen or referred for proper diagnostic evaluation. Asymptomatic carriers are important vectors for transmission. Urine-based NAAT is the best test for detecting asymptomatic genital infection. Any patient with gonorrhea should be presumed to have other STDs, and appropriate tests should be undertaken, including a serologic test for syphilis and a screening test for HIV.

Management and Therapy

Optimum Treatment

For uncomplicated genital gonorrhea in adults, several regimens are highly effective, including a single intramuscular injection of 125 mg ceftriaxone, or a single oral dose of cefixime, 400 mg, or of cefpodoxime, 400 mg. These regimens provide adequate therapy for rectal or pharyngeal infection as well. Penicillins and tetracycline should not be used because resistance has increased substantially due to both plasmid-mediated genes and a variety of chromosomal mutations. Resistance to ciprofloxacin has become a clinical problem in Asia and Africa, and resistance has grown rapidly in the United States, spreading from Hawaii and California through the rest of the country in a west-to-east direction. In many regions, 20% or more of gonococcus isolates are resistant to fluorinated quinolones. Ciprofloxacin therapy therefore should be avoided. In most cases, therapy against chlamydia should be added because of the frequency of coinfection by genital chlamydia; this can be in the form of either a single oral dose of azithromycin of 1 g or doxycycline, 100 mg orally twice daily for 7 days. Directly observed therapy is preferred. For patients with complicated infections, including either salpingitis or DGI, consult standard texts for approaches to therapy.

Sex partners of patients should be screened and treated for probable gonorrhea. Many infections are transmitted by asymptotically infected partners, who do not present voluntarily for diagnosis and treatment. Most health

departments do not have the resources to do contact tracing of partners for diseases other than syphilis and HIV, and the responsibility for partner diagnosis and treatment rests with the clinician and the index patient. If possible, diagnostic tests for gonorrhea as well as other STDs and HIV should be performed on contacts before treatment, but there may be circumstances in which it is most practical to provide medication for treatment of the partners. Many authorities advise expedited partner therapy in such circumstances, whereby the index patient is either given the drug for the partner or a prescription to give the partner. A randomized controlled trial showed that this was safe and effective for partners of patients with gonorrhea or chlamydial infection. Failure to treat infected sexual contacts results in repeated “ping-pong” infections. Infections should be reported to the public health authorities.

Every STD, including gonorrhea, is an opportunity to counsel patients about the risks of unprotected sex, particularly with multiple or high-risk partners. Proper counseling of such patients may prevent other more serious STDs, including HIV.

Avoiding Treatment Errors

There are no problems in regard to accurate choices of drugs as long as the treatment guidelines are followed.

Future Directions

Despite decades of research into the molecular basis of pathogenicity of gonorrhea, there is still no vaccine candidate in site. Previous attempts to create a vaccine against pilin protein failed, and more recent attempts to use porin protein as a vaccine have stalled in early stages of clinical development. A vaccine would be useful not only because gonorrhea is an important disease in its own right, especially regarding women’s health, but also because it is a cofactor for transmission and acquisition of HIV.

Prevention depends on better sexual behaviors (abstinence, fewer partners, less risky partners, use of condoms in all but stable monogamous sexual relationships) and screening to detect infected persons who have yet to seek

treatment. Implementation of screening in women was associated with better control of infection in the United States, but prevalence has stabilized and is increasing in certain communities and groups. Use of the urine-based NAAT test provides a noninvasive, patient-friendly means to screen groups at high risk, including adolescents, persons with a new sexual partner, and emergency room and jail populations.

Dramatic declines in the prevalence of gonorrhea in much of the industrialized world outside the United States show that vaccines are not necessary for disease control. The success of gonorrhea control in these other countries undoubtedly is multifactorial but includes better health care access and less inhibited use of media to promote healthy sexual behaviors, including use of condoms.

Pelvic Inflammatory Disease

Introduction

Pelvic inflammatory disease (PID) is a clinical syndrome defined as inflammation of the upper female genital tract, which may include endometritis, salpingitis, tubo-ovarian abscess, and pelvic peritonitis. The incidence of PID in the United States has been declining since the late 1980s. Still, an estimated 1 million women in the United States are diagnosed with PID annually at a cost of nearly \$2 billion for treatment of PID and management of its sequelae. The reproductive complications of PID include infertility, ectopic pregnancy, and chronic pelvic pain. Clinical diagnosis is imprecise because there are no specific signs or symptoms for the diagnosis of PID. However, it is very important to make the diagnosis of PID because prompt recognition and initiation of effective therapy are critical for preserving fertility.

Etiology and Pathogenesis

PID is primarily due to sexually transmitted organisms, with *Neisseria gonorrhoeae* and *Chlamydia trachomatis* accounting for one third to one half of PID infections. However, organisms associated with the vaginal flora have also been associated with PID and include anaerobes, *Gardnerella vaginalis*, *Haemophilus influenzae*, enteric gram-negative rods, and *Streptococcus agalactiae*. Other organisms associated with PID are cytomegalovirus (CMV), *Mycoplasma hominis*, *Mycoplasma genitalium*, and *Ureaplasma urealyticum*. The polymicrobial nature of infection complicates both the choice of therapy and whether clinical or microbial end points should decide the duration of therapy.

PID primarily occurs with the accession of either one or more sexually transmitted pathogens or organisms present in vaginal flora, from the lower genital tract to the upper tract (Fig. 111-1). Risk factors for PID include those that are modifiable (use of condoms and number of sexual partners) and those related to demographics (i.e., age, race, ethnicity).

Adolescents are at particularly high risk for PID due to anatomic factors, the higher prevalence of *N. gonorrhoeae* and *C. trachomatis* among their male partners, the higher

number of recent sexual partners, and the greater likelihood of partner concurrency (the overlap of sexual partners over a period of time). The adolescent cervix is believed to be at increased risk for sexually transmitted infection acquisition and hence the development of PID because of a larger proportion of columnar epithelium present on the ectocervix (ectopy) relative to that in older women. Columnar epithelial cells are the targeted cells for sexually transmitted infections. Additionally, changes in cervical mucus associated with persistent high-estrogen state seen in adolescence and lower endocervical immunity in those with recent sexual debut may increase the risk for PID.

The role of bacterial vaginosis (BV) as a cofactor for the development of PID is still unclear. The alteration in pH associated with the lack of H₂O₂-producing *Lactobacillus* species is associated with a higher vaginal concentration of anaerobes. The change in vaginal flora associated with BV increases the risk for infection by *N. gonorrhoeae* and *C. trachomatis*. Two studies found conflicting results regarding the risk for PID for women with BV. The PID evaluation and clinical health study (PEACH) found no association of BV with the development of PID. Ness and colleagues did find a twofold increased risk (relative risk = 2.0) associated with the presence of BV-associated microorganisms in the vaginal tract.

Figure 111-1 Pelvic Inflammatory Disease.

The most important risk factors associated with PID are recent infection with either *N. gonorrhoeae* or *C. trachomatis* or a past history of PID. In one study of women with acute PID, *N. gonorrhoeae* and *C. trachomatis* were isolated in 49% and 36% of women, respectively.

Clinical Presentation

The diagnosis of PID is imprecise, with a myriad of signs and symptoms and a wide spectrum in severity. Laparoscopy offers a high degree of sensitivity and allows for a precise microbiologic diagnosis but is limited by the invasiveness of the procedure and the inability to detect endometritis and mild to subclinical involvement of the fallopian tubes. No single clinical sign or symptom is pathognomonic for PID. Because delays in diagnosis can lead to further inflammation of the upper genital tract, there has been much interest in better diagnostic approaches to PID.

Unfortunately, any combination of findings that improves the specificity of a clinical diagnosis of PID tends

to substantially lower sensitivity. As a result, clinicians must maintain a high index of suspicion for the diagnosis of PID and have a low threshold for the initiation of treatment. Therapy can be initiated while ruling out other potential causes of lower abdominal pain including ectopic pregnancy, acute appendicitis, endometriosis, ruptured ovarian cyst, irritable bowel syndrome, inflammatory bowel disease, and urinary tract infection. Considerations that will improve the performance of a clinical diagnosis include an adolescent population, sexually transmitted disease clinic patients, and populations with a high prevalence of chlamydia or gonorrhea.

Empiric antimicrobial therapy should be started in at-risk sexually active women with any of the following findings on pelvic examination: cervical motion tenderness, uterine tenderness, or adnexal tenderness.

The specificity of the minimum clinical findings increases when patients have evidence of lower genital tract inflammation such as abnormal cervical or vaginal mucopurulent discharge or elevated number of cells seen on vaginal wet mount.

Differential Diagnosis

See Box 111-1 for the differential diagnosis of PID.

Diagnostic Approach

No laboratory tests are specific for the evaluation and diagnosis of PID. As mentioned, empiric treatment should be initiated when clinical findings are present. Evaluation for gonococcal or chlamydial infection of the endocervix should be obtained in all patients in whom PID is suspected. Evidence of white blood cells on vaginal saline microscopy and the presence of mucopurulent endocervical discharge increase the probability of PID in the presence of pain. Their absence should prompt investigation for an alternative diagnosis. Endometrial biopsy, transvaginal sonography, magnetic resonance imaging, or laparoscopy may be warranted in limited cases but are either costly or invasive and, in any case, must not delay initiation of therapy. As with all sexually transmitted infections, all patients with PID should be screened for HIV infection.

Other diagnostic tests to exclude alternative diagnoses and assess severity of illness include urinalysis and urine culture, serum or urine pregnancy test, total white blood cell count, and erythrocyte sedimentation rate or C-reactive protein.

Management and Therapy

Optimum Treatment

Treatment of PID must cover a broad spectrum of possible pathogens. All empiric regimens must contain antimicrobial agents effective against *N. gonorrhoeae* and *C. trachomatis* because these are the most common sexually

transmitted infections associated with PID. Treatment directed against these organisms is not dependent on the detection of these organisms because negative cervical screening for these pathogens does not rule out an upper genital tract infection. A more controversial area is the need to take into account the possibility of anaerobic bacteria. Because a number of studies have found upper tract involvement with anaerobic bacteria in women with PID, many experts advocate the use of antimicrobial agents highly active against anaerobes. However, in a study of women with endometrial cultures, reproductive outcomes did not differ by the presence of anaerobes. Furthermore, the results of the PEACH trial, a study comparing intravenous cefoxitin and doxycycline for 48 hours followed by oral doxycycline for a total of 14 days of therapy with an outpatient regimen of a single dose of cefoxitin followed by 14 days of oral doxycycline, did not differ in superiority. This study calls into question the need to include anaerobic therapy in the treatment regimen for acute PID. These studies are limited by the short-term evaluation of cure rates and not the long-term reproductive outcomes, and at present, broader antibiotic regimens are still used preferentially by many experts.

The choice of inpatient or outpatient therapy depends on the severity of PID. Inpatient therapy is recommended when ectopic pregnancy and surgical emergencies have not been excluded, when outpatient management has failed or is not tolerated, in the presence of tubo-ovarian abscess, and for all pregnant women. In a study by Ness and colleagues, outpatient therapy for mild to moderate PID did not differ from inpatient therapy either in short-term clinical-microbiologic outcomes or long-term reproductive outcomes. Duration of therapy depends on clinical response but is recommended for a minimum of 14 days.

Recommended inpatient treatment regimens are shown in Box 111-2; recommended outpatient treatment regimens are shown in Box 111-3.

Management of Sexual Partners

The 2006 Centers for Disease Control and Prevention treatment guidelines recommend that men with sexual contact with women within 60 days of the onset of symptoms for PID should be evaluated for sexually transmitted infections including HIV. These partners should also be treated empirically for *C. trachomatis* and *N. gonorrhoeae*.

Avoiding Treatment Errors

The most important potential for treatment errors lies in failure to treat—that is, a lack of therapy for mild clinical presentations of PID or the delay of therapy. Clinicians must maintain a high index of clinical suspicion for PID and initiate immediate therapy on the basis of a clinical diagnosis. The hope in early initiation of therapy is to

Box 111-2 Recommended Parenteral Antibacterial Therapy for Acute Pelvic Inflammatory Disease***Recommended Parenteral Regimen A**

avoid the long-term sequelae of PID, that is, tubal infertility and chronic pelvic pain.

Future Directions

Future studies are needed to evaluate the utility of monotherapies for PID, short (3 to 5 days) course of therapy, and the effectiveness of current antimicrobial regimens on subsequent reproductive morbidity. The emergence of resistant *N. gonorrhoeae* and anaerobes will require the continued evaluation of the efficacy of treatment regimens.

Genital Warts

Introduction

Genital infection with human papillomavirus (HPV) is extremely common. Most infections are benign and result in no disease. The spectrum of genital HPV infection ranges from asymptomatic infection to warts and cervical cancer. More than 80 types of HPV have been identified, with more than 30 causing genital infection divided into low and high risk for the development of malignant cellular changes such as cervical and anal cancer. The clinical expression of low-risk types is genital warts, a problem that is increasing in incidence worldwide. The genital subgroups of HPV have a predilection for the anogenital squamous epithelium. Their primary mode of transmission is sexual, and genital warts are only one manifestation of a broad spectrum of clinical diseases associated with HPV, including a strong association with genital neoplasia.

Accurate incidence figures for genital warts in the United States are not available. It is estimated that 26.8% of U.S. females 14 to 59 years of age are infected with HPV. The highest prevalence was among those aged 20 to 24 years at 44.8%. More than 70% of the adult population have been or are currently infected with HPV. A 1996 report by the Centers for Disease Control and Prevention (CDC) estimated that 24 million Americans are infected with HPV and that 500,000 to 1 million new cases of condylomata acuminata occur annually. This means that about 1% of sexually active persons in the United States have visible genital warts at any one time. Most cases, about 80%, are caused by HPV-6. The prevalence rates for HPV-11 and HPV-5 in U.S. females 14 to 59 years of age were 0.1% and 1.3%, respectively. HPV-11 and HPV-6 account for more than 90% of genital warts. Epidemiologic studies indicate that independent risk factors for HPV infection include adolescents, young adults, marital status, and increasing number of lifetime and recent sex partners.

Etiology and Pathogenesis

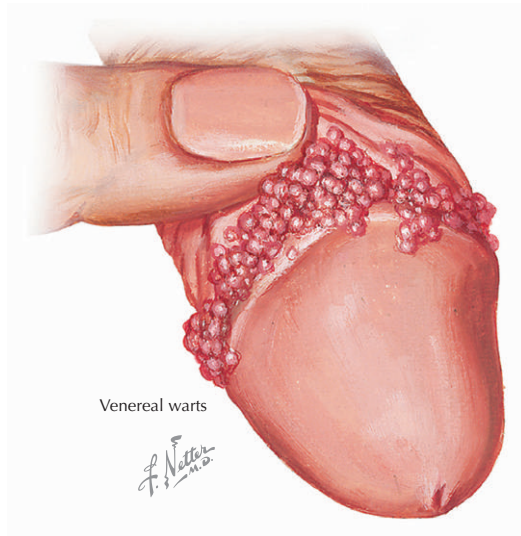

HPV is a protein-encapsulated, nonenveloped icosahedral virus. It contains 8 to 10 genes that are circular, double-stranded DNA. The early region products control viral replication, transcription, and cellular transformation, and encode for the oncoproteins E6 and E7. The late region encodes for structural proteins, whereas the long-control region contains transcription enhancer genes and promoter elements.

HPV infects stratified squamous epithelial cells. HPV-containing cells do not undergo cell lysis and are shed from the surface of the skin. Upon infection with HPV, epithelial cells are transformed to proliferate into benign tumors known as *warts*. In nonkeratinized squamous epithelium,

the exophytic growths are known as *condylomata acuminata*.

Clinical Presentation

In addition to the classic cauliflower-like proliferations, HPV infection may also manifest as smooth, flat lesions (pigmented or nonpigmented), papular warts (flesh-colored, dome-shaped papules), keratotic warts (thick, crust-like layer), or subclinical infections. The lesions most commonly are multiple but may be single, scattered, or confluent. They are seen most often in young adults. The incubation period is 2 to 3 months, although the latency period from exposure to disease development varies greatly.

Figure 112-1 Condyloma Acuminata of Penis.

The entire genital tract, including the vulva, vagina, cervix, penis, perianal area, rectum, and urethra, is susceptible to HPV infection.

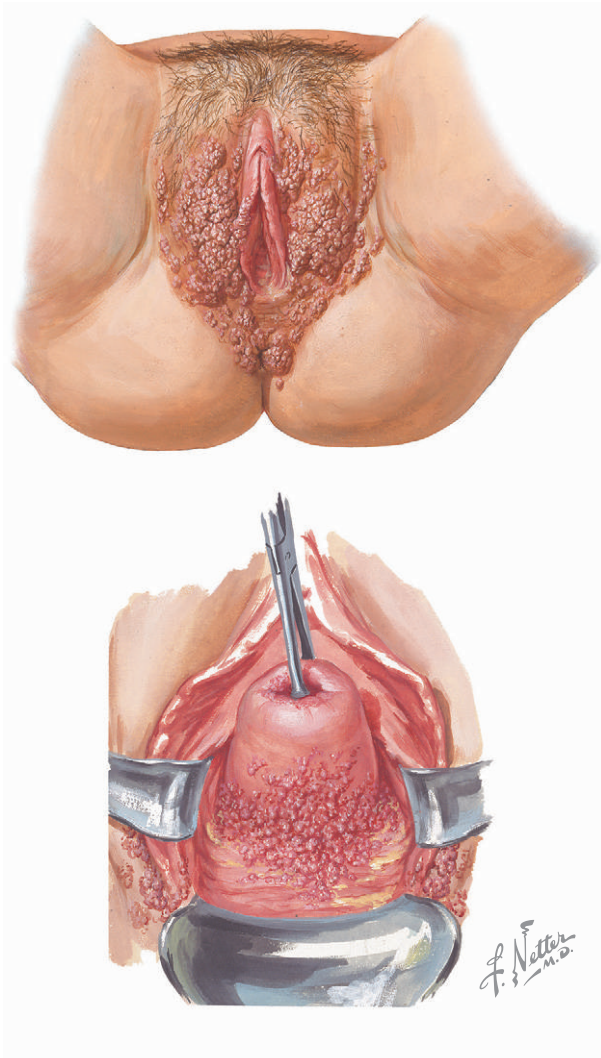

Clinical Features in Males

The classic condylomata acuminata (Fig. 112-1) predominate in moist areas, the inner surfaces of the prepuce, coronal sulcus, and frenum and may spread to the perianal area. More rounded papular warts are seen in drier areas of the penile shaft or perineal skin. Other clinically apparent lesions include sessile lesions and flat keratotic plaques with a roughened, variably pigmented surface. Condylomata may also involve the urethra and urethral meatus, resulting in hematuria and dysuria or discharge.

Clinical Features in Females

Condylomata usually first appear at the posterior part of the introitus and adjacent labia and may involve other parts of the vulva, perineum, and anus, but rarely the adjacent thighs. The vagina (upper and lower third) may be involved and, infrequently, the cervix (Fig. 112-2). More commonly, HPV infection of the cervix is subclinical, visible only after application of 5% acetic acid as flat acetowhite epithelium at colposcopy, or evident on Papanicolaou (Pap) tests (2% to 3% of which are currently positive for warty changes). Subclinical HPV infection can occur elsewhere in the genital tract. Vaginal warts are usually asymptomatic but occasionally present as vaginal discharge, pruritus, or post-coital bleeding.

In pregnancy and in immunosuppressed women, lesions may become exuberant. Occasionally, vaginal delivery may be threatened by obstruction or hemorrhage; however, lesions usually regress or disappear during the puerperium. The natural history of subclinical HPV infection of the

Figure 112-2 Condylomata Acuminata in Females.

vulva and vagina is poorly understood; in the cervix, a proportion will regress, but a group will progress to dysplasia, intraepithelial neoplasia, or frank cancer.

Clinical Features in Children

Genital warts are rare in children. When present, there may be a history of maternal genital warts during pregnancy. In older children, molestation should be considered. Maternal genital warts during pregnancy may, in rare cases, cause laryngeal papillomatosis in infants. This may not become clinically apparent until the second decade of life.

Differential Diagnosis

Other papillomatous lesions that must be differentiated from anogenital warts include (1) anatomic variants (e.g., papillae coronae glandis or the pearly penile papules); (2)

infective conditions (e.g., condylomata lata of secondary syphilis [broader and flatter lesions; positive serologic test for syphilis and dark-field microscopy of lesions] and, in the tropics, donovanosis); and (3) benign and malignant neoplasias (e.g., intraepithelial carcinoma or invasive carcinoma).

Diagnostic Approach

HPV-associated lesions demonstrate specific changes recognized at colposcopy, cytology (Pap test of ectocervical and endocervical smears), and histology of biopsy materials. Although HPV cannot be cultivated *in vitro*, recent advances in molecular biologic techniques utilizing DNA probes can identify HPV DNA. Such techniques show that more than 100 different types of HPV exist, and a subgroup of these (HPV types 6, 11, 16, 18, and less often 31, 33, 35) specifically infects the genital area. HPV types 6 and 11 have a predilection for the external anogenital skin, usually producing the exophytic condyloma of the vulva and perianal area, although occasionally causing subclinical infections or condylomata on the cervix.

HPV types 16 and 18 are associated most often with subclinical lesions of mucosal surfaces, especially the cervix. They have been implicated in oncogenic progression of tissue changes (benign warty to dysplasia, to intraepithelial neoplasia, to invasive carcinoma) in the penis, vulva, vagina, and, especially, the cervix. Other cofactors apart from HPV are no doubt involved in oncogenicity.

Management and Therapy

- Other associated sexually transmitted infections should be excluded, especially condyloma lata of secondary syphilis.
- Warts should be treated as described later. All warts show unpredictable behavior and may regress spontaneously, enlarge and spread, or recur.
- Review weekly or biweekly for treatment and follow-up until lesions have resolved.
- It is important to evaluate for coexisting cervical dysplasia (Pap test). Repeat Pap test should be obtained every 6 to 12 months thereafter.
- Refer for colposcopy if there is evidence of cervical dysplasia or if there is persistent cervical HPV infection.
- Ensure examination of sexual partners and treat those with warts.
- Advise use of condoms until no lesions are apparent.
- Obtain a biopsy specimen of any atypical wart.

Pharmacologic Agents

There is no specific antiviral therapy available for HPV and no one method of treatment that is superior to all others. Therapy often involves methods that attempt to

nonspecifically destroy infected tissue. Most of these cytotoxic therapies are painful and require multiple visits to a provider or require adherence to daily application of a medication. The efficacy of cytotoxic therapies has not been verified in placebo-controlled trials and has highly variable reported rates of success and high recurrence rates. Newer therapies involving pharmacologic approaches that stimulate immunologic or antiviral responses offer promise of higher response rates and lower rates of recurrence. Pharmacologic agents available for treatment include cytotoxic agents (podophyllin), destructive agents (trichloroacetic acid), and immunologic agents (interferon, imiquimod). Therapies can be divided into two categories: provider administered and patient applied.

Provider-Administered Therapies

Podophyllin resin is used for penile and vulvar warts. It should not be used in well-vascularized areas such as the vagina or anus. The major disadvantages of podophyllin are skin irritation, if not properly applied, and systemic toxicity and potential oncogenicity with use of large amounts or repeated application. Its use is contraindicated in pregnancy and if dysplasia or neoplasia is present. Given current treatment options and the toxicities associated with podophyllin therapy, there is little clinical indication for its use.

5-Fluorouracil (5-FU) is used topically as a 5% cream for treatment of vaginal lesions and urethral condylomata and for prophylaxis in immunocompromised patients. Its disadvantages are that an extensive erosive dermatitis may occur with incorrect application and that its use requires a reliable patient to follow instructions. Pregnancy is a contraindication to 5-FU treatment. The 2006 Sexually Transmitted Diseases Treatment Guidelines do not recommend the use of 5-FU for the treatment of genital warts.

Trichloroacetic acid (TCA) and dichloroacetic acid (DCA) are applied undiluted (25% to 85% solution) and washed off after 12 hours. They are weak destructive agents and are sometimes effective against small condylomata. They may be applied weekly for up to 6 weeks. Petroleum jelly or lanolin should be applied around the lesions to prevent spill onto surrounding normal tissue.

Interferon has antiviral, antiproliferative, and immunomodulating properties and has been used for persistent or resistant disease. It is administered by intralesional or intramuscular injection 3 times weekly. However, it is expensive, is nonspecific, and may cause multiple side effects (e.g., flu-like symptoms).

Patient-Applied Therapies

Imiquimod cream (5%) is an immune-response modifier capable of inducing a variety of cytokines, including interferon- α and tumor necrosis factor. It is applied 3 times weekly to affected areas and washed off after 8 hours.

Clinical response may take 2 to 8 weeks, and therapy may be continued for up to 16 weeks. Side effects include local inflammatory reactions with no systemic reactions.

Podofilox (0.5% solution or gel), an antimitotic agent purified from podophyllin resin, is less likely to cause systemic toxicity. It is approved for self-treatment in both men and women. It is applied twice daily for 3 days; this course can be repeated after 4 days and continued for up to 4 weeks if necessary. Safety for use in pregnant patients has not been established.

Other Treatment Methods

Other methods include electrocautery and curettage under local or general anesthesia, depending on the site and extent of the lesions. Cryotherapy is effective for both genital and anal warts, provided they are not too large. Treatment involves applying the cryocautery probe to each wart for 30 to 60 seconds (no anesthetic necessary). Alternatively, genital warts can be frozen with liquid nitrogen. Cautery and cryosurgery are the methods of choice for keratinized warts or for warts refractory to other forms of treatment. They can also be used as primary treatment of mucosal warts. Surgical excision or carbon dioxide laser destruction under general anesthesia may be used for extensive lesions.

Optimum Treatment

Exophytic Condylomata of External Genitals

If lesions are nonextensive, options should be discussed with the patient before therapy. The patient's ability to adhere to the treatment regimen as well as the location and number of warts should be considered. For provider-applied therapy, cryotherapy (weekly until lesions gone) or trichloroacetic or dichloroacetic acid (applied twice weekly) should be used. For patient-applied therapy, imiquimod 5% cream and podofilox 0.5% solution or gel are options as well. If lesions are extensive, laser therapy, cautery, or surgical excision are alternatives. In females, cervical HPV infection (cytology), and in men who have sex with men, rectal HPV infection (anoscopy and rectal cytology), should be excluded.

Cervical HPV Infection

Patients with cervical HPV infection should be referred for colposcopic evaluation with directed biopsy of abnormal areas.

Pregnant Patients

Trichloroacetic acid or cryotherapy should be used for isolated lesions, or laser therapy for extensive lesions. Careful cytologic and colposcopic follow-up is essential. Vaginal delivery, unless obstructed by lesions, is possible because cesarean birth does not prevent infant infection.

Specialist Referral

Referral is advisable for urethral or cervical warts; associated cervical HPV changes on cytology, dysplasia, or neoplasia; immunodeficient patients (who do not respond to conventional treatment); refractory warts; and condylomata in children.

Avoiding Treatment Errors

It is important to consider the potential for other sexually transmitted infections in patients with genital HPV. It is also important to test for pregnancy before considering systemic therapy.

Vaccines

Progress continues to be made on the development of prophylactic and therapeutic vaccines. Two vaccines against the most common HPV types associated with cervical cancer, HPV-16 and HPV-18, have been developed and tested in clinical trials. The first of the two vaccines to be approved is a quadrivalent vaccine (Gardasil) for HPV types 6, 11, 16, and 18. The second vaccine is a bivalent vaccine (Cervarix) for HPV types 16 and 18. Cervarix will be available the fourth quarter of 2007. The approach for both vaccines involved the use of a papillomavirus-like particle vaccine composed of a major structural viral protein, L1, to confer protection against infection. The efficacy of both vaccines for preventing HPV-16- or HPV-18-related cervical intraepithelial neoplasia (CIN) was 100%. Because only Gardasil is currently licensed by the U.S. Food and Drug Administration, recommendations for vaccination are limited to Gardasil. It is anticipated that similar recommendations will be made for Cervarix. Centers for Disease Control and Prevention and the Advisory Committee on Immunization Practices guidelines recommend that females 11 to 12 years of age be routinely vaccinated. Females aged 13 to 26 years of age are also recommended to be vaccinated. No guidelines currently recommend vaccination of young men, but approval for vaccination in men is likely. The duration of efficacy of the HPV vaccines is unknown, but the length of current follow-up and the rate of antibody decay suggest efficacy may be long lived. It is unknown whether vaccinating females alone will be sufficient to stop the HPV epidemic. Progress is also being made in the development of therapeutic vaccines that may prove effective against persistent HPV infection, warts, and premalignant lesions. There are no data to verify the safety of the vaccine in pregnancy; hence, pregnant women should not be vaccinated for HPV.

Future Directions

Future directions will primarily involve the expansion of the indications for HPV vaccination in older women and

males. Future research will also explore the use of the current HPV vaccines for therapeutic benefits in HPV-related diseases.

Syphilis

Introduction

Syphilis, an infectious disease caused by *Treponema pallidum*, usually is sexually transmitted but may be transmitted transplacentally from an infected mother to her infant. Once very common, affecting as much as 10% or more of the general population, it became much less prevalent after the discovery of penicillin. Rates of infection declined steadily in the United States except for a rise among men having sex with men (MSM) at the onset of the HIV era and a brief period in the late 1980s and early 1990s due to an epidemic of trading heterosexual sex for crack cocaine. In the first years of the 21st century, however, there has been an increase in syphilis in the United States among MSM, including college students and others who use the Internet to find sexual partners. The infection continues to be a plague in much of the world, with prevalence of more than 10% in many sub-Saharan African countries. Early syphilis is a recognized cofactor for HIV transmission, warranting the serious attention of clinicians and investigators. In the United States, the infection is more common in some population groups, particularly African Americans who may have disease rates about 20 times those of whites. This probably reflects differences in several behaviors, including sexual and health-seeking behaviors, availability of appropriate health care access, and a complex mix of socioeconomic factors that help to determine behaviors. There has been recent progress in reducing the prevalence of syphilis in African Americans.

Etiology and Pathogenesis

T. pallidum is a spirochetal bacterium whose genome has now been sequenced. Although *T. pallidum* can be introduced in animals, it cannot be cultured in the laboratory and for this reason it is less well understood than many bacterial pathogens. It is a slender, spiral-shaped organism that cannot be seen by ordinary Gram stain but can be visualized by dark-field microscopy and has a characteristic motility that facilitates diagnosis from early infectious lesions. Relatively rare outer sheath proteins include proteins that are under intense current investigation because they appear to undergo rapid variation, possibly helping to account for the ability of the organism to persist in vivo despite an immune response. The organism does not survive drying, and its only natural host is humans, accounting for the usual necessity of contact with lesions in an infected sexual partner for disease transmission.

The median infective dose, the dose required to infect 50% of subjects, is about 10 organisms. Rate of growth in

humans and animals is slow, with a doubling time of about 24 hours, which accounts for the slow progression of disease and helps explain the need for prolonged treatment to effect cure.

The intermittent, relapsing, slowly evolving nature of untreated syphilis suggests a delicate balance between the pathogen and the host immune system. There is partial immunity in late-acquired or congenital syphilis, as demonstrated in human prison volunteers 50 years ago. Immunity can be developed, albeit with difficulty, in experimental rabbit syphilis. Some of the lesions of late syphilis appear to be the result of a hypersensitivity response to infection, perhaps explaining the granulomatous reaction of some lesions (particularly gummas) of late syphilis. Typically, there is a vasculitis of the vasa vasorum, which may account for some late manifestations, including aortitis and some of the central nervous system (CNS) lesions.

Women may transmit infection transplacentally for up to 6 or 7 years after untreated infection, but during about

the last 3 months of gestation only, owing to breakdown of placental barriers later in pregnancy. Routine testing and treatment of pregnant women during the first two trimesters should prevent congenital syphilis.

Clinical Presentation

Syphilis is generally divided into primary, secondary, latent, and late stages. The disease is the result of contact with infected lesions. *T. pallidum* enters the skin or mucosa and then disseminates early to many organs, including the skin, CNS, and others. The illness progresses from a lesion at the site of inoculation to a more generalized disease, punctuated by periods of clinical well-being. Primary and secondary syphilis are termed *early syphilis*. This is followed by a latent period with no abnormalities other than immunologic evidence of infection. Late or tertiary types of clinical disease develop in about one third of untreated persons. The interval between initial infection and recognized onset of late syphilis may be remarkably long, up to 20 years or more, depending on the type of syndrome.

Primary Syphilis

After an incubation period of about 10 to 21 days, there typically is a papule that evolves into a painless ulcer termed *chancre* (Fig. 113-1). About 10% of chancres are extragenital, especially around or in the mouth and anal areas (Fig. 113-2). A classic chancre has rolled margins and a clean nontender base, often with satellite adenopathy. Perirectal or oral chancres may have atypical presentations and may be missed without strong suspicion (see Fig. 113-2). Untreated infection heals spontaneously in about 3 weeks.

Secondary Syphilis

Lesions of secondary syphilis occasionally coincide with the primary lesion but more often occur weeks or months later, up to 6 months from onset of infection (Fig. 113-3). A primary lesion may not have been recognized. The secondary rash heals spontaneously in about 3 weeks but may relapse one or more times over the next 2 years if untreated. The cardinal sign of secondary syphilis is a rash on the mucosa or skin. Often, it starts on the trunk but spreads to involve much of the body, including the palms and soles. Early rash may be subtle and can be missed in persons with dark pigmentation. It varies from copper to brown macules to papulosquamous lesions to nodules but in adults almost never is vesicular or bullous or pruritic. Rash on moist mucosal surfaces may be hyperplastic (condyloma acuminata, or syphilitic warts) or may be flat plaques as in the gray mucous patches of the mouth or elsewhere. Mucosal lesions are quite infectious, but the cutaneous rash is minimally infectious. At this point, the disease is systemic, and there often is fever, sore throat, and generalized adenopa-

thy. Meningitis with headache and a cerebrospinal fluid (CSF) mononuclear pleocytosis occurs in about 30% of patients. Occasional patients have clinical hepatitis or immune-deposit glomerulopathy.

Latent Syphilis

By definition, the latent stage is when the patient is infected and has positive serologic tests for syphilis but is clinically normal, including normal CSF findings. It is divided into early (first year) and late (more than 1 year) latency for epidemiologic reasons because the risk for transmission to sexual partners is essentially zero after 1 year of untreated infection. Untreated, about two thirds of patients do not progress beyond latency, but late syphilis develops in one third of patients.

Late Syphilis

Late syphilis may involve many organs but can be divided into three general types: gumma, neurosyphilis, and cardiovascular syphilis. Gumma usually presents as granulomatous or destructive ulcerative or mass lesions of the skin or viscera. Once common, it is now rare, probably because it responds readily to antibiotics. In the past decade, multiple cases have been documented in patients with HIV infection.

In cardiovascular syphilis, inflammation of the ascending aorta results in aortic wall weakness and aneurysm formation, which may lead to aortic valve insufficiency and, on occasion, occlusion of the coronary arteries. Clinical onset usually is a decade or more after infection, with presentation as aortic insufficiency.

Involvement of the nervous system takes many forms in neurosyphilis, with variable onset after initial infection. Meningitis (headache, stiff neck) may occur coincident with secondary syphilis or in the next 5 or 6 years. The CSF formula is indistinguishable from other causes of aseptic meningitis, but the CSF Venereal Disease Research Laboratory (VDRL) test is positive. Meningovascular syphilis occurs within the first 12 years of infection, with occlusion of small to medium vessels and stroke syndrome. It should be considered in young persons with no obvious cause for stroke. The form of stroke varies from isolated cranial nerve palsies, including the eighth cranial nerve, to hemispheric lesions. The CSF test results are abnormal, including a lymphocytic pleocytosis, and CSF serologic tests for syphilis usually are positive. General paresis occurs from 10 to 20 years after infection, with involvement of the cerebral hemispheres and various signs and symptoms including dementia, paranoia, and delusions of grandeur. Often, the CSF test results are abnormal, but there may not be a pleocytosis, and the serologic test results for syphilis are not always positive. Tabes dorsalis affects the posterior columns of the spinal cord, with loss of proprioception, often with associated severe sharp intermittent

Figure 113-1 Genital Lesions of Primary Syphilis.

radicular pains of the extremities or abdomen. There may be associated optic atrophy and Argyll-Robertson pupils (small pupils that accommodate but do not react to light). The CSF test results often are abnormal (high protein, increased mononuclear cells, positive VDRL), but one or more of these findings may be absent. Tabes typically has late onset. Some of the classic clinical forms may be indistinct or overlap.

Syphilis in Patients with HIV Infection

Anecdotal evidence suggests that syphilis presents differently in the presence of HIV, but there have been no confirmatory studies to substantiate this observation. Serologic tests and response to therapy approximate those in non-HIV-infected patients. Neurosyphilis may present a

particular dilemma, however, because patients with advanced HIV infection have myriad causes of abnormal CSF test results and neurologic illness.

Differential Diagnosis

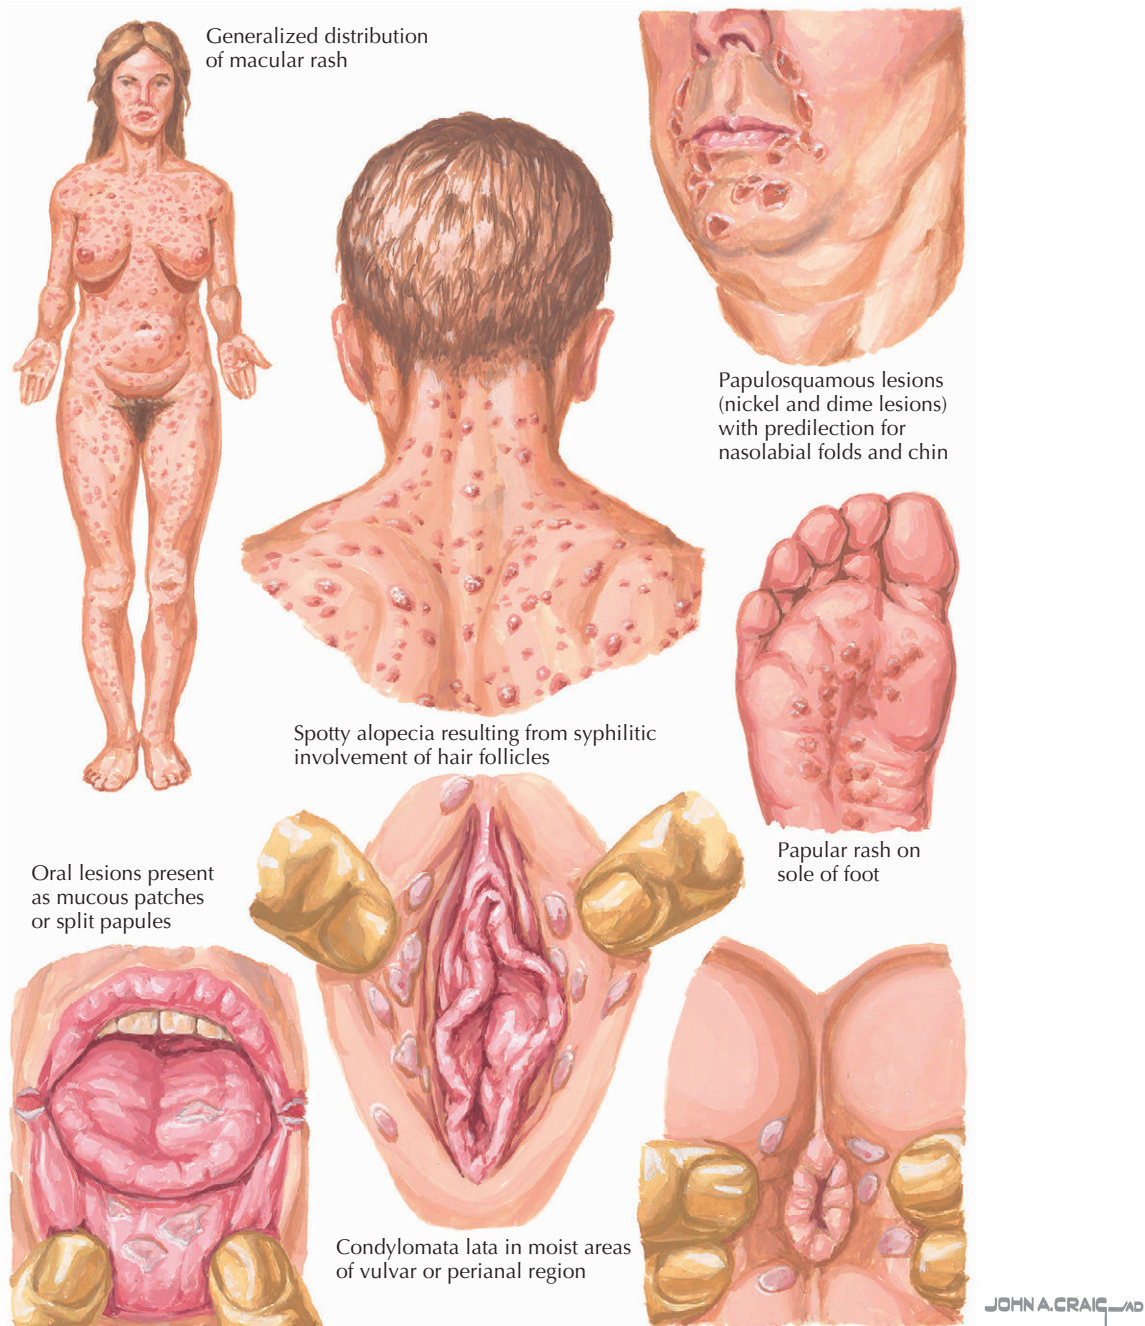

In primary syphilis, the principal differential involves other causes of genital ulcer syndrome, particularly herpes simplex virus (HSV). HSV more often has multiple ulcers, and they are usually painful and tender, whereas the syphilitic chancre is painless unless secondarily infected (see Fig. 113-1). In other parts of the world, chancroid (*Haemophilus ducreyi*) is a common cause of single or multiple, usually tender, genital ulcers. Secondary syphilis has a very broad differential diagnosis, including mononucleosis, drug reactions, viral exanthems, hepatitis, and many more, depend-

Figure 113-2 Extragenital Lesions of Primary Syphilis.

ing on the particular presentation. Late syphilis also has a broad differential diagnosis, but in current practice, the usual problems are limited to neurologic diseases. CNS syphilis is a common question in elderly people with abnormal syphilis serology and abnormal CNS function, and the most extensive workup may not provide definitive answers because of the lack of sensitivity of many of the CSF tests for neurosyphilis.

Diagnostic Approach

There are two principal diagnostic tests: the dark-field examination, by which motile spirochetes may be seen in lesions from primary syphilis; and serology, by which various antibodies are detected. In many centers, it is also possible to obtain polymerase chain reaction molecular amplification tests for *T. pallidum*. Dark-field examination

Figure 113-3 Secondary Syphilis.

requires a special microscope and is used less frequently than in earlier times. A mail-in variation that uses fluorescent antibodies to detect *T. pallidum* on slides has not been widely deployed.

Serologic tests are of two general types: those that detect nonspecific antibodies against diphosphatidyl glycerol, a normal tissue component, and those that detect specific antibodies against *T. pallidum*. Nonspecific tests include the VDRL and rapid plasma reagin (RPR) test. These tests are inexpensive and easy to use; the levels of antibodies detected rise in acute disease and fall after suc-

cessful treatment. Presumably, antibodies rise in syphilis because the spirochete binds host diphosphatidyl glycerol, increasing its immunogenicity. Reasons for false-positive test results include other infections and autoimmune diseases; in the latter, the test results are positive chronically (more than 6 months). Old age is another cause of a chronic false-positive VDRL test result, and a positive test result in a patient older than 80 years should ordinarily be ignored.

Specific tests include the fluorescent treponemal antibody absorbed (FTA-ABS) and the microhemagglutina-

tion against *T. pallidum* test. A variation on this test now widely used is the *T. pallidum* particle agglutination (TPPA) test. These tests are reported without titration, and the result is positive or negative. Once this antibody appears, it usually persists for life; thus, a positive test indicates present or prior infection with *T. pallidum*. There are few false-positive results, but because some studies showed that 1% of persons without any risks for sexually transmitted diseases had a positive FTA-ABS test result, these tests are not used as screening tests. These tests are not useful for following response to therapy.

In primary syphilis, the VDRL or RPR test results are positive in about 80% of patients, and the specific treponemal test results are positive in slightly more (about 85%). All test results are positive in blood in patients with secondary syphilis, and the treponemal test results remain positive in almost all patients with late syphilis. The non-specific test results may be negative in some patients with late syphilis; therefore, a negative blood RPR or VDRL does not rule out late syphilis.

A diagnostic dilemma may occur in patients with possible neurosyphilis. A positive CSF VDRL test result in the absence of a traumatic tap is specific for neurosyphilis, but a negative test result does not rule out the diagnosis because as few as 30% to 40% of patients have a positive CSF VDRL test result. The CSF FTA-ABS appears to be more sensitive than the VDRL, but there are worries that this may reflect passive transfer from blood. Cells or protein may be normal in CSF of patients with neurosyphilis. Some experts use a negative CSF FTA-ABS test to help rule out syphilis of the CNS.

Management and Therapy

The first principle of management is to make a diagnosis, which requires consideration of syphilis in young or old persons with an ulcerative lesion, rash and adenopathy, unexplained stroke, or unexplained neurologic disease, among other syndromes. Assessment of risk is enhanced by a knowledgeable sexual history. In practice, a very common problem is how to diagnose and treat patients with nonspecific neurologic findings and a positive VDRL or TPPA test result and patients with positive serologic studies but no evidence of clinical syphilis. Careful examination and history, and examination of CSF, are helpful in management of problem cases.

Optimum Treatment

T. pallidum is sensitive to many antibiotics, and until recently there has been no evidence for antimicrobial resistance. In recent years, however, there have been reports of failure of therapy with azithromycin and DNA sequence evidence from *T. pallidum* recovered from patients of ribosomal resistance to azithromycin. Standard therapy of early syphilis is one intramuscular injection of 2.4 MU of benzathine penicillin; some experts give two injections a

week apart. Alternatively, ceftriaxone, 1 g intramuscularly or intravenously daily for 8 to 10 days, may be given, although this is not completely safe in patients with penicillin allergy. Doxycycline, 100 mg orally twice daily for 14 days, is an acceptable substitute in patients who cannot tolerate penicillin or ceftriaxone. Use of azithromycin for treatment of early syphilis is discouraged based on the reports of failure, and of genetic evidence for resistance, even though there are reports of clinical trials showing that single-dose azithromycin may be very effective in treatment of early syphilis. Latent or late syphilis is treated with three intramuscular injections of 2.4 MU benzathine penicillin at weekly intervals.

If there is evidence of symptomatic neurosyphilis, most experts advocate intravenous aqueous crystalline penicillin G, 4 MU every 4 hours for at least 10 days, because benzathine penicillin provides low serum levels and undetectable CSF levels of penicillin. Similar considerations apply to patients with HIV who also have any type of neurosyphilis, including asymptomatic neurosyphilis, based on anecdotal evidence of poor response and persistent *T. pallidum* in CSF after benzathine penicillin therapy. There is good evidence that patients with early syphilis who are HIV negative are cured after benzathine therapy, even though one third have abnormal CSF. For this reason, HIV-negative patients with early syphilis ordinarily do not require a lumbar puncture (LP) to examine CSF. In patients with both syphilis and HIV infection, however, an LP may be wise, especially if the CD4 count is less than 350 or the RPR or VDRL titer is at least 1 : 32 because these are strong predictors of neurosyphilis. In patients allergic to penicillin, referral to experts for desensitization to penicillin is recommended because no other therapy has been proved efficacious.

Patients treated for syphilis should be observed at 3-month intervals for 6 months and then at 6-month intervals to complete a second year. In HIV infection, follow-up should be at 3-month intervals during the first year. VDRL or RPR titers decrease at least fourfold if therapy was successful and the patient did not reacquire infection. If titers persist unchanged or fall and then rise at least fourfold, retreatment should be given and CSF should be examined if not done previously. Some patients, especially those with latent or late disease, may continue to have persistently positive VDRL test results in low titer for years, unresponsive to repeated therapy. All infections should be reported to the public health authorities so that partners can be evaluated and treated.

Avoiding Treatment Errors

The only problems might come when prescribing Bicillin, which is a long-acting form of benzathine penicillin G. Other preparations containing shorter-acting penicillins have similar names; check to be sure Bicillin is used and that it contains only benzathine penicillin G.

Future Directions

Prevention requires adoption of better sexual behaviors by the at-risk public, including condom use, and better coordination between private and public medicine. Prevention campaigns focused on the highest risk groups, including MSM and African Americans from disadvantaged socioeconomic backgrounds, hope to essentially eliminate syphilis in this country, but eradication will require a vaccine to be effective. A vaccine may be possible in the distant future.

Contraception

Introduction

Until recently, lack of access to effective methods of birth control meant that family planning was not feasible for most women. In the past 50 years, the development and dissemination of new methods of contraception—most notably the contraceptive pill—have led to a multiplicity of societal changes, including growing acceptance of premarital sexual relations, greater female participation in education and employment, and demographic changes like later age of marriage and smaller family size.

In family planning programs, contraceptives are effective tools. For example, contraception contributed to a decline in total fertility in Kenya from 8 births per woman in the late 1970s to less than 5 in 1998. Contraceptive use among reproductive-age women varies from 3.9% in Niger to 84% in China, with wide variations in rates of use of each method. China, with about one fifth of the world's population and one third of users, has an important impact on summary statistics, strongly affecting the prevalence of data on intrauterine devices (IUDs) and permanent sterilization, which are less commonly used in most countries (Table 114-1).

Benefits

Medical Benefits of Contraception

Beyond the social and economic benefits accrued by having a real choice of whether or when to parent, contraception offers direct medical benefits (attained by preventing pregnancy) and noncontraceptive benefits (beneficial side effects). Health benefits of pregnancy prevention are shown in Box 114-1.

Effectiveness and Failure Rates

Each contraceptive method has a risk for failure, resulting in pregnancy for some users. Contraceptives are most effective when directions for use are followed exactly, every time they are needed, for as long as pregnancy prevention is desired. In reality, most contraceptive failures are related to incorrect use or cessation of use of one contraceptive method before implementing a new method. Methods that do not require any work on the part of the user after the initial choice (IUDs, implants, sterilization) have use effectiveness that is similar to theoretical effectiveness. Providers can help guide patients to suitable methods, reassure patients about risks, instruct in proper use, and give anticipatory guidance about side effects. Nurse prac-

tioners, family planning clinic staff, and peer counselors may be able to spend more time with a patient than physicians and can be very effective, especially when counseling about behavioral issues. Table 114-2 demonstrates the effectiveness of most common methods.

Contraceptive Methods

Behavioral Methods

Abstinence is widely promoted as a method that is 100% effective. However, the use effectiveness of intended abstinence is poorly documented. Some experts have promoted alternate modes of sexual expression (masturbation or “outercourse”) to reduce coital sexual behavior.

Periodic abstinence, or natural family planning (NFP), involves timing intercourse to avoid coitus during the “fertile window” when sex would likely result in conception. Studies have shown that intercourse up to 6 days before ovulation can result in pregnancy, with almost no conceptions from intercourse after the date of ovulation. Importantly, the timing of ovulation is more variable than previously thought. Modern NFP techniques include observation of physiologic changes associated with ovulation (temperature or cervical mucus changes). NFP is also used by couples desiring pregnancy to identify the most

Table 114-1 World Contraceptive Use, 2005

fertile days of the cycle. Withdrawal of the penis from the vagina before ejaculation has similar failure rates, with both typical and perfect use, as NFP.

Barrier Methods

Barrier methods, such as the male condom, female condom, diaphragm, and cervical cap, all work by preventing sperm from reaching the egg. With consistent, correct use they are quite effective, especially in mature, motivated individuals. Latex condoms are extremely important in fighting the spread of HIV infection as well as other sexually transmitted infections (STIs). Female condoms are expensive, but do not require the male partner to cooperate with putting on a condom. They also protect against infection. The diaphragm and cervical cap also reduce STIs, even though they do not prevent semen from coming in contact with the vagina.

Spermicides

Spermicides may be included in condoms, and contraceptive vaginal inserts, gels, film, and foams are also available. Spermicides are directly toxic to sperm. Current spermicides do not kill HIV and may increase the rate of HIV infection.

Hormonal Methods

Hormonal methods include progestin-only methods (implants, IUDs, injections, and minipills) and estrogen-progestin combinations (oral contraceptives, the patch, the vaginal ring, and injections). Progestin-only methods prevent pregnancy by thickening cervical mucus, thinning the uterine lining, and inhibiting ovulation, and include some of the most effective methods available. Emergency (postcoital) contraceptives may inhibit sperm transport or inhibit implantation of a fertilized egg.

Box 114-1

 Health Benefits of Pregnancy Prevention

Help space births, resulting in:

- Lower rates of infant and child mortality
- Decreased risk for anemia in mothers
- More time to breast-feed, resulting in improved infant health and survival

Prevent high-risk pregnancies among:

- Very young adolescents
- Women in their late 30s and 40s
- Women who have had many births
- Women with preexisting medical conditions

Prevent unsafe abortion resulting from unwanted pregnancies, thereby reducing:

- Maternal deaths
- Ill health
- Infertility

Prevent maternal and infant deaths and ill health resulting from unwanted births

Facilitate screening for sexually transmitted infections and other health concerns

Noncontraceptive Benefits

Oral contraceptive pills:

- Protect against ovarian and endometrial cancers
- Decrease benign breast disease
- Decrease pelvic inflammatory disease requiring hospitalization
- Decrease ectopic pregnancy
- Treat menstruation-related iron-deficiency anemia
- Treat dysmenorrhea
- Treat menorrhagia
- Treat acne and hirsutism
- Decrease endometriosis pain

Nonhormonal intrauterine devices:

- Decrease endometrial cancer

Progestin-containing intrauterine devices:

- Decrease menorrhagia and anemia
- Prevent endometrial hyperplasia from tamoxifen or estrogen replacement
- Decrease hysterectomies for menstrual problems

Barrier methods:

- Prevent many sexually transmitted diseases

Data from Singh S, Darroch JE, Vlasoff M, Nadeau J: *Adding it Up: The Benefits of Investing in Sexual and Reproductive Health Care*. Washington DC and New York, The Alan Guttmacher Institute and UNFPA, 2004; Dayal M, Barnhart KT: *Noncontraceptive benefits and therapeutic uses of the oral contraceptive pill*. *Semin Reprod Med* 19(4):295-303, 2001; and Hubacher D, Grimes DA: *Noncontraceptive health benefits of intrauterine devices: A systematic review*. *Obstet Gynecol Surv* 57(2):120-128, 2002.

Combination oral contraceptive pills (OCPs) have been available since the 1960s, but the dose and chemical composition have changed greatly since then. Combining estrogen and progestin increases efficacy when compared with the same dose of progestin alone, and allows a predictable withdrawal bleed (mimicking a menstrual period) every 28 days. Most current OCPs contain ethinyl estradiol, with doses ranging from 20 to 35 µg/day. There are several different progestins, with varying potencies and side effects. OCPs are used continuously (without a placebo

Table 114-2 Percentage of Women Experiencing an Unintended Pregnancy during the First Year of Typical Use and the First Year of Perfect Use of Contraception and the Percentage Continuing Use at the End of the First Year

week) to prevent menstruation-associated illness such as anemia, menorrhagia, premenstrual symptoms, and menstrual exacerbations of migraine, seizures, or sickle cell crisis. Drug manufacturers are now producing extended cycle packs, allowing long-term suppression of menstrual bleeding.

The birth control patch is very similar to a combination OCP in its chemical composition and efficacy. It is applied to the skin once a week for 3 weeks. It is useful to women who have difficulty taking a daily pill. The total amount of drug delivered is higher than the comparable OCP, which may increase thromboembolic risk, but it may also improve efficacy.

The vaginal ring delivers less estrogen and a different progestin than the patch. It is designed to be used for 21 days out of 28 and is well tolerated by users. The amount of drug in the device is adequate to prevent conception for several days after the 21 days it is labeled for, so it can be used for up to 1 month at a time in a continuous cycle.

The combined estrogen-progestin injection is similar in efficacy to the progestin injection but is designed to give

better control of bleeding. It is no longer available in the United States.

All contraceptives that contain estrogenic compounds induce hypercoagulability of the blood in a dose-dependent fashion, increasing the risk for deep venous thrombosis, myocardial infarction, and stroke. Thrombophilia including the increased clotting risk associated with diabetes, obesity, elevated serum lipids, and most importantly, smoking, can multiply the risk for cardiovascular events significantly, even with modern low-dose formulations. Hypertension may also be worsened by OCPs containing estrogen. Prolonged use of depo-medroxyprogesterone acetate, a progestin-only method, has been associated with osteopenia.

Intrauterine Devices

IUDs are devices implanted in the uterus to prevent pregnancy. The effectiveness of current devices is comparable to permanent sterilization but is easily reversible with removal of the device. Copper IUDs cause a local intra-

uterine inflammatory reaction that lyses sperm. IUDs containing progestins deliver a high dose of drug locally to the endometrium, thickening mucus, thinning the endometrial lining, and impairing sperm transport. IUDs have been associated with pelvic infections, such as pelvic inflammatory disease and septic abortion. Although current IUDs are much safer than previous designs, they are still not recommended for women at high risk for pelvic infection.

Permanent Sterilization

Couples who have completed their family size often choose permanent sterilization. Rates are influenced by insurance coverage and by availability of effective long-term methods. Vasectomy is easily performed in an outpatient setting with local anesthetic and is safer and more effective than tubal ligation. Bilateral tubal ligation can be done at cesarean delivery, immediately postpartum through a minilaparotomy incision, or laparoscopically. Risks include regret, especially in the very young and those who begin new relationships, surgical risks, and the risk for method failure (ectopic or intrauterine pregnancy).

Abortion

Abortion is not a primary method of controlling fertility because of its relatively high cost, poor availability, and social, emotional, and moral factors. However, medically supervised abortion, when used as a backup method, is important in reducing maternal morbidity and mortality, especially for women at high risk for pregnancy complications. The safety of the procedure is dependent on gestational age and on system factors such as skilled providers and adequate postabortion care.

Approach to the Patient

In clinical practice, it is common to learn a woman is having regular intercourse, does not want to have a child, and is not doing anything to prevent pregnancy. Reasons for this choice may include lack of access and ambivalence about sexual activity or parenting. Patients may be dissatisfied with available choices because of prior experiences with birth control, real or imagined risks, and side effects of available methods. Among those who do not currently want pregnancy, their goals might be to delay the birth of their first child, space births, or avoid future childbearing. These goals will affect their choice of birth control method. It is important to consider what methods are available regionally and for the patient individually. Some of the most effective and cost-effective methods of contraception, such as implants, IUDs, and permanent sterilization, may have high initial costs that put them out of reach.

Future Directions

Several current contraceptives are nearly 100% effective in preventing pregnancy, but unintended pregnancy is still a global problem because of limited access. Although novel methods of contraception (including male hormonal methods) may be developed in the future, in the next several years, progress will be made by increasing distribution of contraceptives to those who currently have poor access to them. Adherence is also poor for many methods, especially condoms, and research is needed to find the best ways to help women and men to use them consistently. For many women, the greatest risk of intercourse is not pregnancy, it is death from HIV/AIDS. Significant research is now being done on spermicides and microbicides that would be effective against both pregnancy and HIV.

ACOG Committee on Practice Bulletins-Gynecology: ACOG practice bulletin. No. 73: Use of hormonal contraception in women with coexisting medical conditions. *Obstet Gynecol* 107(6):1453-1472, 2006.

This paper describes medical conditions in which estrogen-progestin combination oral contraceptives or progestin-only pills can be safely used as well as their contraindications.

Dickey RP: *Managing Contraceptive Pill Patients*, 12th ed. Durant, OK, Essential Medical Information Systems, 2004.

This book helps with rational explanations of the different pills available, different potencies and side effects of progestins, and detailed information on managing side effects. It also explains the use of extended-cycle pill regimens.

Hatcher RA, Ziemann M, Cwiak C, et al: *A Pocket Guide to Managing Contraception*, 8th ed. Tiger, GA, The Bridging the Gap Foundation, 2005.

The WHO Medical Eligibility Criteria for Starting Contraceptive Methods is included as an appendix, and it explains patient selection and medical contraindications for each method. The full text is available online as a free downloadable PDF at <http://www.managingcontraception.com/cmanager/publish/>.

EVIDENCE

- Dayal M, Barnhart KT: Noncontraceptive benefits and therapeutic uses of the oral contraceptive pill. *Semin Reprod Med* 19(4):295-303, 2001.

This article summarizes a number of medical benefits that accrue to pill users, and the use of the pill as therapy for different medical conditions.

- Department of Economic and Social Affairs, Population Division: *World Contraceptive Use 2005*. Available at: <http://www.un.org/esa/population/publications/contraceptive2005/WCU2005.htm>. Accessed September 24, 2007.

This comprehensive dataset on contraceptive use by reproductive-age women is downloadable as an Excel spreadsheet or as a wall chart. Differences in use by region and level of economic development are listed.

- Edelman AB, Gallo MF, Jensen JT, et al: Continuous or extended cycle versus cyclic use of combined oral contraceptives for contraception. *Cochrane Database Syst Rev* 3:CD004695, 2005.

This review of several studies comparing traditional oral contraceptive dosing to regimens using active pills for greater than 28 days showed

similar efficacy, safety, and patient satisfaction. Menstrual symptoms and bleeding patterns were better in the longer cycle regimens.

4. French R, Van Vliet H, Cowan F, et al: Hormonally impregnated intrauterine systems (IUSs) versus other forms of reversible contraceptives as effective methods of preventing pregnancy. *Cochrane Database Syst Rev* 3:CD001776, 2004.

This meta-analysis showed that users of the levonorgestrel intrauterine system, IUDs containing more than 250 mm² of copper, and Norplant-2 had similar (very low) rates of pregnancy, but different effects on menstrual bleeding patterns.

5. Gallo MF, Grimes DA, Schulz KF: Skin patch and vaginal ring versus combined oral contraceptives for contraception. *Cochrane Database Syst Rev* 1:CD003552, 2003.

This study found three randomized controlled trials comparing the combination contraceptive patch to a combination oral contraceptive, showing similar efficacy but more breast tenderness with the patch. Adequate trials comparing the ring to the pill were not found.

6. Gallo MF, Grimes DA, Schulz KF, et al: Combination injectable contraceptives for contraception. *Cochrane Database Syst Rev* 3:CD004568, 2005.

In a meta-analysis, combination injectable contraceptives were associated with more regular bleeding patterns than progestin-only injectables were.

7. Hubacher D, Grimes DA: Noncontraceptive health benefits of intrauterine devices: A systematic review. *Obstet Gynecol Surv* 57(2):120-128, 2002.

This review documents a large number of gynecologic conditions that are ameliorated by intrauterine devices.

8. Kulier R, Helmerhorst FM, O'Brien P, et al: Copper containing, framed intra-uterine devices for contraception. *Cochrane Database Syst Rev* 3:CD005347, 2006.

This analysis of multiple studies showed that those containing a higher dose of copper are more effective in preventing pregnancy over a longer time period.

9. Nardin JM, Kulier R, Boulvain M: Techniques for the interruption of tubal patency for female sterilisation. *Cochrane Database Syst Rev* 4:CD003034, 2002.

A review of nine trials found that all techniques studied (e.g., clips, rings, cautery, resection) effectively prevent pregnancy, although there were minor differences in morbidity with different techniques.

10. Singh S, Darroch JE, Vlasoff M, Nadeau J: Adding it Up: The Benefits of Investing in Sexual and Reproductive Health Care. Washington, DC and New York, The Alan Guttmacher Institute and UNFPA, 2004.

This document describes in economic, medical, and social terms the recognized and potential benefits of family planning services worldwide, including contraception, maternal health services, and prevention and treatment of sexually transmitted infection.

11. Trussell J: Contraceptive efficacy. In Hatcher RA, Trussell J, Nelson A, et al (eds): *Contraceptive Technology*, 19th revised ed. New York, Ardent Media, 2007, Table 27-1.

This chapter includes very detailed information about each method of contraception, including information for counseling patients. It also covers related health matters such as prevention of sexually transmitted infection, sexuality, and issues related to the study of family planning and population.

12. Wilcox AJ, Dunson D, Baird DD: The timing of the "fertile window" in the menstrual cycle: Day specific estimates from a prospective study. *BMJ* 321(7271):1259-1262, 2000; and Wilcox AJ, Weinberg CR, Baird DD: Timing of sexual intercourse in relation to ovulation: Effects on the probability of conception, survival of the pregnancy and sex of the baby. *N Engl J Med* 333(23):1517-1521, 1995.

In a large cohort, a study showed that pregnancy could result from intercourse up to 6 days before ovulation, but not after ovulation, and the day of ovulation was more variable than previously believed.

Common Problems in Pregnancy

Introduction

Pregnancy is a time of extraordinary maternal adaptation. Some symptoms of pregnancy, such as nausea, breast tenderness, urinary frequency, low back pain, and fatigue, occur almost universally. These so-called minor discomforts of pregnancy cause significant morbidity. Benign conditions such as constipation, hemorrhoids, nasal congestion, peripheral swelling, and carpal tunnel syndrome are very common in pregnancy but are treated identically as in nonpregnant individuals. Common problems encountered in pregnancy are presented in Table 115-1, followed by a discussion of the use of medications in pregnancy.

Management and Therapy

Optimum Treatment

Rational Use of Medications in Pregnancy

Prescribing medications for pregnant women is difficult because the provider must tread a narrow path between excessively restrictive practices that deny women needed therapies and a casual approach that assumes most pregnancies will turn out fine. The following are general guidelines for treatment of women with routine pregnancies. Women with significant preexisting medical illness or complicated pregnancies should be referred to a perinatologist. It is never a mistake to call a specialist for management advice. Informal consultations give the consultant an opportunity to intervene early and to identify those cases where complex management and transfer of care are necessary.

Plan for Pregnancy

Ideally, the planning for use of medications in pregnancy begins before conception, especially in women with chronic illness. For conditions such as phenylketonuria, diabetes mellitus, hypertension, smoking, and obesity, the desire for a healthy baby may spur marked improvements in lifestyle and disease management. In these conditions, preconceptional improvements in maternal health status decrease problems such as miscarriage, fetal malformations, gesta-

tional hypertension, or delivery complications. In diseases such as hypertension or diabetes mellitus, for which there are several effective therapies but some are believed to be safer in pregnancy, it is best to switch therapies before conception is attempted.

Expect the Unplanned Pregnancy

In all women of reproductive age, it is worthwhile to explore plans and desires for future pregnancy. In the United States, more than half of all pregnancies are unplanned. A realistic assessment of the risk for pregnancy, including sexual activity, contraceptive choice, and correct use of the method chosen, is helpful for those who do not desire pregnancy. Women who do not expect to become pregnant may have delayed entry into prenatal care and prolonged exposure to medications that may be harmful in pregnancy. Alternatively, women may discontinue medications in early pregnancy in hopes of protecting their child, although in some cases, this can be harmful to both the woman and the developing embryo. Generally, however, a multivitamin containing 400 µg of folic acid is recommended for reproductive-age women, to decrease neural tube defects that occur before recognition of pregnancy.

Current Prescriptions, Over-the-Counter Drugs, Herbs, and Drugs of Abuse

Pregnant women often assume that drugs they used before pregnancy, especially those sold over the counter, are safe

Table 115-1 Common Pregnancy Problems

Problem	Etiology, Pathogenesis	Clinical Presentation, Differential Diagnosis, Diagnostic Approach	Serious Conditions to Consider	Management and Therapy
First-trimester vaginal bleeding	Cervical bleeding: inflammation or polyp Uterine bleeding: implantation of zygote, threatened pregnancy loss	Ultrasound shows gestational sac, embryo, cardiac activity. Findings should correlate with quantitative β -hCG and gestational age In early gestation, β -hCG doubles every 48-72 hours; decreasing or plateauing level indicates abnormal pregnancy Avoid digital examination of cervix if placental location is unknown. Doppler ultrasound may show vessels Braxton-Hicks contractions are painless and irregular; may increase with dehydration	Threatened, incomplete, or completed spontaneous abortion, ectopic pregnancy, ruptured hemorrhagic ovarian cyst. Pain and bleeding in early pregnancy equals ectopic till proven otherwise	Threatened abortion: observation; many continue with no sequelae Incomplete or inevitable abortion: vacuum aspiration Missed abortion or blighted ovum; expectant management, misoprostol, or aspiration. Ectopic: methotrexate or surgery
Third-trimester vaginal bleeding	Hemorrhage from placental separation Bloody show resulting from cervical changes in labor Uterine muscular activity	Avoid digital examination of cervix if placental location is unknown. Doppler ultrasound may show vessels Braxton-Hicks contractions are painless and irregular; may increase with dehydration	Placenta previa, abruptio placentae, vasa previa, uterine rupture	For hemorrhage threatening mother or fetus, cesarean section, transfusion
Contractions	Uterine muscular activity	Braxton-Hicks contractions are painless and irregular; may increase with dehydration	Contractions leading to cervical change (often with bloody show or rupture of membranes) define labor.	For preterm labor, steroids given before birth improve neonatal outcome. Long-term tocolysis is ineffective, but short-term tocolytics may allow steroids to work
Rapid heartbeat	Increased cardiac output	Sustained tachycardia is usually of supraventricular origin	High-risk conditions include Marfan syndrome, aortic stenosis, pulmonary hypertension, and New York Heart Association class III or IV, regardless of etiology. Hyperthyroidism may cause tachycardia, palpitations, anxiety, and thyroid storm	Reassurance, caffeine restriction, and change in activities if transient or mild. Cardiology evaluation (electrocardiogram, Holter monitor) if severe/persistent. Abortion for cases with high risk for maternal mortality Treat hyperthyroidism with β blockers, propylthiouracil
Nausea and vomiting of pregnancy	Central effect of β -hCG, estrogen, vitamin side effect	Begins by 10 weeks, not accompanied by fever, headache, abdominal pain or jaundice	Hyperemesis gravidarum: weight loss >5% of prepregnancy weight, large ketonuria. May occur in multiple gestation or molar pregnancy	Frequent small, bland, or salty meals, high in carbohydrate, low in fat. Ginger or peppermint. Avoid rapid position changes, odors, iron pills. Acupuncture or acupressure wrist bands. Vitamin B ₆ , doxylamine, phenothiazines Severe vomiting: metoclopramide, ondansetron, droperidol, or corticosteroids. IV fluids, hyperalimentation as needed

Continued

Table 115-1 Common Pregnancy Problems—cont'd

Problem	Etiology, Pathogenesis	Clinical Presentation, Differential Diagnosis, Diagnostic Approach	Serious Conditions to Consider	Management and Therapy
Indigestion (heartburn, reflux)	Progesterone relaxes lower esophageal sphincter	Worse after meals, improved by keeping head elevated	HELLP (hypertension, elevated liver enzymes, low platelets) syndrome: right upper quadrant pain, nausea, vomiting from liver involvement, or fatty liver	Small meals, elevate head of bed. Antacids, H ₂ -receptor antagonists, metoclopramide, proton pump inhibitors
Dyspnea of pregnancy	Progesterone increases respiratory rate Large uterus restricts diaphragmatic excursion	Worse in late pregnancy, better with sitting	Cough or fever may indicate asthma or infection. Severe symptoms, blood-tinged sputum, or acute change may indicate pulmonary embolus	Reassurance. Asthma treatment is similar to nonpregnant; adequate treatment prevents intrauterine growth retardation, death
Fatigue, syncope	Decreased blood pressure. Hormonal effects	Worst in first and third trimesters. Screen for anemia if persistent	Hypovolemic shock (ectopic pregnancy, ruptured hemorrhagic cyst)	Arise slowly, remain well hydrated
Anemia	Volume expansion, iron use by fetus	Detected on routine screening	Screen for thalassemia or sickle cell disease in high-risk populations	Iron-containing foods, oral iron supplements
Gestational diabetes	Secretion of diabetogenic hormones by placenta	Detected on routine screening	Pregestational diabetes	Diet, glucose monitoring, moderate exercise, insulin when needed
Gestational hypertension	Preeclampsia is likely caused by placental growth factors	Measurement of blood pressure and urine protein at prenatal visits	Chronic hypertension, preeclampsia, eclampsia	Antihypertensives if severely elevated pressures; delivery is treatment for preeclampsia
Headache	Hormonal (vasodilation), postural	Headache frequency (including migraine) may increase or decrease in pregnancy	Preeclampsia: headache accompanied by hypertension, proteinuria	Rest, massage, postural change, acetaminophen, narcotics. (Avoid nonsteroidal anti-inflammatory drugs due to risk for bleeding and closure of fetal patent ductus arteriosus.)
Back pain	Mechanical strain	Worse in late pregnancy	Costovertebral angle tenderness may indicate pyelonephritis. Preterm contractions may be felt in low back	Erect posture, avoid high heels, use elastic support for uterus, acetaminophen
Abdominal or pelvic pain	Mechanical (stretching of round ligament and other structures)	Common with walking or arising	Ectopic pregnancy, preterm or term labor. Pain of appendicitis is noted in abnormal location (higher) in pregnancy	Reassurance, analgesics
Varicose veins, dependent edema	Expanded blood volume; uterus impedes venous return	Worse in late pregnancy	Deep venous thrombosis: unilateral pain, redness, swelling. Nerve compression may cause weakness or numbness in lower extremities	Elastic stockings, or pad to compress vulvar varices, rest in horizontal position

Table 115-1 Common Pregnancy Problems—cont'd

Problem	Etiology, Pathogenesis	Clinical Presentation, Differential Diagnosis, Diagnostic Approach	Serious Conditions to Consider	Management and Therapy
Leg cramps	Cause unknown	Worse in late pregnancy	Deep venous thrombosis	Magnesium supplements
Respiratory infections	Viral or bacterial infection, may be more symptomatic in pregnancy	Incidence similar to nonpregnant state	Suspect pulmonary embolus if patient has been sedentary or symptoms are severe	May use acetaminophen, antihistamines, guaifenesin, saline nasal spray/neti pot. Pneumonia in pregnancy requires hospitalization
Urinary tract infections	Stasis caused by increased glomerular filtration rate, compression of ureters, relaxed smooth muscle tone, glycosuria	Frequent urination is normal in first and third trimester. Asymptomatic bacteriuria is common in pregnancy, diagnosed by routine urinalysis	Pyelonephritis with costovertebral angle tenderness and fever	Penicillins, cephalosporins are safe. Trimethoprim-sulfamethoxazole and nitrofurantoin are effective but may cause neonatal jaundice. Pyelonephritis in pregnancy requires hospitalization
Vaginal discharge	Estrogen increases physiologic discharge. Bacterial vaginosis is an alteration of vaginal flora	Vaginal pH, saline, and KOH prep and whiff test diagnose <i>Candida</i> , <i>Trichomonas</i> , and bacterial vaginosis	Amniotic fluid leakage may cause watery discharge	Topical azole antifungals for <i>Candida</i> . Metronidazole treats bacterial vaginosis or <i>Trichomonas</i> ; some providers defer treatment until second trimester. Bacterial vaginosis increases risk for preterm rupture of membranes, preterm labor and delivery, and amnionitis
Dental problems	Edema and hyperemia of gums lead to gingivitis	Dental examination and radiography (with abdomen shielded) should be done as early as possible, so preventive care can begin	Periodontal infection may cause preterm labor	Dental cleaning, extractions, and other needed treatments may be done in pregnancy
Dermatologic problems	Hormonal changes cause hyperpigmentation, skin tags. Abdominal distention causes striae	Common dermatoses of pregnancy include pruritic urticarial papules and plaques of pregnancy, which cause an abdominal rash with intense itching and prurigo of pregnancy (itchy papules on extremities). Check liver function tests with itching to rule out cholestasis	Herpes gestationis (large blisters) may increase risk for premature delivery	Most changes improve after delivery. Antihistamines or topical fluorinated steroids are used for pruritus
Anxiety, depression	Multifactorial, including adjustment to new roles and body changes, hormonal influences, and social factors	Substance abuse is common in pregnancy; diagnosis often missed in nonminority patients. Domestic violence increases in pregnancy, in all social classes	Previous mood disorder or mental illness can recur in pregnancy or postpartum, with risk for suicide or infanticide	Reassurance and social support are needed in each pregnancy. Antidepressant, antipsychotic, or anxiolytic medications are used for mental illness that cannot be controlled without drugs. Victims of abuse may initially decline help, but later accept help from battered women's shelter, hospital, or police

β-hCG, β-human chorionic gonadotropin.

in pregnancy. These often contain aspirin, nonsteroidal anti-inflammatory drugs, or other medications that are contraindicated in pregnancy. Combination medications, such as antihistamine-decongestant combinations, are also problematic because many prescribers are unaware of the exact components of these drugs. Popular cold remedies may contain six or more drugs, when a patient's symptoms could be treated with just one or two. Herbal preparations are also a concern because there is a dearth of research on their risks in pregnancy, and physicians may be unaware of the available data. Other drugs to consider include alcohol and illicit drugs, which have teratogenic or toxic effects. For many illnesses and discomforts of pregnancy, nonpharmacologic treatments are effective. These include foods, reassurance, social support, rest periods or alteration in working conditions, postural changes, local heat or ice, and use of braces or supports.

Use Minimum Effective Dose

Physiologic changes of pregnancy include increased plasma volume and cardiac output, increased glomerular filtration rate, decreased protein binding, delayed gastric transit, altered hepatic metabolism, and other changes that affect pharmacokinetics. These may require adjustment of drug doses. Use the minimum dose that works for the patient.

Stop Ineffective Drugs Rapidly

Prenatal visits in the first trimester are usually scheduled at 4- to 6-week intervals. When a drug is prescribed, the effectiveness of the therapy is often known in just a few days, but patients may obediently use an ineffective medication until the next scheduled visit. Rapid follow-up after starting a new medication is preferred, whether it is accomplished by a telephone call or an office visit.

Know a Few Drugs Well

Doctors who regularly care for pregnant women should have a personal formulary of treatments that they are comfortable prescribing. It is reasonable to start with a few drugs (e.g., acetaminophen, doxylamine, vitamin B₆, penicillins, cephalosporins, folic acid, and levothyroxine) and add only those drugs for which the literature shows effectiveness and not harm. The best approach favors drugs for which evidence has accumulated over years, rather than new drugs that have not previously been used in pregnancy.

Look Up What You Don't Know

There are excellent reference texts about drug risks in pregnancy and lactation as well as online resources such as REPROTOX. The Organization of Teratology Information Services and its member organizations in several states offer free information to providers and patients as well as informative fact sheets that can be printed directly from the Internet.

Well-known teratogens include alcohol; radioactive iodine; lithium; mercury; thalidomide; isotretinoin; angiotensin-converting enzyme inhibitors; coumarins; misoprostol; methimazole; penicillamine; tetracyclines; sex steroids, such as diethylstilbestrol and androgens; antiepileptic drugs, such as phenytoin, trimethadione, carbamazepine, and valproic acid; and many antineoplastic agents.

Although the developing fetus is at risk for teratogenesis, a policy of complete abstinence from drugs is dangerous. For certain diseases, the benefits of treatment may significantly outweigh the risks. The benefits may accrue to the fetus (e.g., treatment of severe maternal fever with antipyretics), to the mother (e.g., treatment of nausea and vomiting of pregnancy), or to both (e.g., treatment of asthma, varicella, thyroid disease, and HIV/AIDS). The risks of a drug should be compared to the risks of other possible disease treatments, the risks of untreated maternal disease, and the risks of preterm delivery to avoid fetal exposure to the drug. Even drugs that are known to cause fetal harm (antiepileptics, antineoplastic agents, anticoagulants) may be used in conditions in which risks of nonuse are extreme.

Avoiding Treatment Errors

Because hypertension is common, women with hypertensive disorders of pregnancy are occasionally misdiagnosed and treated with standard antihypertensive therapies. A pregnant or newly postpartum woman may present to an emergency room at night, away from her usual site of care, because of symptoms that indicate severe preeclampsia. These include severe headache, visual changes, and epigastric or right upper quadrant pain from liver damage. Other abnormalities in severe preeclampsia include blood pressure of 160/110 mm Hg or higher, oligohydramnios or intrauterine growth restriction, or HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome. Although antihypertensives may be used in the management of preeclampsia, prompt delivery is the most important treatment for women near term and for women developing severe preeclampsia.

Peripartum cardiomyopathy is a rare disease that develops in the last month of pregnancy or within 6 months of delivery, in women with no previous cardiac disease. Initial symptoms include fatigue, chest pain, and shortness of breath. The patient may be tachycardic, with low blood pressure, which may prompt aggressive resuscitation with intravenous fluids. Although young, previously healthy women can usually tolerate rapid volume expansion, women with peripartum cardiomyopathy are in failure when they are diagnosed, and aggressive hydration may cause pulmonary edema and death. Echocardiogram, electrocardiogram, and chest x-ray help to diagnose the condition, which is treated with digoxin, diuretics, sodium restriction, β blockers, and afterload reduction.

Future Directions

Research on pregnant women had long been hampered by the perception that women's symptoms were minor discomforts and by hesitancy to include pregnant women and their fetuses in research trials. The generally good outcomes of pregnancies also contributed to acceptance of traditional methods of care without critical review. The current trend toward evidence-based medicine should help us determine what care is effective and what should be abandoned.

Additional Resources

Briggs GG, Freeman RK, Yaffe SJ: *Drugs in Pregnancy and Lactation: A Reference Guide to Fetal and Neonatal Risk*, 7th ed. New York, Lippincott Williams & Wilkins, 2005.

This book covers more than 1000 drugs commonly used by pregnant or nursing women, outlining the risks of each drug to the fetus and nursing infant. It is especially useful in determining which drug to choose when there are a number of treatments available.

European Network of Teratology Information Services. Available at: <http://www.entis-org.com/>. Accessed February 12, 2007.

This website rapidly provides information for providers on drugs that may affect the fetus or breast-feeding infant.

MotheRisk. Available at: <http://www.motherisk.org/women/index.jsp>. Accessed February 12, 2007.

This website provides online information on teratology and medical treatment during pregnancy for providers and patients.

EVIDENCE

1. Levichek Z, Atanackovic G, Oepkes D, et al: Nausea and vomiting of pregnancy. Evidence-based treatment algorithm. *Can Fam Physician* 48:267-268, 277, 2002.

This article describes Motherisk's treatment algorithm, with supporting data on both safety and efficacy. Doxylamine with pyridoxine is a first-line therapy, with other drugs and tests used for refractory cases. The treatment algorithm is also described—"The Management of Nausea and Vomiting of Pregnancy"—and a tutorial is also presented at the Motherisk e-learning center: <http://www.motherisk.org/prof/elearning.jsp#2>. Accessed February 12, 2007.

2. Nanda K, Peloggia A, Grimes D, et al: Expectant care versus surgical treatment for miscarriage. *Cochrane Database Syst Rev* 2: CD003518, 2006.

This meta-analysis found that women randomized to expectant management instead of surgical evacuation had a higher rate of incomplete abortion and a greater chance of unplanned surgery, but a lower risk for infection than women randomized to surgery, when the groups were followed for up to 2 weeks.

3. Roberts D, Dalziel S: Antenatal corticosteroids for accelerating fetal lung maturation for women at risk of preterm birth. *Cochrane Database Syst Rev* 3:CD004454, 2006.

In 21 studies testing corticosteroids given to mothers at risk for preterm delivery, including studies of preterm rupture of membranes, treatment did not increase maternal infection. It did decrease neonatal respiratory distress, brain hemorrhage, necrotizing enterocolitis, and systemic infections in the first 48 hours of life.

Diabetes in Pregnancy

Introduction

Diabetes mellitus (DM) is the most common medical complication of pregnancy. Diabetes may predate pregnancy (pregestational diabetes, PGDM) or may be diagnosed during gestation (gestational diabetes mellitus, GDM). DM complicates 2% to 5% of all pregnancies, with 90% of cases represented by GDM. However, a number of cases of GDM may represent an unmasking of previously undiagnosed diabetes. Despite improved understanding of the disease and its management, diabetes remains a significant cause of perinatal morbidity and mortality. Fetal effects may include major anomalies, as high as 22% if the HbA_{1c} exceeds 8.5%, involving the cardiovascular, central nervous, skeletal, and urinary systems; growth restriction; macrosomia; in utero demise; neonatal hypoglycemia; and respiratory distress. Most fetal anomalies are directly related to early antenatal glycemic control. Furthermore, 10% to 15% of mothers will have persistent glucose intolerance or overt DM after pregnancy, with more than 50% diagnosed with disease by 10 years. Unfortunately, only 23% to 45% of women undergo the recommended follow-up testing.

Etiology and Pathogenesis

The production of placental hormones including progesterone, estradiol, prolactin, and human somatomammotropin lead pregnancy to become a diabetogenic state (Fig. 116-1). Estrogen increases insulin binding at the cellular level; however, decreased binding secondary to progesterone and cortisol offsets this effect. A postbinding defect in insulin action is also caused by progesterone, cortisol, prolactin, and human somatomammotropin. In an effort to offset these changes, there is a marked increase in insulin secretion that peaks in the third trimester.

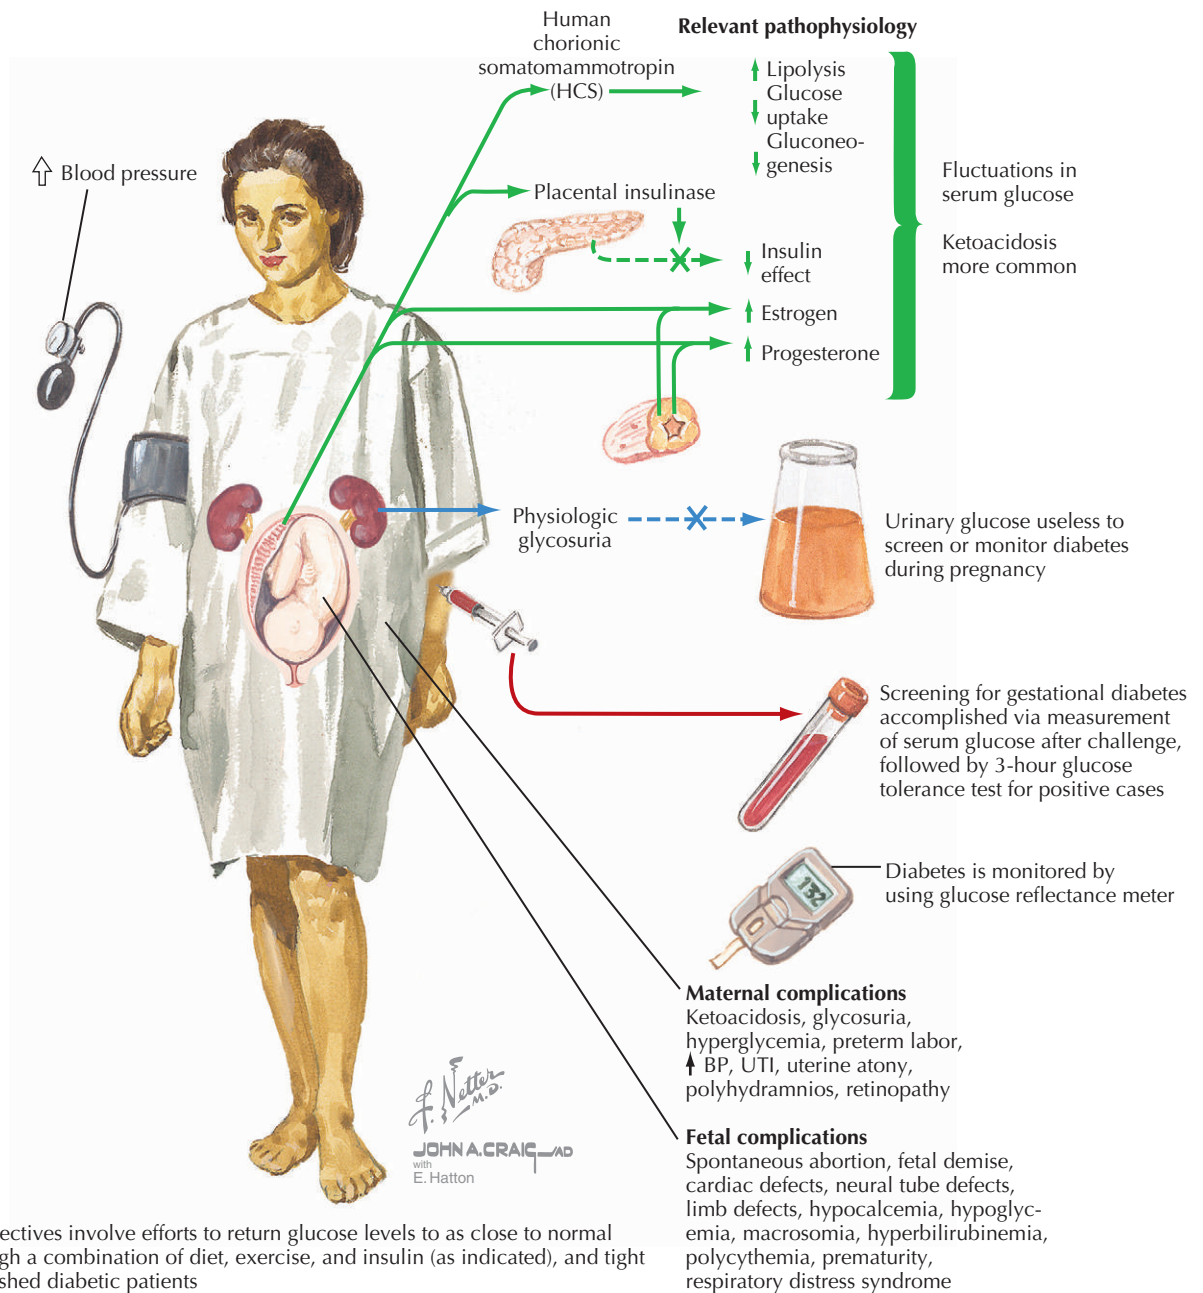

GDM shares many of the same features as type 2 DM. Hyperglycemia is related to two defects. First, there is a reduction in insulin secretion as compared with that in normal pregnancy. This is evidenced by a diminished first-phase insulin response and a delayed and reduced incremental response to a peak in serum glucose after oral loading. Second, insulin sensitivity is reduced to almost one third of the nonpregnant state.

Fetal effects are manifest through a number of pathways, with more implicated as research continues. Fetal glucose levels are typically 20 mg/dL lower than those in maternal serum. With significant hyperglycemia, decreased myoinositol and arachidonic acid, and aberrations in other

eicosanoid biosynthetic pathways are present, leading to higher levels of free radicals and glucose within cells. Each of these may be implicated in the genesis of fetal anomalies, and interplay among them is most likely. Fetal hyperglycemia may also lead to acidosis, hypoxia, and hyperinsulinemia with consequent macrosomia. The effect of hyperglycemia on fetal cortisol levels has been implicated in decreased surfactant production by type II pneumocytes, leading to delayed pulmonary maturity.

Diagnostic Approach

Significant controversy remains regarding universal screening for GDM (Fig. 116-2). Low-risk women (<25 years old; not a member of an ethnic or racial group with a high prevalence of DM such as Hispanic, American Indian, South or East Asian, Pacific Islander, or African American; body mass index (BMI) <25; no history of abnormal glucose tolerance; no history of adverse obstetric outcomes related to GDM; and no first-degree relative with DM) probably do not need to be screened. Patients with high-risk factors, including morbid obesity, previous unexplained fetal death, a previous infant weighing more than 4 kg, and a history of GDM or glycosuria warrant screening at their first or

Figure 116-1 Diabetes in Pregnancy.

Management objectives involve efforts to return glucose levels to as close to normal as possible through a combination of diet, exercise, and insulin (as indicated), and tight control in established diabetic patients

second prenatal visit. If normal, such patients are screened again at 26 to 28 weeks. All other patients are usually screened once between 24 and 28 weeks' gestation.

Typically, a 50-g oral glucose load is given with a plasma glucose measurement performed 1 hour later. The patient need not be in the fasting state. A value of more than 140 mg/dL warrants evaluation with a 3-hour glucose tolerance test after a 100-g glucose load. Some centers choose to use a threshold of 130 mg/dL because the higher threshold is 10% less sensitive for the diagnosis of GDM. See Table 116-1.

Management and Therapy

Preconceptional Counseling

Patients with PGDM contemplating pregnancy should be under tight glucose control before conception. Because more than 50% of pregnancies are unplanned, the primary care physician caring for the woman of reproductive age must inquire about contraceptive practices and plans for conception at each visit. Hemoglobin A1C levels should be measured and be well within the normal range. A multivitamin containing a minimum of 0.4 mg of folate taken

daily for at least 3 months before conception has been shown to reduce the risk for neural tube defects, cleft lip, and certain congenital heart diseases. If the patient is taking an angiotensin-converting enzyme (ACE) inhibitor for coexisting hypertension, consider changing to a calcium channel blocker because ACE inhibitors are associated with fetal renal damage, especially if taken in the second trimester of pregnancy.

Glucose Control

Diet

The patient with PGDM or newly diagnosed GDM should undergo dietary counseling. Table 116-2 can be used to calculate the total caloric needs.

Although traditional recommendations call for 50% to 60% of calories to be in the form of carbohydrate, recent studies indicate that limiting carbohydrates to 40% of calories results in less fetal macrosomia. Protein should constitute about 20% of calories, with fats making up the remaining 40%. More frequent intake makes for smoother glycemic control, with one suggestion to distribute calories as follows: breakfast, 10% to 15%; morning snack, 0% to 10%; lunch, 20% to 30%; afternoon snack, 0% to 10%; supper, 30% to 40%; and bedtime snack, 0% to 10%.

Insulin

PREGESTATIONAL DIABETES MELLITUS. Patients taking oral hypoglycemics are usually switched to twice-daily insulin therapy using a combination of regular and neutral protamine Hagedorn (NPH) formulations, although recently patients are continuing oral hypoglycemics if they are taking glyburide, and occasionally if they are taking metformin. Typical needs include a total daily dose of 0.5 U/kg from conception until 12 weeks, 0.8 U/kg from

Table 116-2 Calculation of Caloric Needs for the Gestational Diabetic Patient

Weight Category	Body Mass Index*	Caloric Needs†
Underweight	<19.8	40 kcal/kg
Normal weight	19.8-26.0	30 kcal/kg
Obese	26.0-29.0	24 kcal/kg
Morbidly obese	>29.0	12 kcal/kg

* Actual weight at start of pregnancy divided by height in meters squared.

† Based on weight in pregnancy when diet is prescribed.

12 to 28 weeks, and 1 U/kg thereafter. Caution should be exercised in patients on insulin pump therapy. Decreased appetite in the first trimester and changing sleep patterns related to pregnancy place the patient at increased risk for hypoglycemia. Instructing patients on a protocol for oral glucose supplementation when they experience early signs of hypoglycemia is especially important. Family members should be educated on the proper use of a glucagon pen. Home glucose monitoring is undertaken daily with four to seven measurements. The motivated patient can use e-mail messages or fax to report her values weekly for insulin adjustment.

GESTATIONAL DIABETES MELLITUS. Many practitioners use once-weekly fasting and 1- or 2-hour postprandial plasma venous glucose determinations performed in the office, despite studies indicating a higher incidence of fetal macrosomia as compared with the use of home glucose monitoring. The decision to begin insulin therapy should be based on home capillary glucose monitoring using reflectance meters. The use of memory chips and computer software to calculate mean glucose values allows for ease and accuracy of reporting. A minimum of four daily values should be obtained fasting and 1 or 2 hours after each meal. The use of postprandial values to adjust the dose of insulin has proved more efficacious in preventing neonatal hypoglycemia and macrosomia than using preprandial values. A more intensive surveillance program includes preprandial values (seven determinations daily) with calculation of a daily mean glucose value. When measurements conducted on a daily basis confirm good control, the patient can decrease to determinations 3 times a week. Repetitive fasting values of more than 95 mg/dL or 1-hour postprandial values of more than 140 mg/dL warrant insulin therapy. A total insulin dose of 0.7 U/kg actual body weight is calculated and divided into 2 daily injections given before breakfast and before supper. The morning dose usually consists of a 2 : 1 ratio of regular and NPH insulin; the evening dose consists of a 1 : 1 mix of these preparations. On some occasions, a persistently elevated fasting value may require that the evening NPH dose be moved to bedtime and only regular insulin given before supper. Target capillary glucose values should include

fasting less than 95 mg/dL, preprandial less than 95 mg/dL, 1-hour postprandial less than 140 mg/dL, and mean glucose values of 90 to 100 mg/dL.

Oral Hypoglycemics

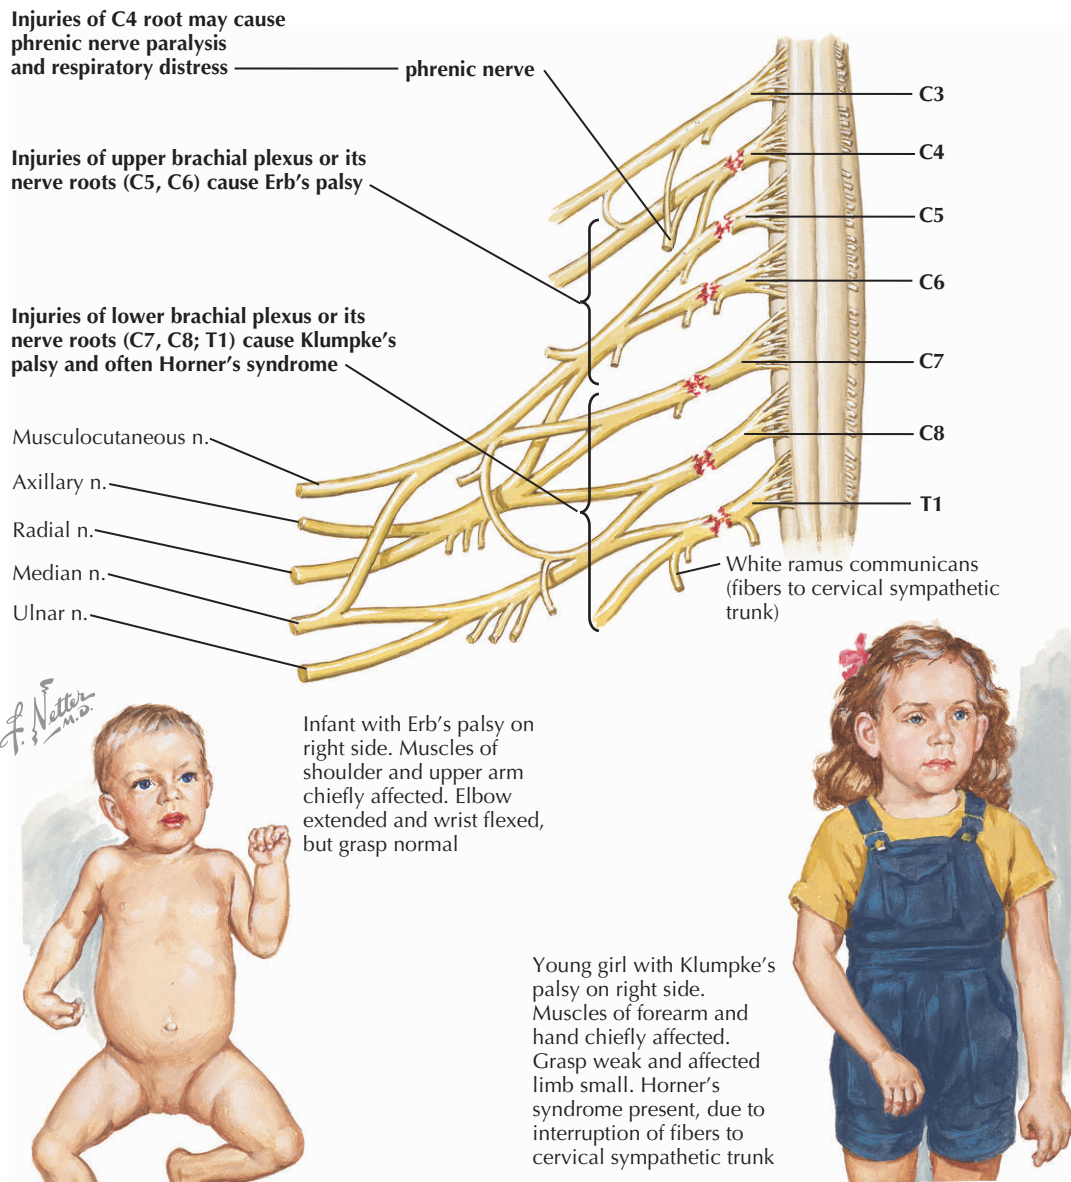

Until recently, oral hypoglycemics were not used in pregnancy because of concerns regarding fetal anomalies and neonatal hypoglycemia. The finding that GDM and type 2 diabetes have a similar pathophysiology has led to renewed interest in oral hypoglycemics for the treatment of GDM. Newer agents such as glyburide are tightly bound to protein and have a short elimination half-life, thereby minimizing fetal exposure. Recent studies in GDM have noted equivalent rates of macrosomia and neonatal hypoglycemia when compared with insulin therapy, with improved compliance and fewer hypoglycemic episodes. There is inadequate experience and data with other oral therapies to determine teratogenicity. Many studies to date have been unable to differentiate drug-related effects from those of poor glycemic control.

Other Prenatal Care

All PGDMs should undergo baseline ophthalmic examination to determine the presence of retinopathy. If proliferative changes are noted, photocoagulation can be undertaken during pregnancy. Benign retinopathy requires follow-up each trimester because institution of tight glycemic control has been associated with rapid deterioration. A baseline urine culture, as well as determination of 24-hour protein excretion and creatinine clearance, should be assessed early in gestation. Patients with DM of more than 10 years' duration should have an electrocardiogram, as should those with nephropathy or hypertension.

Fetal Surveillance

Because DM is associated with a higher incidence of congenital anomalies, a first-trimester hemoglobin A1C level should be obtained. All patients with DM should be offered serum and ultrasound-based screening for anomalies. First-trimester options include serum markers and ultrasound for nuchal translucency, associated with cardiac defects and aneuploidy. Second-trimester tests include alpha fetoprotein and comprehensive ultrasound at 18 to 20 weeks. If the hemoglobin A1C is elevated in the first trimester, a fetal echocardiogram at 22 weeks should be undertaken to assess for congenital heart disease. Cardiac lesions may include septal defects, transposition of the great vessels, tetralogy of Fallot, truncus arteriosus, and hypoplastic left heart. Antenatal testing may be warranted as early as 28 weeks' gestation in the patient with poorly controlled diabetes, vascular complications, or comorbidities. In most cases, testing is initiated by 32 weeks' gestation. Many centers use a modified biophysical profile consisting of a nonstress test (NST) performed in conjunc-

Figure 116-3 Brachial Plexus and Cervical Nerve Root Injuries at Birth (Erb's Palsy).

tion with an ultrasound determination of amniotic fluid volume; others prefer to use the NST alone or full biophysical profile (BPP). Testing is undertaken at least weekly, although for the patient with type 1 DM or GDM requiring insulin, twice-weekly testing may be preferable.

Delivery

Optimal timing of delivery in the patient with diabetes is debated. In the case of poor metabolic control and documentation of fetal lung maturity by amniocentesis, induction of labor should be undertaken at 37 to 38 weeks' gestation. Some studies have confirmed a reduced incidence of fetal macrosomia with routine induction at 38

weeks' gestation. Most centers will not allow the diabetic patient (with PGDM or GDM) to proceed past 40 weeks' gestation even in light of good metabolic control and reassuring antenatal fetal testing.

Fetal macrosomia is among the most feared complications of diabetes secondary to its association with shoulder dystocia and possible brachial plexus injury in the neonate. Ten to 50% of fetuses who weigh more than 4500 g experience a shoulder dystocia at the time of vaginal delivery. Erb's palsy (Fig. 116-3) develops in 4% to 8% of macrosomic infants delivered vaginally, but only 10% to 20% of cases persist after age 1 year. Current clinical and ultrasonographic techniques are poor predictors of fetal macrosomia. However, because of medicolegal concerns, the

prevailing practice is to offer the diabetic patient delivery by cesarean birth if the estimated fetal weight is 4500 g or greater.

Neonatal hypoglycemia can be reduced when maternal glucose levels are tightly controlled in labor. A dextrose-containing intravenous fluid prevents ketosis. Continuous low-dose insulin infusion, in conjunction with hourly capillary glucose measurements, is then used to maintain the maternal glucose at 90-120 mg/dL.

Postpartum Care

Glucose Control

Because of the acute loss of placental hormones with delivery, the patient with type 1 DM is extremely sensitive to insulin in the first 24 hours postpartum. Permissive hyperglycemia is allowed with maintenance of glucose levels less than 200 mg/dL. Typically the patient will only require half of her prepregnancy dose in the first 24 hours; a sliding scale can be used for additional control. By the second postpartum day, she can be placed back on her full prepregnancy dose if oral intake is adequate. If the patient is nursing, caloric intake should be increased by 500 kcal over her pregestation caloric needs. Patients who were taking oral hypoglycemic agents before pregnancy are maintained on low-dose insulin while breastfeeding because these agents are readily excreted into the breast milk and can cause profound neonatal hypoglycemia.

The patient with GDM requiring insulin should continue glucose monitoring in the immediate postpartum period, which may be discontinued or reduced over time. For all others, a 75-g oral glucose tolerance test is recommended at the 6-week postpartum visit. A fasting value of more than 126 mg/dL or a 2-hour glucose measurement of more than 200 mg/dL is the provisional diagnostic criterion for diabetes. An impaired fasting glucose is defined as a value between 110 and 125 mg/dL, whereas impaired glucose tolerance is defined as a 2-hour postglucose value of 140 to 199 mg/dL. These patients require careful follow-up because they are at high risk for the development of overt diabetes.

Contraception

Today's oral contraceptives contain reduced amounts of estrogen and progestin and therefore have minimal effect on glucose control; their use in the diabetic patient is acceptable with monitoring of glucose and lipid levels. New intrauterine devices are not contraindicated in the diabetic patient. Injectable or implantable progestins can also be used. One study has indicated a higher rate of progression to type 2 DM in Hispanic patients with GDM who, because of concerns about milk production, were taking progestin-only birth control pills.

Optimum Treatment

Dietary therapy or modification is the primary foundation of the treatment regimen for the pregnant mother with diabetes. Intensive dietary counseling, education, and support are critical components of success. A general scheme of caloric needs is outlined in Table 116-2. However, even greater attention should be given to the proportions of specific macronutrients in the diet. Appropriate vigilance over blood glucose levels through home monitoring, to include fasting and postprandial values, is the basis on which key treatment decisions are made. Once threshold values are exceeded, treatment should be initiated early. Initial treatment with glyburide is recommended, however, for those with more severe hyperglycemia, insulin should be first line. Frequent assessment of glycemic control through visits every 1 to 2 weeks and review of logbook values should guide further adjustments. Surveillance of fetal growth with ultrasound is mandated in severe cases, and at least a one-time assessment is recommended in the latter third trimester for all diabetic mothers. Delivery should be effected before 40 weeks, and earlier with very poor control and fetal lung maturity, with cesarean birth reserved for those with estimated fetal weights beyond 4500 g. Fetal well-being should be assessed once or twice weekly with NST or BPPs. Postpartum, patients requiring insulin during pregnancy should continue to monitor blood glucose, and all patients should undergo a 2-hour oral glucose tolerance test between 2 and 4 months after delivery.

Avoiding Treatment Errors

Because of the increased risk for hypoglycemia in pregnancy, aggressive therapy with insulin early in the course of disease should be avoided. Some practitioners suggest starting with insulin doses of 0.5 to 0.7 U/kg, slightly lower than the typical doses listed earlier. Not only is hypoglycemia potentially harmful to mother and fetus, but also significant symptoms may impair future compliance. Also, not following through with dietary counseling and support, and not reinforcing home glucose monitoring are serious pitfalls to successful management. Initial therapy with glyburide will likely improve compliance and, thereby, treatment success. It is important to recognize key drug interactions with glyburide, such as aspirin, which displaces drug from protein, H₂ blockers that competitively inhibit metabolism, and β -blockers, which antagonize regulatory hormones.

Long-Term Outcome

Maternal

Women in whom GDM develops are at substantial risk for the subsequent development of type 2 DM. The rate of development is dependent on several factors, most notably

race and ethnic background. About 10% of white women with GDM have type 2 DM within the first decade postpartum; the rate increases to 30% to 40% by the third decade. In contrast, 50% of Latina women with GDM have type 2 DM within 5 years of delivery. Although parity does not appear to influence the risk, women with GDM in successive pregnancies are at further increased risk for the development of type 2 DM. Obesity also is a major risk factor. The risk for DM increases almost twofold with each 10-pound weight gain over postpartum weight. Thus, knowledge of a woman's health status during her pregnancies offers a unique window into her risk evaluation, enabling opportunities in preventing disease and in more optimally targeting screening activities.

Neonatal

Macrosomia, hypoglycemia, hyperbilirubinemia, and polycythemia are the short-term detrimental effects of poorly controlled maternal DM. More concerning are the results of long-term studies that indicate that in utero modeling occurs when there is poor maternal metabolic control. A higher incidence of obesity, persisting into adolescence; glucose intolerance; and even poorer intellectual and psychomotor development have been noted.

Future Directions

Randomized trials are desperately needed regarding therapeutic interventions in GDM and the relationship to short- and long-term neonatal outcome. In addition, newer treatment modalities such as intranasal insulin and new types of oral hypoglycemics should be studied in pregnancy.

The authors present a comprehensive review of the types and mechanisms of development for major congenital anomalies seen in diabetic pregnancies. Hyperglycemia, ketone bodies, and triglycerides and the secondary effects of increased oxidative stress have been shown to exert adverse effects on developing embryos.

Menstrual Disorders

Introduction

Menstruation, the periodic bleeding caused by shedding of the uterine lining at regular intervals, is a normal event. It signals sexual maturity, fertility, and good health for many women, but it may be accompanied by significant morbidity. Common menstrual complaints are excessive bleeding, bleeding that occurs too frequently or too infrequently, painful menstruation, and premenstrual syndrome (PMS).

The menstrual cycle (Fig. 117-1) is described both in terms of ovarian hormonal events and in terms of endometrial responses to hormonal changes. The first day of bleeding is defined as day 1 of the cycle. The ovarian cycle begins with the follicular phase. Several follicles (small cysts, each containing an oocyte surrounded by estrogen-producing granulosa cells) begin maturing in response to follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secreted by the anterior pituitary gland. Through positive feedback, the follicle that secretes the most estradiol (the dominant follicle) becomes more sensitive to FSH stimulation and enlarges to about 2 cm in diameter, whereas the others atrophy. The hypothalamus and pituitary gland respond to ovarian hormones with a surge in LH and FSH secretion. Ovulation occurs within 24 to 48 hours of the LH surge. After ovulation, the granulosa and theca cells of the ovulatory follicle become the corpus luteum and produce estrogen and progesterone during the luteal phase. Rising ovarian hormone levels exert negative feedback on FSH and LH production. As FSH and LH fall (in the absence of pregnancy), the corpus luteum degenerates.

The uterus responds to ovarian or pharmacologic hormonal stimulation in a stereotypical fashion. During menstruation, there is shedding of the hormonally responsive upper zone of the endometrium, due to declining hormonal support. While the lining sheds down to its basal layer, new ovarian follicles are forming. Estrogen causes thickening of the lining and cessation of bleeding. This growth of glands and stroma that occurs before ovulation is the proliferative phase. After ovulation, progesterone and estrogen cause increased tortuosity of endometrial glands and secretion from the gland lumen, the secretory phase.

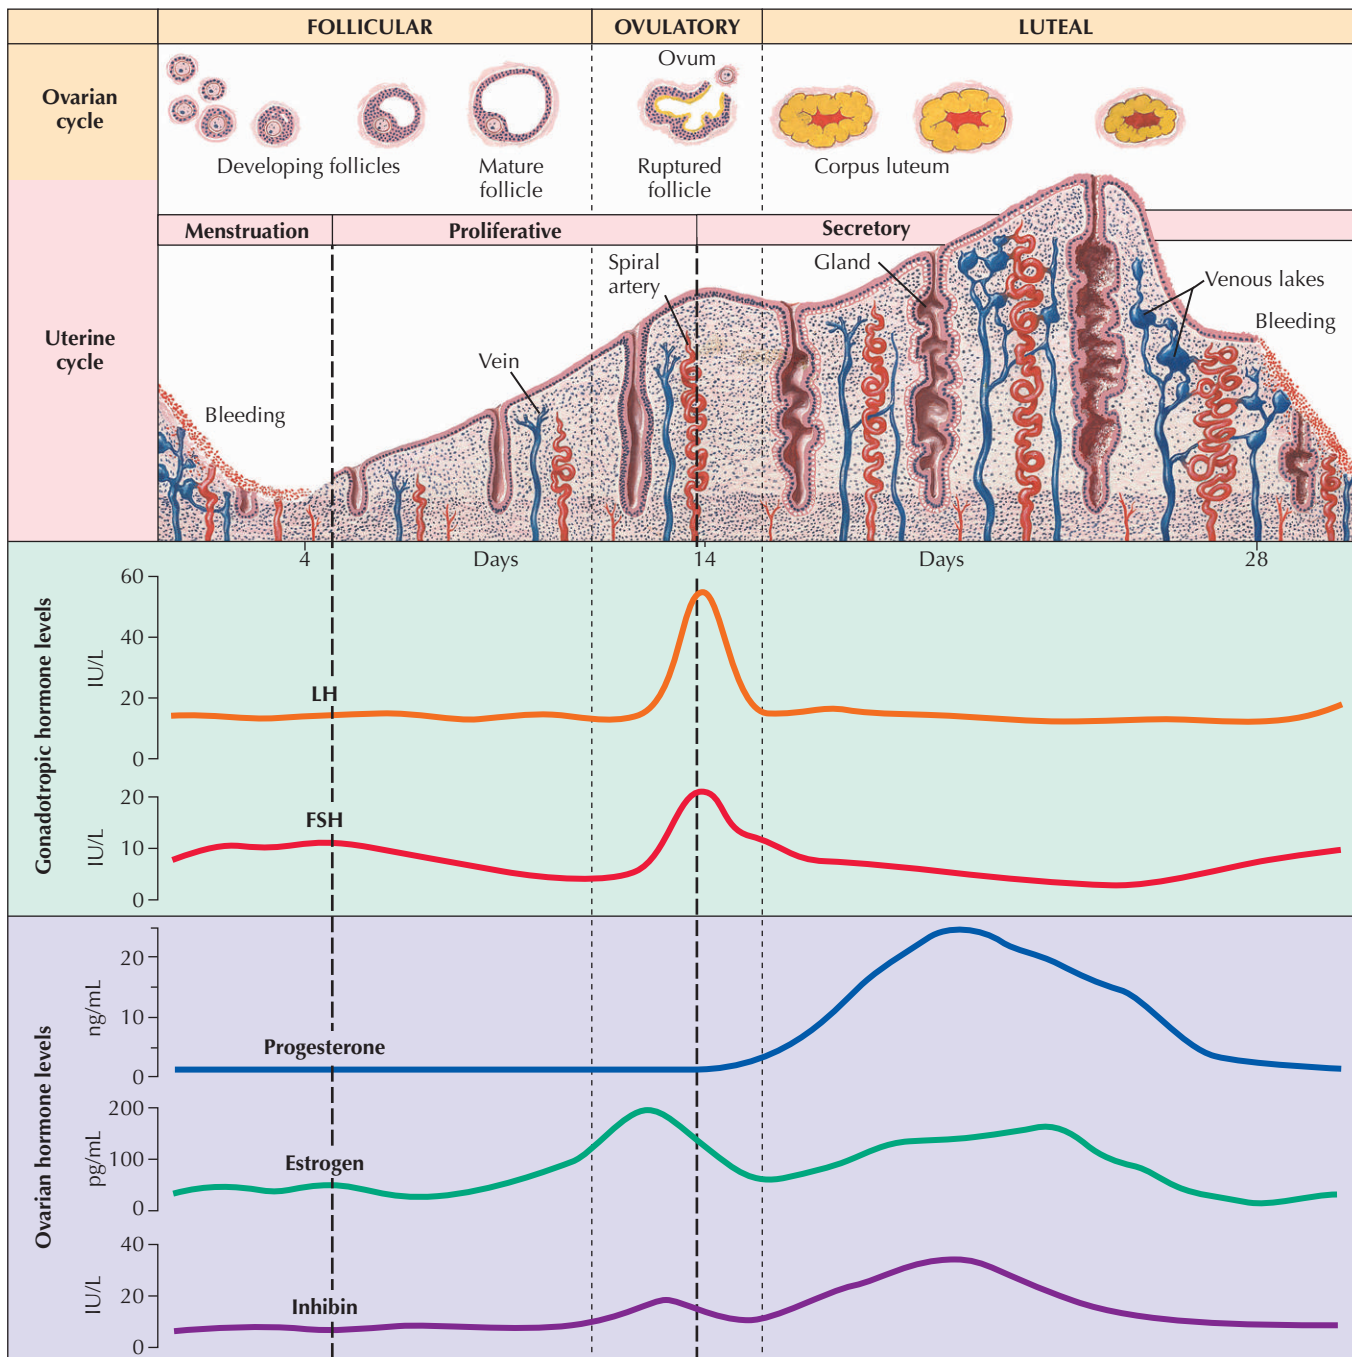

Normal menses occur every 24 to 35 days. The average is 28 days, with ovulation occurring on day 14. There is considerable variation in cycle length among women, and a significant chance that a woman will experience long or short cycles each year. Healthy women aged 20 to 40 years usually have regular cycles. The chance of irregular cycles is increased for 5 to 7 years after menarche and for several years before menopause.

In ovulatory cycles, bleeding averages 3 to 6 days, with the heaviest bleeding usually on day 2. Average blood loss is 30 to 40 mL per cycle.

DISORDERS OF TIMING AND AMOUNT OF BLEEDING

Menstruation may be excessive in amount, frequency, or duration, or a combination of these. Menorrhagia (hypermenorrhea) is prolonged (over 7 days) or heavy (greater

than 80 mL/menses) bleeding, occurring at regular intervals. Polymenorrhea is regular menses occurring more often than every 21 days. Metrorrhagia is irregularly timed, frequent bleeding; menometrorrhagia is both frequent and heavy. Amenorrhea is the absence of bleeding. Oligomenorrhea refers to irregularly timed, infrequent periods. Dys-

Figure 117-1 Menstrual Cycle.

functional uterine bleeding refers to abnormal menstrual bleeding for which an organic cause cannot be found.

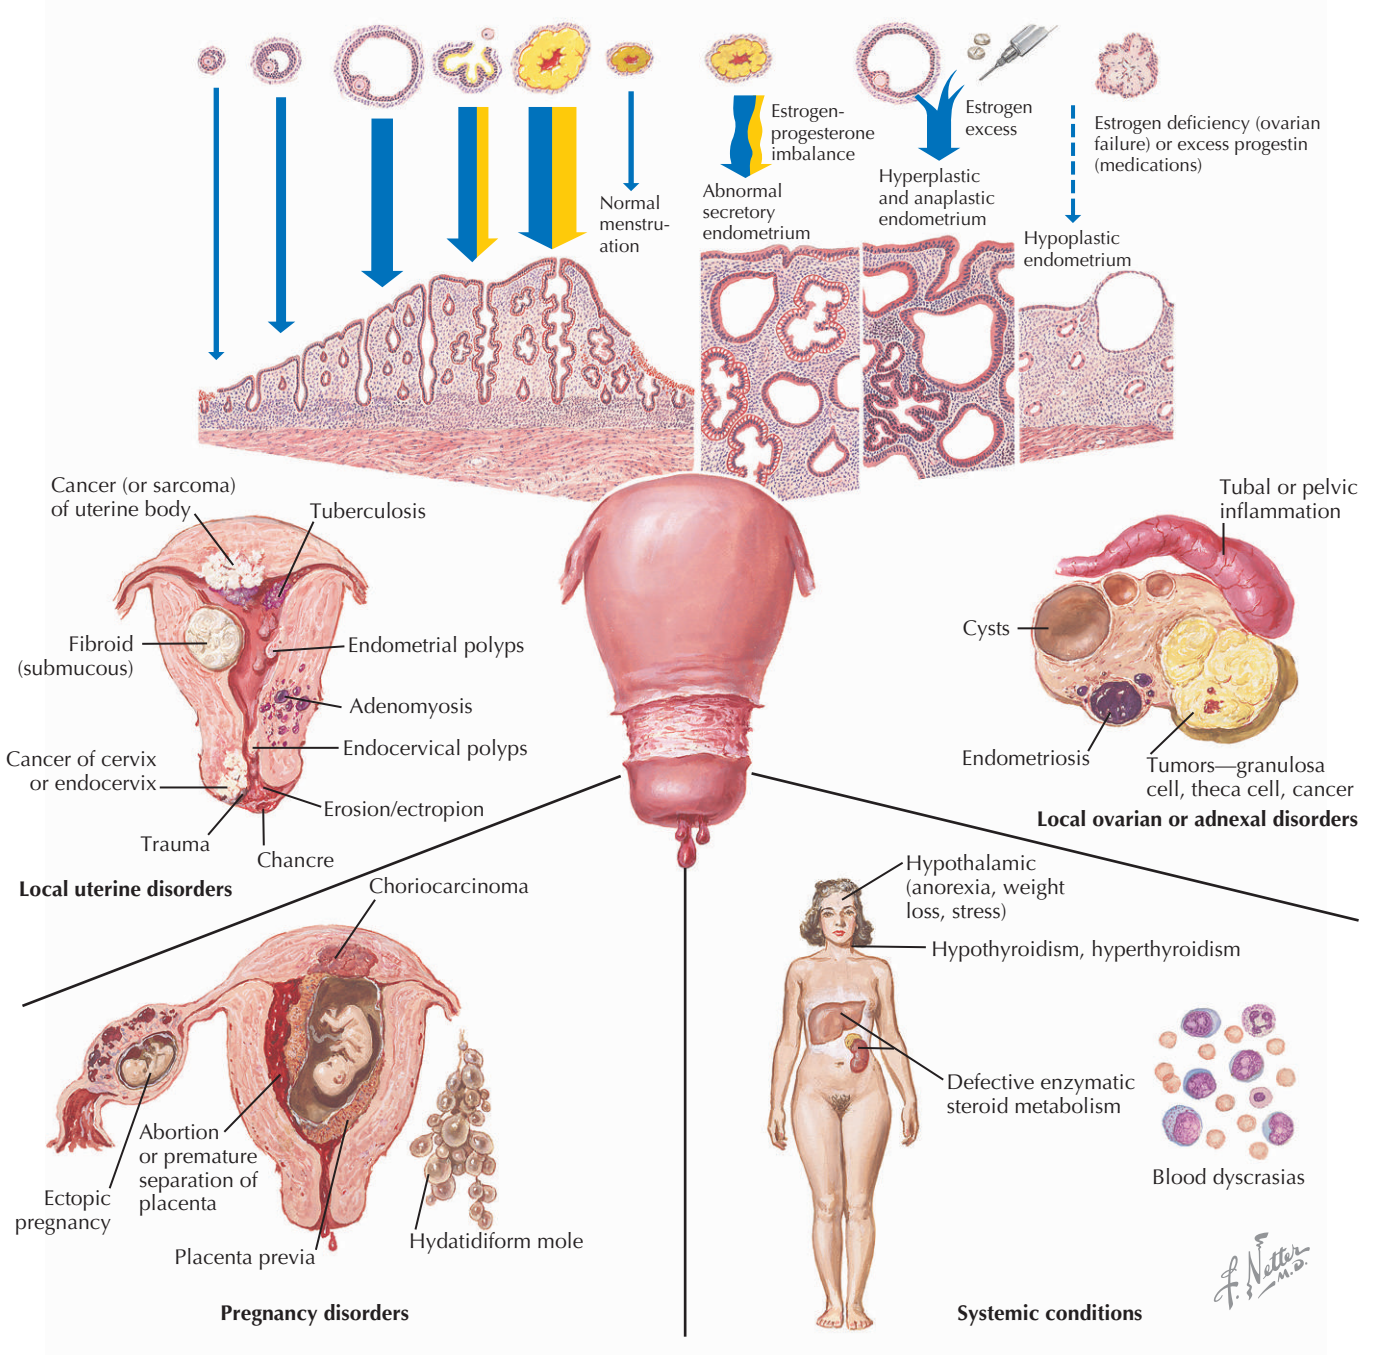

Etiology and Pathogenesis

Heavy regular bleeding is often due to an anatomic distortion of the uterus (Fig. 117-2). Uterine fibroids (submucous or large intramural leiomyomas), adenomyosis, and endometrial polyps cause heavy bleeding, possibly by

increasing endometrial surface area. Nonhormonal intra-uterine devices can also cause heavier, longer periods by creating a local foreign-body reaction. Inherited coagulation disorders (e.g., von Willebrand's disease) and alterations in clotting from use of anticoagulants or aspirin also increase menstrual blood loss.

Irregularly timed excessive bleeding may result from important pathologic circumstances. These include abnormal pregnancies—threatened or incomplete abortion,

Figure 117-2 Causes of Abnormal Uterine Bleeding.

ectopic pregnancy, or molar pregnancy. Endometritis causes irregular uterine bleeding and uterine tenderness from inflammation. Anatomic distortions such as fibroids or polyps can cause irregular bleeding. Endometrial carcinoma is associated with irregular, sometimes heavy bleeding. Adenocarcinoma, the most common endometrial neoplasm, usually arises from cystic hyperplasia with atypia. This condition often causes bleeding, which may lead to evaluation and treatment before development of cancer. For this reason, prompt evaluation of irregular bleeding,

particularly in perimenopausal or postmenopausal women, is important.

Bleeding from the cervix or vagina (e.g., cervicitis, ectropion, invasive cancer, severe atrophic vaginitis, or trichomoniasis) may be confused with uterine bleeding. Rectal and anal bleeding and gross hematuria are occasionally misinterpreted as genital in origin.

Amenorrhea is most often caused by pregnancy. Other causes are hyperprolactinemia, hypothyroidism or adrenocorticotropic hormone deficiency, hypogonado-

tropic hypogonadism, menopause or premature ovarian failure, anorexia nervosa, sudden weight loss, severe stress, strenuous exercise, and numerous medications.

Prolonged anovulation may cause a period of amenorrhea, followed by heavy bleeding from uterine lining hyperplasia. In polycystic ovary syndrome (PCOS), elevated pituitary LH secretion and excessive ovarian androgens prevent follicle maturation in the ovary. Ovarian androstenedione is converted peripherally to estrone, which stimulates further LH release, and a vicious cycle ensues. Estrogens cause prolonged proliferation of the endometrium, but without ovulation—normal menstruation does not occur. Eventually the thick but fragile endometrium breaks down, causing heavy bleeding. Physical stigmata include obesity, acne, hirsutism, and multiple ovarian cysts in severe cases. Milder cases of hyperandrogenic oligo-ovulation may not have these signs. PCOS may be associated with elevated serum lipids, centripetal obesity, insulin resistance, and an increased risk for diabetes mellitus and heart disease.

Clinical Presentation

Patients complain when their menstrual pattern changes, when they pass large clots, or when bleeding overflows sanitary protection. Chronic menorrhagia also frequently causes iron deficiency anemia. Occasionally, women with severe anemia from menstrual bleeding do not recognize that their periods are abnormal. Absence of anemia does not exclude menorrhagia because women may compensate for significant losses by increasing iron consumption.

Differential Diagnosis

See Box 117-1 for the differential diagnosis of menstrual disorders.

Diagnostic Approach

A menstrual history should include an estimate of the timing, duration, and amount of bleeding (size of clots, the type of protection needed, and the time needed to soak a maxi pad or tampon.) Age at menarche and the presence of perimenopausal symptoms such as hot flashes and night sweats help to diagnose age-appropriate anovulatory cycles. The history should address diseases or medications that can affect the hypothalamic-pituitary-ovarian axis. Galactorrhea, hirsutism, acne, and weight gain and loss are important associated symptoms to consider. Rapidly progressive virilization (deepening voice, clitoral enlargement, temporal balding, and increased muscle mass or libido) raises concern about ovarian or adrenal neoplasms. A family history of menstrual disorders, hysterectomy, and bleeding disorders should be investigated for heritable causes of menstrual disorders. Physical examination should assess height, weight, blood pressure, hair distribution, and

acne. Speculum examination may demonstrate vaginal inflammation, cervical erosion, tumor, or cervical polyps. Bimanual examination reveals a firm lumpy texture with leiomyomas. Tenderness to uterine palpation may occur with infection or adenomyosis, and enlarged ovaries or cysts may develop in patients with anovulation. In obese patients, the ovaries are usually not palpable. In menopausal women, it is abnormal to palpate the ovaries; any palpable ovary must be evaluated by ultrasound.

Useful laboratory tests include a sensitive pregnancy test, complete blood cell count, ferritin and serum iron levels for women with menorrhagia, and prothrombin time and partial thromboplastin time in women suspected of bleeding disorders. In amenorrheic patients, measurement of β -human chorionic gonadotropin, prolactin, thyroid-stimulating hormone, FSH, and estradiol are helpful. When signs of excess androgen are present, check total testosterone and 17-hydroxyprogesterone (morning and fasting.) Because chronic anovulation may be associated with the metabolic syndrome, it is also important to measure serum lipids, and consider testing hyperinsulinemia and impaired glucose tolerance. Endometrial biopsy may show polyps, infection, endometrial hyperplasia, or carcinoma. Ultrasound shows the total uterine size and the thickness of the endometrial stripe, as well as leiomyomas and ovarian cysts or polycystic ovaries. Hydrosonography and hysterosalpingography are useful to outline lesions such as polyps in the endometrial cavity. Hysteroscopy allows visualization of the uterine cavity, and many lesions, such as submucous or pedunculated leiomyomas, or endometrial polyps, can be treated during the same procedure.

Management and Therapy

Optimum Treatment

Hormonal treatment is useful in treating excessive bleeding, even that due to nonhormonal causes. Estrogen stops bleeding by stimulating growth of new tissue to cover the denuded endometrium. Progestins mature the uterine lining, making it compact and ready to slough off after the drug is withdrawn, mimicking the normal changes that occur in the secretory phase of the menstrual cycle. Progestins are also used diagnostically in cases of amenorrhea because a withdrawal bleed induced by progestin (e.g., medroxyprogesterone acetate, 10 mg daily for 10 to 14 days) demonstrates adequate estrogen stimulation of the uterine lining and a patent outflow tract. In anovulation, cyclic use of progestins prevents the buildup of a thick endometrium by allowing regular withdrawal bleeding and prevents development of hyperplasia and carcinoma. High doses of combined (estrogen-progestin) oral contraceptive pills (e.g., 4 tablets a day for several days) will arrest heavy bleeding, and normal doses will establish predictable withdrawal bleeding every 28 days. The programmed “period”

Box 117-1 Differential Diagnosis of Menstrual Disorders**Menorrhagia**

Leiomyomas
 Endometrial or endocervical polyps
 Endometrial hyperplasia or carcinoma
 Anovulation (hypothalamic, pituitary, polycystic ovary syndrome, perimenopause)
 Bleeding disorders (von Willebrand's disease, hemophilia, thrombocytopenia, anticoagulant use)
 Hypothyroidism
 Endometriosis
 Endometritis
 Systemic lupus erythematosus
 Leukemia
 Scurvy

Metrorrhagia

Pregnancy (intrauterine, ectopic, threatened abortion)
 Anovulation
 Breakthrough bleeding (progestin or estrogen-progestin contraceptives)
 Endometrial or endocervical polyps
 Leiomyomas
 Adenomyosis
 Endometritis
 Endometrial hyperplasia or carcinoma
 Bleeding disorders
 Retained products of conception

Primary Amenorrhea

Müllerian anomalies (uterine or vaginal agenesis, vaginal septum, imperforate hymen)
 Androgen insensitivity
 Ovarian dysgenesis (Turner's syndrome, Swyer's syndrome, mosaicism)
 Delayed puberty
 Hypothyroidism, hyperthyroidism
 Hypopituitarism
 Pregnancy

Androgens
 Androgen-producing tumors
 Hysterectomy or oophorectomy
 History of chemotherapy or radiation
 Toxicities like lead, mercury, and alcohol
 Malnutrition
 Exercise
 Chronic disease
 Pituitary tumors like craniopharyngioma
 Anorexia or depression

Secondary Amenorrhea

Pregnancy
 Anovulation, polycystic ovary syndrome
 Functional ovarian cyst
 Menopause, premature ovarian failure
 Hyperthyroidism, hypothyroidism
 Elevated prolactin (normal lactation, prolactinoma)
 Hypopituitarism (tumor, Sheehan's syndrome, genetic syndromes)
 Hypothalamic (GnRH suppression from stress, anorexia nervosa, bulimia, acute weight loss, malnutrition, depression, strenuous exercise, chronic disease)
 Drug effect (hormonal contraceptives, GnRH agonists, androgens, phenothiazines)
 Heavy metal poisoning (lead, mercury)
 Chemotherapy, radiation
 Endometrial damage (Asherman's syndrome, tuberculosis, schistosomiasis)
 Diabetes
 Systemic lupus erythematosus
 Vasculitis
 HIV infection
 Tuberculosis
 Surgical causes of hypopituitarism
 Hysterectomy or oophorectomy
 Androgen-producing tumors

in pill users and breakthrough bleeding, are both effects of the drug, and they represent neither normal menstruation nor a menstrual abnormality. Oral contraceptives can be taken continuously (without placebos) to prevent withdrawal bleeding and blood loss. A levonorgestrel-containing intrauterine device and implanted or injected progestins also decrease menstrual blood loss, although irregular bleeding in the first months of use is expected. Nonsteroidal anti-inflammatory drugs (NSAIDs) decrease the total amount of uterine bleeding and pain associated with menses, and NSAIDs can be useful in conjunction with oral contraceptives or cyclic progestins. Tranexamic acid (not available in the United States) effectively reduces menstrual blood loss.

Surgical treatments include curettage, numerous procedures to ablate or resect the endometrial lining, myomec-tomy and destructive procedures for fibroids, and hysterectomy.

Avoiding Treatment Errors

The most serious error in treating abnormal bleeding is a missed diagnosis of endometrial cancer or precancer. Endometrial carcinoma has a long premalignant phase, and early-stage carcinoma is often curable with surgery. Endometrial biopsy will diagnose most endometrial cancer and precancer. False-negative results do occur, so in patients at high risk (those with family history of uterine cancer, obesity, diabetes mellitus, African American race, and those with prior concerning biopsy results), curettage should be considered if irregular bleeding does not resolve promptly with hormonal treatment.

Oral contraceptives and other hormones often cause breakthrough bleeding in the first several cycles of use. Patients should be advised of this, so that they do not stop therapy too soon. With prolonged use of progestins or estrogen-progestin combinations, the endometrial lining

may become atrophic, so a woman who initially had too thick a lining can bleed when it becomes too thin. Ultrasound or hysteroscopy shows a very thin lining in such cases. Hormonal therapy works best in women with hormonal imbalance such as anovulation. When the anatomy is distorted by submucosal fibroids or polyps, hormonal treatment often improves symptoms, but surgery is more successful.

For severe endometriosis and adenomyosis, hysterectomy may provide welcome relief from symptoms, especially in women who have completed childbearing. When resources are limited, careful history taking will identify patients in greatest need of hysterectomy.

DYSMENORRHEA AND PREMENSTRUAL SYNDROME

Menstrual discomfort affects 30% to 60% of women. About 5% have symptoms severe enough to interfere with daily activities. PMS, a group of physical and emotional symptoms that occur in the luteal phase of the cycle, affects more than half of menstruating women intermittently, although severe symptoms occur in only 2% to 3% of women.

Etiology and Pathogenesis

Primary dysmenorrhea is caused by prostaglandin F_{2a}, which causes uterine contractions. Secondary dysmenorrhea is caused by inflammation in acute or chronic pelvic infection, excessive prostaglandin production in endometriosis and adenomyosis, or cervical stenosis. The physical symptoms of PMS, such as bloating and breast tenderness, are hormonal in origin. Emotional symptoms, such as anger, irritability, and depression, are serotonin mediated.

Clinical Presentation

Presentation is straightforward because the patient notes a symptom pattern and requests treatment.

Differential Diagnosis

PMS and premenstrual dysphoric disorder (PMDD) must be distinguished from chronic mood disorders. Because mental illness is stigmatized, women with depression or anxiety often seek treatment for PMS. However, the emotional symptoms of PMS and PMDD occur only in the luteal phase, clearing during the menstrual and follicular phases. PMDD may be isolated, or a woman may have premenstrual exacerbations of an underlying mood disorder. In either case, the symptoms of depression, irritability, and inappropriate behaviors may cause severe impairment in a woman's work and family relationships and subsequent feelings of guilt and shame.

Diagnostic Approach

Menstrual history is important to elucidate the age at onset because symptom changes with age, contraceptive use, pregnancy and lactation, associated symptoms such as backache or dyspareunia, and response to previous treatments. For PMS, a menstrual calendar is used to document symptoms over several cycles. Family history of menstrual disorders may affect a woman's response to menstruation, whereas a history of endometriosis or adenomyosis increases suspicion of these conditions. Pelvic examination may demonstrate cervical motion tenderness or adnexal tenderness in infection, uterosacral nodularity in endometriosis, or a boggy, tender uterus in adenomyosis.

Management and Therapy

Optimum Treatment

Menstrual pain can be treated with NSAIDs, which decrease prostaglandin production, hypertonic uterine contractions, and menstrual blood loss. Oral contraceptives also decrease menstrual pain in 90% of users and can be used together with NSAIDs. Heat, transcutaneous electrical nerve stimulation, acupuncture, and acupressure are also effective. Severe pain refractory to treatment should be evaluated with laparoscopy, and endometriotic lesions can be fulgurated simultaneously. Presumed endometriosis can be empirically treated with gonadotropin-releasing hormone (GnRH) agonists. Improvement with this treatment does not confirm a diagnosis of endometriosis because ablation of menstruation treats several menstrual disorders. Pregnancy and vaginal delivery are associated with lower rates of dysmenorrhea, but the stress of parenting may increase PMS. Hysterectomy is effective in relieving pure dysmenorrhea. Chronic pelvic pain often recurs after hysterectomy even if the pain is localized to the uterus on examination.

The physical symptoms of PMS can be effectively treated with mild diuretics and analgesics. Emotional symptoms may improve with selective serotonin reuptake inhibitors (dosed continuously or in the luteal phase only), anxiolytics, tricyclic antidepressants, or suppression of menses with danazol, GnRH agonists, or oral contraceptives.

Avoiding Treatment Errors

Endometriosis, adenomyosis, and chronic pelvic inflammatory disease can all cause vague abdominal discomfort and bloating that are worse around the time of the menses. A careful pelvic exam and laparoscopy will help distinguish these conditions from the premenstrual syndrome.

A woman who is suspected of having premenstrual dysphoric disorder may have PMDD, depression, or both. Symptom charting will help distinguish among these possibilities. Misdiagnosis of depression as PMDD may lead

to undertreatment because fewer drugs have been tested for PMDD than for depression. Ignoring the cyclic pattern of PMDD might lead to missed opportunities for therapy with hormonal or surgical ablation of the menstrual cycle.

Future Directions

For heavy and painful bleeding, hormonal contraceptives are often used. As the selection of delivery systems increases (intrauterine, implant, injection, patch, ring, or pill) and the dosing regimens are varied (from the traditional 21-day regimen to extended regimens), it will be important to know which methods have the most favorable effect on bleeding patterns and associated symptoms. Hysterectomy is 100% effective in stopping menstruation, but it is expensive and has significant operative morbidity. Many less invasive techniques to resect or ablate the endometrium have been developed. Research is needed to determine which among these is most safe, effective, and cost-effective.

As overweight and obesity become endemic around the world, the problem of anovulation and its relation to the metabolic syndrome will become more important. Primary prevention of these syndromes and the role of insulin-sensitizing agents, diet, exercise, and other treatments must be studied in detail.

This analysis of 16 randomized controlled trials showed that NSAIDs reduced menstrual blood loss, although danazol and tranexamic acid were more effective.

4. Lethaby AE, Cooke I, Rees M: Progesterone or progestogen-releasing intrauterine systems for heavy menstrual bleeding. *Cochrane Database of Systematic Reviews* 2005, Issue 4. Art. No.: CD002126. DOI: 10.1002/14651858.CD002126.pub2.

An analysis of 10 randomized controlled trials of the levonorgestrel-releasing intrauterine device (LNG IUS) showed that the LNG IUS was more effective than cyclic progestin treatment. It was less effective than surgical ablation and hysterectomy, but there was no difference in quality-of-life measures between these groups.

5. Lethaby A, Hickey M, Garry R: Endometrial destruction techniques for heavy menstrual bleeding. *Cochrane Database of Systematic Reviews* 2005, Issue 4. Art. No.: CD001501. DOI: 10.1002/14651858.CD001501.pub2.

This meta-analysis lists a large number of techniques for destroying the endometrium. Women undergoing new techniques such as balloon, microwave, cryoablation, thermal laser, bipolar electrode ablation, and hydrothermal ablation had fewer complications than women undergoing traditional hysteroscopic ablation or resection.

6. Lord JM, Flight IHK, Norman RJ: Insulin-sensitising drugs (metformin, troglitazone, rosiglitazone, pioglitazone, D-chiro-inositol) for polycystic ovary syndrome. *Cochrane Database of Systematic Reviews* 2003, Issue 2. Art. No.: CD003053. DOI: 10.1002/14651858.CD003053.

Multiple studies demonstrated that metformin increases ovulation in women with PCOS, and metformin with clomiphene increases ovulation more. Additionally, fasting insulin levels, blood pressure, and low-density lipoprotein cholesterol (LDL) all improved on metformin.

7. Marjoribanks J, Lethaby A, Farquhar C: Surgery versus medical therapy for heavy menstrual bleeding. *Cochrane Database of Systematic Reviews* 2006, Issue 2. Art. No.: CD003855. DOI: 10.1002/14651858.CD003855.pub2.

In studies comparing oral therapy with hysterectomy, more than half the women randomized to medication eventually required hysterectomy. Studies of the levonorgestrel intrauterine system was less effective at controlling bleeding, but patient satisfaction was similar to that in women undergoing resection or hysterectomy.

Endometriosis

Introduction

A benign gynecologic condition with occasional invasive properties reminiscent of malignancies, endometriosis has long frustrated both physicians and patients. Defined as the presence and growth of both endometrial glands and stroma outside the endometrial cavity, endometriosis can lead to symptom manifestations of cyclical pelvic pain, dyspareunia, dysmenorrhea, and less frequently, abnormal uterine bleeding and gastrointestinal and urinary tract symptoms. There is speculation about the relationship between endometriosis and fertility.

The true incidence and prevalence of endometriosis are unknown because it is identified often incidentally at surgery for other indications. Estimates commonly cited include a 5% to 15% incidence in reproductive-aged women. Active endometriosis is found in about one third of women with chronic pelvic pain.

Etiology and Pathogenesis

No single theory has emerged as dominant for the pathogenesis of endometriosis. It is unclear why endometriosis develops in some, but not all, women. Proposed explanations include anatomic (retrograde menstruation, vascular and lymphatic dissemination), histologic (coelomic metaplasia), immunologic, genetic predisposition, and other theories.

Retrograde menstruation, found in up to 90% of women in any particular cycle, is clearly a common occurrence. Implantation of endometriotic cells shed during menstruation may lead to the development of endometriosis. Viable endometrial cells have been demonstrated in both menstrual effluent and in peritoneal fluid of reproductive-aged women. Supporting evidence for this theory includes work demonstrating endometriosis in women with genital tract outflow obstruction (up to 10% of teenagers with congenital outflow obstruction) and the fact that endometriotic implants most frequently appear in areas immediately adjacent to the tubal ostia and in the dependent regions of the pelvis (Figs. 118-1 and 118-2).

Endometriosis may arise from metaplasia of the multipotential coelomic epithelium. This epithelial metaplasia may occur in response to an inducing event such as expo-

sure to menstrual effluent, estrogen, and progesterone. Supporting evidence includes ovarian surface epithelium differentiation into a variety of histologic cell types; peritoneal decidual reaction during pregnancy; and the rare occurrence of endometriosis in prepubertal girls and women with congenital absence of the uterus.

Research is continuing on the relationship between endometriosis and the immune response. The failure of the immune response may involve decreased cellular immunity with impaired natural killer cell cytotoxicity and decreased humoral response with impaired secretory product elaboration from B-cell lymphocytes. Combined, these defects in both cellular-mediated and humoral-mediated immunity likely contribute to faulty clearance of ectopic endometriotic implants and subsequent development of the disease. The exaggerated response may involve overactive peritoneal macrophages that secrete multiple growth factors and cytokines and exhibit impaired phagocytic properties in patients with endometriosis.

Lymphatic and vascular dissemination have been proposed to explain the development of endometriosis in sites distant from the pelvis including the lung, brain, and spinal column. Endometriotic involvement of pelvic lymph nodes has been reported in 30% of women with the disease. Iatrogenic spread has been implicated to explain the

Figure 118-1 Endometriosis: Laparoscopic Views.

Figure 118-2 Endometriosis: Pelvis—Sites of Implantation.

Diffuse pelvic endometriosis: ruptured endometrial (chocolate) cyst

appearance of endometriosis in the anterior abdominal wall after abdominal surgery and, more rarely, in episiotomy scar sites.

Genetic predisposition has also been described. A study has shown a sevenfold increase in the incidence of endometriosis in relatives of women with the disease and that 1 in 10 women with severe disease have a mother or sister with symptomatic disease.

Clinical Presentation

The heterogeneity of endometriosis symptom expression should not be overlooked, with as many as one third of patients lacking symptoms. The classic presentation is that of cyclical pelvic pain that develops 2 to 4 days before the onset of menses. A more traditional clinical picture of endometriosis includes secondary dysmenorrhea, dyspareunia, infertility, a fixed retroverted uterus, and tender nodularity of the cul-de-sac. However, in a Brisbane study, only 5% of 717 patients with endometriosis had this complete clinical picture. Moreover, clinicians have often observed an inverse relationship between the extent of observable endometriotic disease and the extent of pain.

Symptoms include cyclical pelvic pain, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, constitutional symptoms, and infertility. Cyclical pelvic pain may result from cyclical swelling of endometriosis implants with blood extravasation into surrounding tissues. Secondary dysmenorrhea, described as a constant pain, may occur in 30% of patients and is a dominant symptom in adolescents. Dyspareunia, a deep pelvic pain during intercourse, occurs in about 30% of patients and may be secondary to immobility of pelvic organs or stretching of scarred tissues and uterine support tissues. Abnormal bleeding occurs in up to 15% of patients and may be secondary to ovulatory dysfunction, coincidental fibroids, or adenomyosis. Constitutional symptoms such as cyclical gastrointestinal complaints (cyclical diarrhea or constipation, abdominal pain) or urinary complaints (urinary frequency, hematuria, or dysuria) are experienced in as many as 15% of patients. Infertility may accompany endometriosis; however, in the work of O'Connor, it occurred in a minority of patients (13%).

Findings on examination include fixed uterine retroversion (up to 15% of patients); tenderness and nodularity in the cul-de-sac and rectovaginal septum (up to 30% of patients), best confirmed by rectovaginal examination; and uterine tenderness or enlargement with adnexal swelling (up to 20% to 30% of patients).

Differential Diagnosis

The differential diagnosis includes pelvic inflammatory disease, ovarian neoplasms, intermittent ovarian torsion,

hemorrhagic ovarian cysts, uterine myomas with degeneration, adenomyosis, primary dysmenorrhea, and functional bowel disease such as irritable bowel syndrome.

Diagnostic Approach

Although symptoms are strongly suggestive of the disease process, definitive diagnosis requires biopsy samples taken at the time of laparoscopy or laparotomy to confirm the presence of extrauterine endometrial glands and stroma. Staging is based on the updated scoring system from the American Society for Reproductive Medicine.

Management and Therapy

The goal of therapy is relief of pain and preservation of fertility. Both medical and surgical options have been effective in relief of pain when compared with expectant management. Medical therapies available are designed to suppress estrogen synthesis, thereby inducing atrophy of endometriotic implants. Medical options include gonadotropin-releasing hormone (GnRH) agonists, oral contraceptives and other hormonal treatments, and danazol. Surgical options include ablation or excision of implants, excision of endometriomas, lysis of adhesions, and even appendectomy. The appendix is involved in up to 13% of cases. Presacral neurectomy and uterosacral nerve ablation provide additional options. The surgical approach can involve laparoscopy or laparotomy. Finally, definitive surgical management, when other alternatives have proved unsuccessful in symptom relief, requires total abdominal hysterectomy with or without bilateral salpingo-oophorectomy.

Optimum Treatment

Medical Therapy

Although the ultimate goal of endometriosis therapy is pain relief and protection of fertility, the goal of medical therapy is amenorrhea. Available medical therapies appear equally effective for treatment of symptoms and improvement in American fertility staging of disease scores and recurrence rates when compared with placebo. Recurrence rates after discontinuation of therapy have been reported as 5% to 15% in the first year and as high as 40% to 50% in 5 years. Recurrence appears directly related to the extent of the original disease, occurring in 35% in women with minimal disease and 75% in women with severe disease. The side-effect profile appears to be the primary factor in selection of the medical option used.

GnRH agonists bind to receptors leading to decreased gonadotropin secretion and subsequent decreased ovarian steroidogenesis. Therapy is usually recommended for 6 months. Agents available (leuprolide acetate, nafarelin acetate, and goserelin acetate) can be administered through

intramuscular, intranasal, and subcutaneous routes. Medical oophorectomy leads to endometriosis pain relief in 75% to 90% of women with disease. Bothersome side effects include hot flashes, vaginal dryness, insomnia, headaches, diminished libido, mood swings, and breast changes. Bone density may decrease by 2% to 7% during the 6-month course of treatment but completely recovers by 12 to 24 months after completion of therapy. Add-back therapy with low doses of estrogen and progesterone has been used to ease side effects associated primarily with estrogen deficiency and appears to attenuate loss of bone mineral density while not interfering with the effectiveness of GnRH agonist therapy.

Oral contraceptives taken continuously to induce amenorrhea are effective therapy for endometriosis. Although 80% of women experience symptom improvement, side effects most common with this therapy include weight gain and breast tenderness. Other hormonal therapies include daily medroxyprogesterone (10-30 mg po qd) and depo-medroxyprogesterone (150 to 200 mg intramuscularly every 3 months). The antiprogestone mifepristone (RU486) has also demonstrated success in inducing amenorrhea, decreasing pain symptoms, and decreasing endometriotic lesion size. No large randomized controlled trial has been performed to date on the use of mifepristone in women with endometriosis.

Danazol, an attenuated androgen, is a derivative of 17 α -ethinyltestosterone. Although its mechanism of action is not entirely clear, danazol binds to androgen and progesterone receptors as well as to sex hormone-binding globulin, inhibiting ovarian steroidogenesis as well as midcycle luteinizing hormone release. Amenorrhea is usually induced within 6 to 8 weeks of initiating therapy. Side effects include acne, hot flashes, depression, headaches, weight gain, and altered libido. Other androgen-related effects such as increased facial hair, clitoral hypertrophy, and voice changes are experienced by 80% of patients. As a result, 20% of women discontinue treatment.

Surgical Therapy

Surgical therapy is often used for diagnostic purposes and after the failure of medical therapy. Conservative therapy includes diagnostic laparoscopy accompanied by laser or electrocautery ablation of implants. Laser ablation has been effective in 95% of women at 18 months after surgery. Midline pelvic pain has been relieved by laparoscopic uterosacral nerve ablation and presacral neurectomy; however, there are no evidence-based studies comparing these procedures to placebo or sham procedures. More definitive surgical therapy includes hysterectomy with preservation of one or both ovaries for women in their 20s and 30s. In women for whom future fertility is not a consideration, definitive surgical therapy by total abdominal hysterectomy with bilateral salpingo-oophorectomy may be warranted.

Avoiding Treatment Errors

Contraindications to estrogen therapy include unexplained vaginal bleeding, the presence of breast or endometrial cancer, active liver disease, and active thrombophlebitis. Conservative therapy, particularly conservative surgical therapy, should be considered in all cases where future fertility is desired.

Future Directions

The remarkable heterogeneity of endometriosis provides both a diagnostic and management challenge. Although current therapy is focused on steroidogenesis suppression or surgical ablation or excision, future therapies may be directed toward some of the multiple immunologic mediators potentially involved in endometriosis development. Animal studies currently suggest that aromatase inhibitors, selective estrogen and selective progesterone receptor modulators, and immunomodulatory agents such as tumor necrosis factor- α may eventually have a role in therapy. Evidence-based medicine should guide therapy based on trials designed to study the effectiveness of current therapies, including the comparison of medical and surgical approaches. With this information, both the patient and her clinician can make better-informed treatment decisions in dealing with this common and at times disabling condition.

Menopause

Introduction

Menopause is technically defined as the permanent cessation of menses, although the term is commonly used in association with the clinical manifestations and consequences of ovarian failure. Menopause is a physiologic event in the lives of all women. The clinical manifestations and consequences vary in type and intensity. The age of onset is genetically predetermined and independent of factors such as race, education, and socioeconomic status, as well as weight, height, and age at time of last pregnancy. Cigarette smoking has been shown consistently to hasten menopause by about 1 year. The average age of menopause in the United States is 51 years, and although this is normally distributed with 95% confidence limits between 45 and 55 years of age, about 1% of women experience menopause before age 40. The climacteric, the time during which women transition from reproductive years to postmenopausal years, usually lasts 4 years. The average life expectancy in the United States is 78 years; most women will live one third of their lives in the postmenopausal state. It is estimated that there are 60 million women in the United States older than 50 years.

Etiology and Pathogenesis

Ovarian failure leads to menopause (Fig. 119-1). Diminished ovarian function is present several years before the permanent cessation of menstruation. The number of ovarian follicles and follicular cell production of the glycoprotein inhibin, which functions to inhibit pituitary production of follicle-stimulating hormone (FSH), decrease with age, causing FSH levels to rise. Because FSH release is primarily controlled by inhibin, measurement of FSH levels is not a useful approach to determining therapeutic doses of postmenopausal estrogen replacement; FSH levels remain elevated even with the administration of large doses of exogenous estrogen. Granulosa and thecal cells degenerate, with ovarian estradiol secretion waning significantly up to 1 year before menopause, whereas stromal cells continue to produce the androgens androstenedione and testosterone.

Premature ovarian failure, or ovarian failure before the age of 40 years, occurs in up to 1% of women, with X chromosome abnormalities accounting for most cases. Women with a family history of early menopause may have as much as 6 times the likelihood of menopause before age 46 years, with the strongest association seen in women who had mothers or sisters undergoing menopause before age 40 years. Surgical removal of the ovaries and chemother-

apy can induce menopause and associated postmenopausal symptoms.

Clinical Presentation

Although hot flashes and vaginal dryness are commonly associated with the postmenopausal state, change in menstrual cycle length is one of the first signs of menopause. A consequence of waning ovarian function, this change in cycle length reflects increasing anovulatory cycles and can occur up to 4 years before menopause.

Hot flashes, which occur in up to 50% of women, likely result from a central nervous system-mediated change in hypothalamic thermoregulation. The frequency and severity of this symptom corresponds to the magnitude of estrogen level fluctuation; the greater the estrogen level fluctuation, the more frequent and severe the hot flashes. The incidence of flushes declines with time, with only 20% of women reporting such symptoms 4 years after menopause. Obesity leads to fewer complaints of hot flashes given increased peripheral aromatization of androstenedione to estrone in adipose tissues.

Vaginal dryness and genitourinary atrophy are frequent complaints of women in the climacteric. Estrogen deficiency may lead to atrophy of vaginal epithelium, causing

Figure 119-1 Pituitary and Ovarian Hormone Changes in Menopause.

Hormone levels increase and decrease cyclically during menstrual cycle. Modulation occurs by pulsatile release of gonadotropins and positive and negative feedback loops.

In postmenopausal period, gonadotropin levels increase and ovarian hormone levels decrease secondary to ovarian failure. Endogenous estrogen is primarily of adrenal origin, and E₁/E₂ ratio is reversed.

LH and FSH (mIU/mL)

Estrogen (pg/mL) and progesterone (ng/mL)

the symptoms of itching, light vaginal discharge, dyspareunia, and even vaginal bleeding (Fig. 119-2). Decreased libido has also been associated with menopause. Decreased collagen content associated with estrogen deficiency may lead to loss of support of the vaginal walls and uterus. Other estrogen-deficiency related symptoms include urinary urgency, frequency, nocturia, and dysuria as estrogen-dependent lower urinary tract epithelial tissues atrophy.

Menopause is also associated with change in body weight and total body fat. The randomized Postmeno-

pausal Estrogen/Progestin Interventions study reported less weight gain in women on hormone replacement as compared with placebo. A reduced shift in body fat to the abdominal area was also noted, a factor associated with higher cardiovascular morbidity and mortality.

Other symptoms include increased insomnia, anxiety, mood lability, and depression. What is unclear is whether estrogen administration, which has been shown to improve such symptoms, works directly on the symptom of concern or alleviates hot flashes, allowing women to sleep better, thus leading to resolution of symptoms. Migraine head-

Figure 119-2 Target Organ Changes in Menopause.

aches may improve with menopause, whereas tension headaches typically remain unchanged. Cognitive function may also be affected. In one study, reported mental status examination scores of postmenopausal women taking estrogen were significantly higher than those of women not taking estrogen.

Differential Diagnosis

The differential diagnosis for menopausal symptoms is narrow. The most common additional diagnosis to consider is anxiety.

Diagnostic Approach

The diagnosis of menopause relies primarily on the history. Menstrual cycle irregularity secondary to oligo-ovulation or anovulation is commonly reported. Intermittent hot flashes secondary to fluctuating estrogen levels may lead to interrupted sleep, fatigue, irritability, anxiety, and depression. Personal and family history regarding cardiovascular and osteoporosis risk factors is important.

Physical examination should include weight, height, and blood pressure. Pelvic examination may reveal atrophic changes of the external genitalia, including thinning of the labial tissues and fusion of labial minora folds with the labia majora. Thinning of vaginal mucosa with loss of rugation commonly occurs, as does decreased vaginal pH. Serum FSH and luteinizing hormone concentrations are elevated.

Yearly mammograms should be obtained in all postmenopausal women older than 50 years presenting for annual care. It is difficult to set an upper age range for

cervical cancer screening. It is generally recommended that women older than 30 years who have had three consecutive negative Papanicolaou tests should be screened at 2- to 3-year intervals.

Management and Therapy

Why attempt to manage and treat a physiologic condition? This is a question posed to clinicians by many patients. The answer lies in the appreciation of the health problems of postmenopausal women and the preventative measures available. Two major health problems for which preventative measures are available include cardiovascular disease and osteoporosis.

Cardiovascular Disease

Cardiovascular disease is responsible for more postmenopausal deaths than all other causes of death combined. Cardiovascular disease is 3 times as common in men as in women before menopause. This ratio of myocardial infarction in women to men older than 50 years changes to 2 : 1. As such, it is important that postmenopausal women address cardiovascular risk factors aggressively, including control of hypertension, hypercholesterolemia, and diabetes mellitus, and cessation of cigarette smoking.

Controversy in the literature about the use of estrogens to reduce cardiac risk has existed for many years. On the basis of observational and epidemiologic studies and strong experimental data, estrogen therapy was long recommended for cardiac risk reduction in women. This recommendation came under question after the Women's Health Initiative Randomized Controlled Trial, in which a small increased cardiac risk of nominal statistical significance was seen in postmenopausal women taking combination (estrogen-progestin) hormone replacement therapy. However, estrogen-only therapy did not significantly affect the incidence of coronary heart disease (CHD). *Interestingly, younger women taking estrogen alone may have a reduced risk for CHD.* Thus, initiation of combination hormone replacement therapy solely for prophylaxis against myocardial infarction is not currently recommended. Estrogen-only therapy for CHD prophylaxis may have a role in younger postmenopausal women without preexisting heart disease.

Osteoporosis

Characterized by decreased bone mass, osteoporosis is usually asymptomatic and often not detected until fracture occurs. In the United States, about 800,000 fractures occur per year; 300,000 of these are hip fractures, with 15% of hip fractures in women older than 80 being fatal within 6 months. Fractures may occur many years after onset of the disease. The underlying pathophysiology in postmenopausal women is increased osteoclastic activity associated

with a normal rate of bone formation. Dual-energy x-ray absorptiometry is currently the most accurate test for measurement of bone density, although 25% of bone needs to be lost before osteoporosis can be detected by routine examination. Markers of bone resorption, such as urinary excretion of collagen degradation products, are of limited use in the diagnosis of osteoporosis.

The most rapid phase of bone mass accrual occurs during puberty into the mid-20s. Bone mineral density may continue to improve until women reach their mid-30s, when peak bone mass is reached. After menopause, bone density decreases by 1% to 2% per year, more rapidly in trabecular than in cortical bone, with 25% of white and Asian women experiencing vertebral compression fractures by age 60 years if not taking hormone replacement. Risk factors include family history, race (white, Asian), body type, sedentary lifestyle, dietary calcium deficiencies, and tobacco use. Notably, these risk factors only identify 30% of women with osteoporosis.

Although weight-bearing exercise is important for overall health, exercise alone does not prevent postmenopausal bone loss. Recommendations from the National Institutes of Health (NIH) consensus panel of 1994 include that postmenopausal women take 1000 to 1500 mg of calcium per day along with vitamin D, 400 to 800 IU. Current data suggest that this level is too high and that calcium supplementation is necessary only for those women ingesting less than 500 mg per day if they are taking estrogen replacement therapy. NIH recommendations remain in place at this time.

Estrogen replacement appears to retard bone resorption. Estrogen and progesterone receptors have been identified in osteoblasts. Decreased postmenopausal bone loss and a decreased incidence of hip and spine fracture have been reported. The minimum estrogen dose observed to prevent bone loss was 0.625 mg of conjugated equine estrogens, 0.5 mg of esterified estrogens, or 0.3 mg of conjugated equine estrogen in the presence of 1500 mg of calcium each day, or 0.05 mg of transdermal estrogen. The addition of progestins to hormone replacement regimens does not appear to attenuate this bone-protective effect.

When hormone replacement is not an option, bisphosphonates such as alendronate and risedronate are available to decrease bone resorption and reduce fracture incidence. Calcitonin through nasal spray is also available for osteoporosis treatment and has been shown to increase vertebral bone mass. Finally, the selective estrogen receptor modulator (SERM) raloxifene has been shown to increase vertebral bone mass, although data available at this time do not demonstrate protective effects against hip fracture.

Optimum Treatment

Hormone Replacement Therapy

The importance of preventative measures has risen to new prominence since the publication of the Women's Health

Initiative Randomized Controlled Trial. Such measures include balanced diet, multivitamin and calcium supplementation, and regular exercise. In some circumstances, selective serotonin reuptake inhibitors (SSRIs) may play a role in symptom relief, particularly relief from the estrogen deficiency symptom of hot flashes. Hormone replacement therapy (HRT) with either estrogen alone in those women who have undergone hysterectomy or with estrogen-progestin combination in women with an intact uterus continues to play a central role in postmenopausal medical management. HRT remains extremely effective for relief of estrogen deficiency symptoms such as hot flashes and for relief of symptoms of urogenital atrophy such as vaginal dryness, dyspareunia, and urinary frequency. HRT regimens are numerous. In the United States, continuous and cyclical regimens are most commonly used. The continuous regimen uses conjugated equine estrogen, 0.625 mg, and medroxyprogesterone acetate, 2.5 mg, given daily. The cyclical regimen uses 0.625 mg of conjugated equine estrogen given on days 1 to 25 and 5 mg of medroxyprogesterone acetate given on days 14 to 25. On the continuous regimen, women frequently have some degree of irregular spotting for up to 3 months after initiating therapy. On the cyclical regimen, most women demonstrate withdrawal bleeding.

Avoiding Treatment Errors

The area of most potential concern for patients and physicians is estrogen replacement therapy, and it is important to elicit a history of potential complications. Contraindications to estrogen replacement therapy include unexplained vaginal bleeding, the presence of breast or endometrial cancer, active liver disease, and active thrombophlebitis.

Future Directions

Postmenopausal health is affecting an ever-increasing number of women in the United States, and preventative health care is, at long last, becoming a focus for women and health care providers alike. The health benefits of hormone replacement have been outlined; however, concerns remain regarding breast cancer risks, particularly in long-term users. The Women's Health Initiative Randomized Controlled Trial has provided some insight into this problem. The development and longer-term use of agents such as the SERMs may also provide preventative health advantages without the potential adverse effects on endometrium and breast. Evidence-based medicine will continue to provide guidance in efforts to optimize the health care of postmenopausal women.

Erectile Dysfunction

Introduction

Erectile dysfunction (ED) is the inability to achieve or maintain an erection adequate for sexual intercourse. Based on extrapolated data from the Massachusetts Male Aging Study, ED affects some 20 to 30 million American men, most of whom are older than 50 years. This epidemiologic study of a homogeneous suburban Boston community surveyed 1709 men and reported that 52% of men aged 40 to 70 years had ED: 10% of the total sample had complete ED, 25% moderate, and 17% minimal. The prevalence of ED increases with age, with moderate and complete ED increasing most markedly. The percentages of ED were increased substantially in men with risk factors including cardiac disease, antihypertensive and vasoactive drug use, obesity, and tobacco use.

Physiology of Erections

Sexual stimulation causes release of the neurotransmitter nitric oxide (NO) from nerve endings in the corpus cavernosum, in turn increasing blood flow to the corpora cavernosa (Fig. 120-1). NO production results in relaxation of the corpus cavernosum smooth muscle tissue. The venous structures beneath the tunica albuginea are compressed, inhibiting venous outflow and producing a rigid erection. In the penis, NO is available from nitrergic nerve and endothelial cells. By stimulating the guanylate cyclase system and increasing cyclic guanosine monophosphate (cGMP), NO causes an efflux of calcium from the smooth muscle cell, producing relaxation. cGMP is broken down by the enzyme phosphodiesterase (PDE). The predominant PDE type in corpus cavernosum is type 5 (PDE5). The PDE5 inhibitors (PDE5i) such as sildenafil, tadalafil, and vardenafil, prolong the presence of cGMP and facilitate the relaxation of corpus cavernosum smooth muscle.

Etiology and Pathogenesis

ED has both organic and psychogenic etiologies, with 60% of patients having organic ED caused by vasculogenic, neurogenic, hormonal, or smooth muscle abnormalities (Fig. 120-2). Fewer than 40% of patients have pure psychogenic ED. The etiology of psychogenic ED remains controversial. Stress, anxiety disorders, and depression produce an overactivity of α agonists in the corpus cavernosum smooth muscle tissue, and this imbalance of α stimulation may inhibit smooth muscle relaxation.

nosum smooth muscle tissue, and this imbalance of α stimulation may inhibit smooth muscle relaxation.

Clinical Presentation

Risk Factors

Risk factors for ED include systemic diseases that produce vascular abnormalities, including hyperlipidemia, diabetes mellitus, the effects of hypertension and antihypertensive therapy, and atherosclerosis.

Neurogenic ED is seen with multiple sclerosis, diabetes mellitus, and paraplegia, and following radical pelvic surgery or radiation for pelvic malignancy such as prostate, colon, or bladder cancer.

Hormonal abnormalities and hypogonadism are also risk factors for ED, producing not only central nervous system abnormalities and low libido but also local changes in corpus cavernosum smooth muscle relaxation.

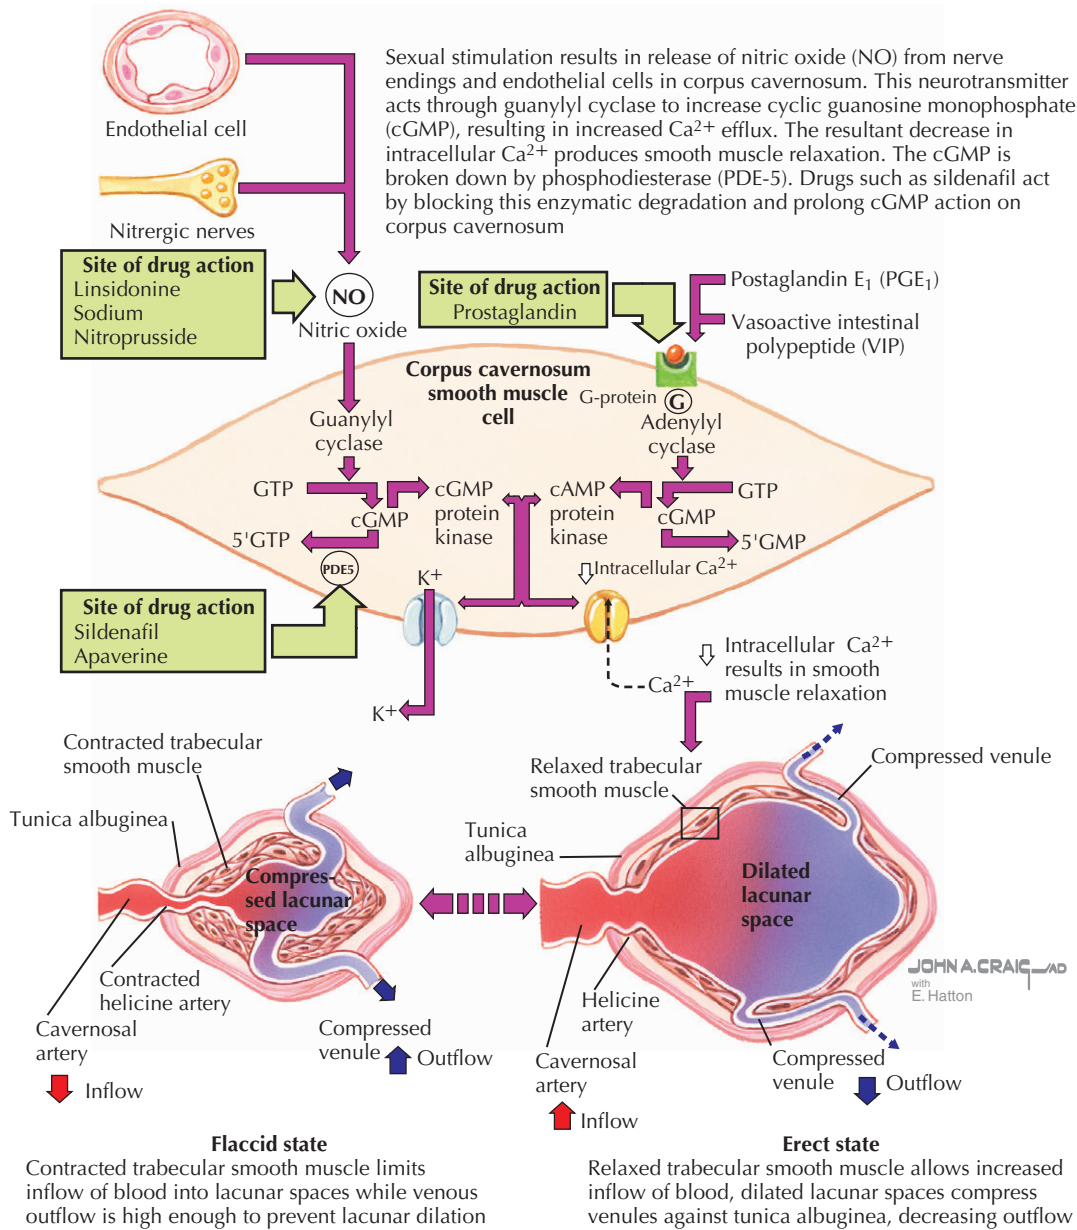

Psychologic causes are significant, and ED is frequently associated with depression, even of mild degree. Treatment of depression using selective serotonin reuptake inhibitors (SSRIs) further enhances ED by decreasing and delaying ejaculatory function.

Evaluation

A careful general and sexual history is the cornerstone in the evaluation and treatment of patients with ED. History

Figure 120-1 Cellular Mechanisms of Penile Smooth Muscle Relaxation.

cAMP, cyclic adenosine monophosphate; GTP, guanosine 5'-triphosphate.

should include information regarding age of onset, associated lifestyle changes at onset, speed of onset, and the presence or absence of erections with other partners, during masturbation, and at night and in the early morning. Patients should be asked about ejaculatory function, postejaculatory pain, and ejaculatory volume. Careful questioning regarding decreased libido may suggest a hormonal cause but more often is associated with clinical depression. Because ED is highly associated with lower urinary tract symptoms, patients should be asked about voiding symptoms.

Patients who present with organic ED most often have a gradual onset beginning with intermittent loss of erec-

tions, decreased duration, and difficulty with maintaining erections until ejaculation. History is the most proficient method of identifying patients complaining of premature ejaculation who may also present for evaluation of ED.

Psychogenic ED most often begins with abrupt onset precipitated by psychological abnormalities such as depression, anxiety disorder, changes in lifestyle, or relationship problems. These men usually have preserved nocturnal and morning erections and may be functional with masturbation. Patients with organic ED also have secondary psychological ED. Patients with pure loss of libido or with other symptoms of androgen deficiency of the aging male can be identified by a hormone profile.

Figure 120-2 Etiology and Pathogenesis of Erectile Dysfunction.

Physical Examination

The physical examination is focused on secondary sex characteristics, hair distribution, and genitalia. Evaluation of peripheral pulses, neurologic reflexes such as the bulbocavernosus reflex, and anal sphincter tone may help to identify some patients with peripheral neuropathy from nerve injury or diabetes. Changes in testicular size and consistency may be associated with primary hypogonadism. General physical examination of blood pressure, lower

extremity reflexes and pulses, and visual fields (to evaluate pituitary tumors) may suggest underlying systemic causes for ED.

Differential Diagnosis

A careful history and laboratory studies are most important in the differential diagnosis. Differentiation of ejaculatory dysfunction and other nonerectile sexual dysfunction is

imperative in recommending the best treatment. Many men complain of premature ejaculation (PE) as ED. Because the treatment for PE is an SSRI antidepressant, these must be differentiated. Androgen deficiency should also be excluded by history and a morning testosterone measurement. In couples with significant relationship issues, sexual counseling should be encouraged.

Diagnostic Approach

Because ED may be the first symptom of diabetes, hypercholesterolemia, hypertension, or other systemic disease, it is important to evaluate patients thoroughly for each of these disorders. A hormone profile should include a morning total testosterone. If the total testosterone is abnormal, a follow-up repeat total testosterone, free testosterone, luteinizing hormone, and prolactin may identify patients with androgen deficiency, pituitary tumors, or other causes of hypogonadism. Testosterone is typically low and prolactin high in patients who have pituitary tumors or chronic renal failure on hemodialysis. A lipid profile, hemoglobin A1C, and other general medical studies may be helpful.

For patients requiring additional investigation before surgical reconstruction or vascular bypass, specialized investigation such as Doppler penile blood flow studies following injection of vasoactive agents, nocturnal penile tumescence monitoring studies, and pelvic angiography may be helpful. Candidates for vascular bypass are usually young men with solitary pelvic artery lesions and a strong history of perineal or pelvic trauma. Vascular bypass surgery in older patients is rarely successful, especially if ED is associated with hypercholesterolemia, diabetes, hypertension, or smoking.

Nocturnal penile tumescence monitoring studies may be helpful in differentiating organic and psychogenic ED in some patients.

Management and Therapy

Initial treatment should focus on modifying medication and lifestyle abnormalities. Smoking cessation, managing diabetes, hypercholesterolemia, and hypertension may improve erectile function and facilitate medical treatment.

Modifying antihypertensive medications to include erection-hospitable agents such as α blockers, angiotensin-converting enzyme inhibitors, and calcium channel blockers may maintain antihypertensive therapy with restoration of erectile function. Patients with low testosterone levels should receive injectable or topical testosterone supplements.

If depression or relationship issues are a significant problem, sexual counseling may be helpful in addition to pharmacologic treatment. Office counseling with patient

and partner may facilitate understanding of the probable causes of erectile dysfunction, treatment alternatives, and expectations.

Optimum Treatment

First-Line Therapy

Oral agents such as sildenafil, tadalafil, and vardenafil are now established as first-line treatment of ED. These selective PDE5i agents facilitate cGMP concentration, duration, and subsequent corpus cavernosal smooth muscle relaxation. There is improvement in erectile function 30 to 60 minutes following ingestion of a PDE5i. The most popular starting dose is 50 mg sildenafil or 10 mg of vardenafil or tadalafil, although most patients respond best to 100 mg or 20 mg, respectively. As many as eight trials may be required for full success and effectiveness. Side effects include headache, dyspepsia, facial flushing, myalgias, and blue vision. PDE5i drugs have been reported to be significantly better in producing erections than placebo in patients with diabetes mellitus, spinal cord injury, hypercholesterolemia, depression, or cardiac disease, following radical prostatectomy, and in psychogenic erectile dysfunction. Although PDE5i drugs are effective in virtually all etiologies and severities of ED, they are least effective in patients with severe vascular disease. PDE5i agents are generally extremely safe; however, they do have additive effects with nitrate agents used for coronary artery disease, producing severe transient hypotension. For this reason, the use of PDE5i agents with nitrate drugs is contraindicated. In patients taking sildenafil after radical prostatectomy, results are best after a bilateral nerve-sparing radical prostatectomy. PDE5i treatment following non-nerve-sparing prostatectomy or pelvic radiation therapy is often unsuccessful.

Second-Line Therapy

Additional therapeutic alternatives are available if oral agents fail to improve erectile function. Intracavernosal pharmacotherapy is most effective in producing physiologic erections. This therapy can be carried out with prostaglandin E₁ (PGE₁) or a combination of papaverine and phentolamine. PGE₁ can be administered by intracavernosal injection or transurethral pellet.

Transurethral PGE₁ is available in 250-, 500-, or 1000- μ g doses. Its effectiveness is about 30% in large clinical studies. A small applicator with a pellet of PGE₁ is placed in the urethra. After the pellet is deposited and the applicator removed, the patient stimulates the urethra to allow PGE₁ to enter the corpus cavernosum. Erection usually occurs in 10 to 15 minutes and is maintained for as long as 40 minutes. Rarely, side effects include prolonged erection or priapism, and significant penile pain, aching, and urethral burning can occur. Although this agent is an excellent addition to use of penile prostheses

for further engorgement, its success in patients with ED of significant organic etiology has been disappointing.

Intracavernosal injection of PGE₁ has been widely used for more than two decades. It appears to be safe, although penile aching and occasional prolonged erections do occur. Initial dose of PGE₁ varies from 2.5 to 5 µg. Patients with significant vasculogenic ED require higher starting and maintenance doses. After an initial in-office titration to a dose that produces a firm erection satisfactory for sexual intercourse that lasts no longer than 60 minutes, many men may require at-home dose adjustment. If erections last more than 4 hours, patients should be advised to go to the emergency room for treatment using an α agonist such as intracavernosal phenylephrine or aspiration therapy. Although this complication is rare, early treatment will preserve future erectile function. If intracavernosal PGE₁ is ineffective or produces excessive pain, a combination of papaverine with or without phentolamine and PGE₁ may produce satisfactory erectile function with less penile discomfort. Side effects from this combination include prolonged erections and priapism, corpus cavernosum fibrosis, and occasional transient hypotension.

In addition to prolonged erections and priapism, side effects from PGE₁, as well as papaverine and phentolamine, include penile pain. This complication is most marked with PGE₁ and occurs in about 20% of injections. Patients may also observe hematoma, edema, and occasional corpus cavernosum fibrosis (<5%). Despite initial success rates in excess of 70%, few patients continue injection therapy for more than 3 to 4 years. The reasons for discontinuation include mental anxiety, inadequate erections, penile pain, and poor patient and partner satisfaction.

Avoiding Treatment Errors

Treatment errors include prescribing PDE5 inhibitors for PE because PE is best treated with SSRI agents. Also, many patients in whom PDE5 is unsuccessful require education about use of these drugs and may have improved response with normalization of decreased testosterone levels. PDE5 drugs are contraindicated in men using nitrate medications and in those with cardiovascular status that precludes moderate exercise tolerance.

Devices for Treatment of Erectile Dysfunction

For many years, vacuum erection devices have been used to stimulate, facilitate, and prolong duration of erections. These external devices create a vacuum around the penis to produce engorgement and tumescence, maintained by a constrictive ring placed at the base of the penis. Although the erections that ensue are less natural, they are satisfactory for vaginal penetration and sexual intercourse. The

constriction devices may produce penile pain, bruising, scarring, and Peyronie's disease. They may also inhibit ejaculations. Although the cost is low, patient satisfaction is limited. Counseling and careful instruction before initiating use can increase patient satisfaction.

Implantation of penile prostheses is a successful, important method for restoring erectile function in severe ED and for reconstructing the penis of patients with significant Peyronie's disease or priapism. These surgically implanted devices are most often of the inflatable variety and consist of two hollow cylinders placed in the corpora cavernosa of the penis and connected to a small pump device placed in the scrotum. Fluid (normal saline) is supplied by a reservoir placed beneath the rectus muscles. Patients can feel and compress the pump device in the scrotum, fill the cylinders of the corpora cavernosa, and maintain an erection of normal sensation and rigidity throughout sexual intercourse. The device can then be deflated for concealment with excellent cosmetic results. The longevity of these devices is quite satisfactory, with 93% of devices functional at 3 years, 86% at 5 years, and 76% at 10 years after implantation. Mechanical malfunction is treated with device replacement. Patient and partner satisfaction has been reported in excess of 90%.

Androgen Replacement Therapy

In patients with androgen deficiency of the aging male or hypogonadism, testosterone replacement is necessary to enhance libido and facilitate other medical treatment. Testosterone replacement therapy is carried out using long-acting injectable agents, such as testosterone enanthate or cypionate, 200 mg every 2 to 3 weeks, and topical testosterone patches or gel. Topical treatment is more physiologic, with high testosterone levels in the morning and low in the evening, similar to the testosterone levels of young, sexually active males. Similarly, testosterone metabolites estradiol and dihydrotestosterone are maintained best with the topical preparations. The goal of testosterone replacement therapy is to restore testosterone levels to the normal physiologic range. The use of testosterone in eugonadal men with psychogenic erectile dysfunction, while raising testosterone beyond normal levels, is both ineffective and associated with significant potential complications. Testosterone supplementation can be associated with activation of carcinoma of the prostate, increased hematocrit and lipid levels, and increased benign prostatic hyperplasia. Patients treated with testosterone supplementation should be carefully evaluated twice yearly with digital rectal examination, prostate-specific antigen, lipid profile, and hematocrit. For patients with chronic renal failure or macroprolactinomas, normalization of prolactin before testosterone treatment is critical. Use of agents such as bromocriptine or cabergoline, in addition to testosterone replacement, will produce the best subsequent results.

Future Directions

The treatment of ED was revolutionized by the introduction of sildenafil in 1998. Newer agents are being investigated and will provide additional methods of treatment for patients with ED. Central nervous system-acting agents will be available for stimulating erections. The first of these agents, apomorphine SL (sublingual), is currently approved and in use in Europe, whereas the melanotropin agonist PT-141 is undergoing clinical trials. These agents, which stimulate dopamine receptors in the erectile center of the midbrain, have been demonstrated in clinical trials to be effective in producing erectile function. Side effects include nausea, vomiting, and syncope in small numbers of patients with predominate first-dose effect. Treatment of PE with the on-demand serotonin reuptake inhibitor dapoxetine has shown great promise in clinical trials.

Active research is underway to evaluate the feasibility and effectiveness of gene therapy for ED. Gene therapy to restore NO synthase concentrations, endothelial cell function, and potassium channel function in the corpus cavernosum smooth muscle appears, in animal models, to be an excellent method for restoring erectile function lost through diabetes, hypercholesterolemia, and other causes of vascular disease. This mode of therapy may provide a long-term solution for many patients with vasculogenic ED.

Despite the strides made in pharmacologic treatment, many patients will still require surgical reconstruction using penile prostheses. The currently available penile implant and prostheses have been modified and improved during the past 25 years to provide safe, reliable reconstruction for penile abnormalities and ED with low expected complications and morbidity and high patient satisfaction. Newer antibiotic-coated devices have reduced infection risks to less than 1%.

Disorders of Consciousness

Introduction

Consciousness is the state of being alert, aware, and responsive by thought and physical action to internal and external stimuli. Disorders of consciousness disrupt the level of consciousness, the content of consciousness, or both. More commonly, patients present with depressed levels of consciousness. This chapter focuses on the initial evaluation and treatment of patients presenting acutely with altered levels of consciousness. The etiologies of altered consciousness are varied, and great care must be taken to rapidly identify and treat acute causes, especially those that are potentially life-threatening.

Etiology and Pathogenesis

Anatomically, consciousness is the result of reciprocal interactions of ascending and descending systems. The reticular activating system (RAS) is a collection of nuclei and tracts originating in the medulla and projecting to the thalamus, and subsequent projections from the thalamus ascend to the cortex. Regions of the cortex send descending projections back to the thalamus in a feedback fashion. Arousal is generally attributed to the circuits of the RAS. Awareness is attributed to activity in the higher cortical centers. Impairments of either or both of the ascending and descending systems result in alterations of consciousness. Such impairments may be the result of focal or multifocal structural lesions that injure or compress vital areas of the brain or brainstem, or they may be the result of global neuronal dysfunction resulting from generalized medical disorders.

Clinical Presentation

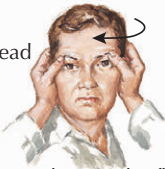

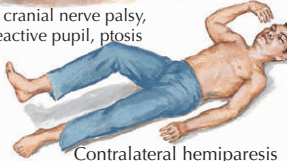

Patients with disorders of consciousness present with variable degrees of disturbance of both the level and content of consciousness. Disturbances of the level of consciousness are characterized by impaired arousal and wakefulness. Such disturbances may be transient, resolving within

seconds to minutes, or prolonged, lasting hours or much longer. Most disturbances of arousal make complete assessment of content of consciousness difficult. However, certain conditions disrupt content without altering the level of consciousness. The various dementias are conditions that may present in such a fashion. Lesions of the hippocampus may also present with isolated memory loss, and dominant hemisphere strokes may present with isolated aphasia.

Patients with altered levels of consciousness vary in the degree of response to stimuli. *Coma* is the most severe degree of depressed consciousness, and patients in coma are unresponsive and unarousable. Patients who are disoriented, sleepy, or inattentive are often described as *confused*, *clouded*, or *lethargic*. *Delirium* is used to describe patients with depressed consciousness and signs of elevated sympathetic tone, such as agitation, elevated heart rate and blood pressure, and hallucinations. *Obtunded* patients require repeated stimuli to maintain attention. *Stuporous* patients provide only minimal response to frequent or constant stimulation.

Other presenting features depend on the etiology of the alteration of consciousness. Patients may present with focal neurologic deficits, especially if the etiology is a structural lesion, and the nature and degree of these deficits depend on the location and size of the lesion or lesions

Figure 121-1 Differential Diagnosis of Altered Consciousness.

	Clinical features	Pathology (examples)	Etiologies
Bilateral cerebral hemisphere disease	 <p>Normal pupils (equal, reactive)</p>  <p>Normal doll's head phenomenon</p>  <p>Normal corneal reflex</p> <p>Absent or minor focal features (lateral paralysis, sensory or visual loss)</p>	 <p>Bilateral hemispheric swelling (small ventricles, obliterated sulci, rounded edges)</p>	<p>Increased intracranial pressure</p> <p>Meningitis</p> <p>Subarachnoid hemorrhage</p> <p>Metabolic disorders</p> <p>Electrolyte disturbances</p> <p>Endocrine disorders</p> <p>Organ dysfunction</p> <p>Nutritional deficiencies</p> <p>Drugs or toxins</p> <p>Alcohol and other sedatives</p> <p>Opiates and anticholinergics</p> <p>Cholinergics</p> <p>Sympathomimetics</p> <p>Multifocal cerebral disease</p> <p>Infarctions</p> <p>Hypoxia</p> <p>Encephalitis</p> <p>Abscesses</p> <p>Tumors (usually metastatic)</p> <p>Contusions</p> <p>Vasculitis</p> <p>Autoimmune disorders</p>
Unilateral cerebral hemisphere lesion with compression of brainstem	 <p>Third cranial nerve palsy, nonreactive pupil, ptosis</p>  <p>Contralateral hemiparesis</p>	 <p>Right temporal hemorrhage from trauma, with swelling of right hemisphere</p>	<p>Cerebral</p> <p>Infarction</p> <p>Hemorrhage</p> <p>Contusion</p> <p>Abscess</p> <p>Tumor</p> <p>Extracerebral</p> <p>Subdural hematoma</p> <p>Epidural hematoma</p>
Primary brainstem lesion	 <p>Small pinpoint pupils, absent horizontal eye movements</p>  <p>Rigid limbs</p>	 <p>Large pontine hemorrhage</p>	<p>Infarction</p> <p>Hemorrhage</p> <p>Severe metabolic derangements</p> <p>Central pontine myelinolysis</p> <p>Anoxia</p>
Cerebellar lesion with secondary brainstem compression	 <p>Vomiting</p>  <p>Ataxic movements</p>  <p>Sixth cranial nerve palsy</p>	 <p>Large cerebellar hemorrhage</p>	<p>Infarction</p> <p>Hemorrhage</p> <p>Tumor</p> <p>Abscess</p> <p>Contusion</p> <p><i>F. Netter M.D.</i></p>

(Fig. 121-1). Patients with generalized disorders may also present with focal signs. Isolated cranial nerve deficits can occur in patients with meningitis. Patients in postictal states may manifest transient weakness (Todd's paralysis).

Headache is a common symptom, especially when there is elevated intracranial pressure (ICP) or meningeal irritation. Patients with elevated ICP sometimes complain of visual disturbances and have papilledema or oculomotor abnormalities on examination. Elevated muscle tone is

another association. Cases of subarachnoid hemorrhage (SAH), meningitis, and meningoencephalitis may present with meningismus.

Signs of brainstem compression develop in patients with uncal herniation, brainstem lesions, and large cerebellar lesions. Depending on the severity of the compression, patients may have asymmetric pupils, a unilateral fixed and dilated ("blown") pupil, or bilateral fixed and dilated pupils. A third nerve palsy, hemiparesis, and flexor (decorticate) or extensor (decerebrate) responses to painful stimulation

are other possible findings. The examiner should observe carefully for abnormal respiratory patterns (e.g., Cheyne-Stokes respirations, hyperventilation, and apneustic breathing). Patients presenting with evidence of brainstem compression require rapid confirmation of the diagnosis and treatment.

In cases of severe brain injury, patients may present with minimal clinical neurologic function on examination. In situations in which the proximate cause is known and demonstrably irreversible and when coma, absence of brainstem reflexes, and apnea are present, the condition is referred to as *brain death*. In the United States and many other countries, this condition is a legal form of death.

Differential Diagnosis

The causes of altered consciousness are numerous and varied (see Fig. 121-1). Conceptually, causes are often separated into structural lesions and generalized disorders. Structural lesions are divided into traumatic lesions and nontraumatic lesions and can be further divided by location: supratentorial (cerebral hemispheres), brainstem, and cerebellar. Epidural hematomas, subdural hematomas, contusions, and shear injuries occur secondary to trauma. Nontraumatic causes include ischemic strokes, intraparenchymal and intraventricular hemorrhages, SAH, tumors, and abscesses.

A large number of generalized disorders lead to altered consciousness: metabolic disorders, drug intoxication and withdrawal, hypoxia, central nervous system infections, sepsis, autoimmune diseases, hematologic disorders, diffuse vascular disorders (e.g., vasculitis), and seizure disorders (e.g., nonconvulsive status epilepticus and postictal states). Common metabolic causes to consider are electrolyte disturbances (hyponatremia, hypocalcemia, and hypercalcemia), endocrine disorders (hypoglycemia, hyperglycemia, diabetic ketoacidosis, hypothyroidism, hyperthyroidism, hypoadrenalism, and hyperadrenalism), organ dysfunction (uremia and hepatic encephalopathy), and nutritional deficiencies (Wernicke's encephalopathy). Drugs commonly associated with altered mental status include alcohol and other sedatives, opiates, cholinergics, anticholinergics, and sympathomimetics; however, many other drug associations have been reported. Meningitis is associated with many etiologies: bacteria, tuberculosis, syphilis, fungi, viruses, and metastases. Viruses, including herpes simplex virus (HSV), are also commonly associated with encephalitis.

Conditions Often Mistaken for Coma

In locked-in states, patients are fully alert and aware but have disrupted efferent pathways, leading to minimal motor output. Bilateral pontine infarcts resulting from basilar artery occlusion, pontine tumors, pontine hemorrhages, central pontine myelinolysis, brainstem encephalitis, severe myasthenia gravis, and severe acute inflammatory

demyelinating polyneuropathy may present in this fashion.

Patients with akinetic mutism have preserved consciousness and retain the ability to move and speak but lack any initiative to respond to the environment. They often have brain lesions that disrupt reticular-cortical and limbic-cortical integration but spare corticospinal pathways. Abulia is a milder form of this condition.

Catatonia is often associated with psychiatric illnesses but may also be seen with metabolic derangements and drug intoxication. Patients may appear unresponsive to stimuli but will otherwise have a normal neurologic exam. Patients usually lie with their eyes open and may not blink to visual threat, but optokinetic responses are normal. Waxy flexibility of limbs is common, and features of catalepsy, such as rigid limbs and fixed postures, may be seen.

Psychogenic coma is a dissociative psychiatric disorder. Patients often have active resistance to passive opening of the eyelids, and eyelids may flutter when the eyelashes are stroked gently. Motor examination is often inconsistent and may reveal active resistance when examining tone or cogwheeling resistance with sudden "giving away." The patient may occasionally make voluntary movements or change body position in bed. Signs based on reflex self-protection may be seen, as when a hand held above the face drops to the side instead of hitting the face.

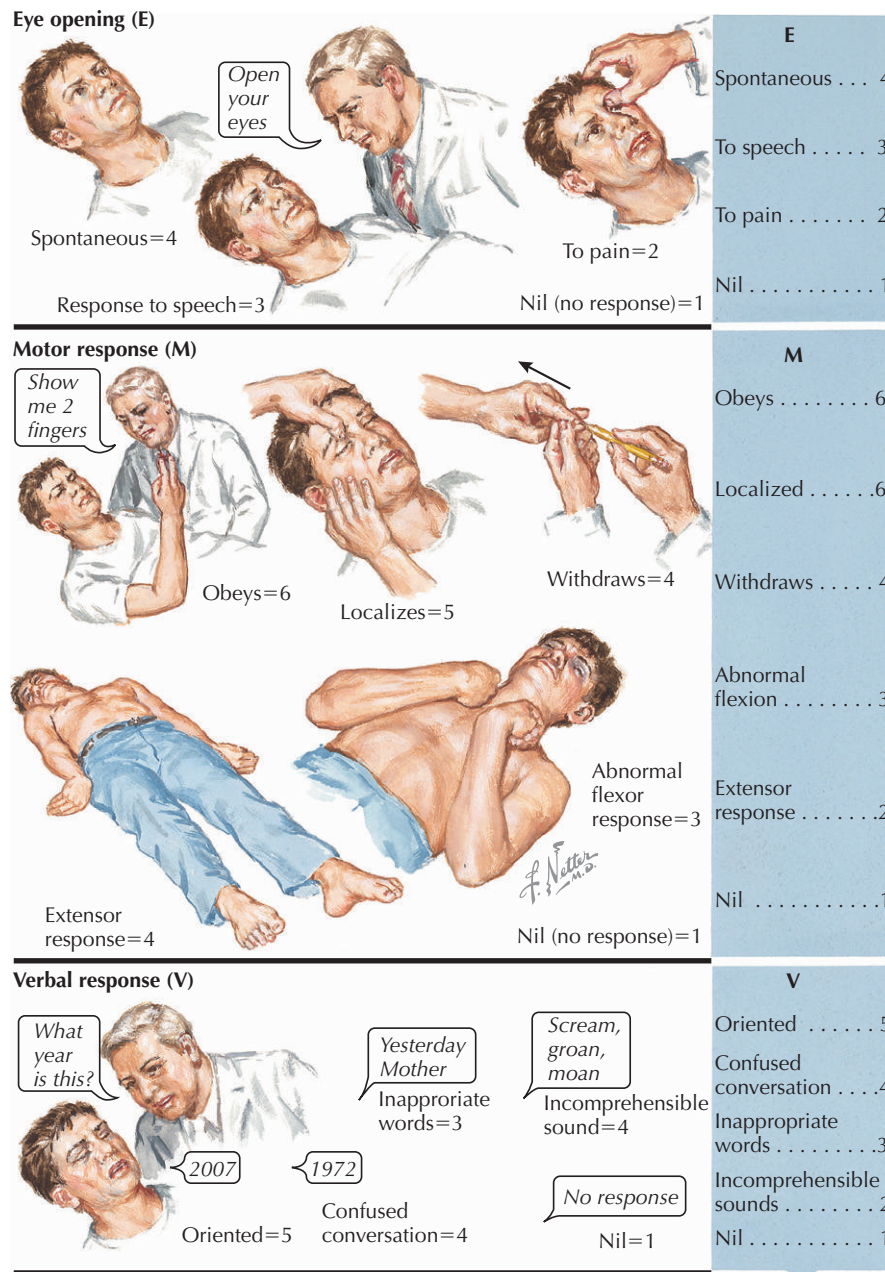

Diagnostic Approach

Acute alterations of consciousness should be approached as medical emergencies because the worst-case situations are generally life-threatening. An expedited medical history and physical should focus initially on excluding life-threatening conditions.

Because most patients with altered consciousness are unable to provide a detailed history, it is important to obtain information from available witnesses, family members, and emergency medical personnel. It is important to obtain information regarding details of the presenting event (e.g., Was there trauma? Did the patient have a seizure? Were there any precedent complaints or prodromes?); past medical history (i.e., diabetes, liver disease, renal failure, neurologic disorder, or psychiatric disorder); and medications (i.e., prescription medications and drugs of abuse).

On general physical examination, abnormal vital signs provide useful diagnostic clues and identify parameters (e.g., hypotension, high fever, and arrhythmias) that require immediate treatment. In cases of severely elevated ICP, an increase in systemic blood pressure, with simultaneous reduction in heart rate and respiration, may be seen (Cushing's phenomenon). General examination should also include evaluation for signs of head trauma, such as periorbital ecchymoses ("raccoon eyes"), postauricular ecchymoses (Battle's sign), hemotympanum, and cerebro-

Figure 121-2 Glasgow Coma Scale.

Coma score (E + M + V) = 3 to 15

spinal fluid (CSF) otorrhea or rhinorrhea. The neck should be evaluated for signs of injury and meningismus. Skin should be examined for rash, purpura, cyanosis, jaundice, and needle marks. Presence of organomegaly or lymphadenopathy may provide further insights into causation.

Neurologic evaluation of any patient with altered consciousness should begin with a quick assessment of the degree of the disturbance. The revised Glasgow Coma Scale (GCS) is a clinical score that quantifies the level of consciousness by assessing three parameters: eye opening, motor response to verbal commands or noxious stimuli,

and verbal response (Fig. 121-2). Although the 15-point scale was originally developed as a prognostic tool for traumatic brain injury, it has proved useful as a reproducible measure of level of consciousness in all patients. For patients with any scored abnormality (GCS score <15), brain imaging and observation are recommended in the acute setting. A GCS score of less than 9 is indicative of coma, and patients should be evaluated promptly for airway management. Additionally, a thorough neurologic examination should be performed, with greatest attention directed toward detecting signs of brainstem compression.

Presence of focal neurologic findings may provide clues to causation and assist in determining what additional studies are needed for diagnosis.

Blood samples should be drawn for glucose, serum electrolytes (including calcium and magnesium), complete blood counts, renal function tests, liver profile, coagulation studies, cardiac enzymes, and drug screens. When infection is suspected, blood cultures should be drawn, and a lumbar puncture should be performed to obtain CSF for cell count, glucose, protein, Gram stain, cultures, and HSV polymerase chain reaction. Secondary blood tests such as arterial blood gas, thyroid function tests, blood smear, ammonia, syphilis testing, and anticonvulsant drug levels may be indicated by the patient's history and examination findings. An electrocardiogram should be obtained, and the patient should have continuous cardiac monitoring.

Emergent imaging of the brain is generally indicated when the cause is uncertain, and computed tomography (CT) is the preferred modality in the acute setting because many structural etiologies may be identified quickly with this modality. If ischemic stroke or SAH is suspected, CT angiography is useful for identifying vessel occlusion or aneurysm, respectively. Magnetic resonance imaging is better for visualizing pathology of the brainstem and cerebellum, demonstrating acute infarcts, and detecting diffuse injuries such as encephalitis, laminar necrosis of hypoxia and ischemia, and the shear injuries seen with trauma; however, logistical issues, such as longer acquisition times and limited availability of scanners and specialists needed to interpret the images, often make use of this modality difficult in the acute setting.

An electroencephalogram (EEG) should be performed whenever seizures or status epilepticus is part of the differential diagnosis. EEG is also helpful in the diagnosis of toxic or metabolic encephalopathy, sedative overdose, and HSV encephalitis. EEG may be used to differentiate coma from locked-in states, psychogenic coma, and catatonia.

Management and Therapy

Optimum Treatment

Treatment of the patient should occur concomitantly with the diagnostic evaluation and should begin with evaluation of airway patency, breathing, and circulation. Effective ventilation and oxygenation may require the use of supplemental oxygen, mask ventilation, or intubation. The cervical spine should be immobilized until injury can be excluded. Hypotension, cardiac ischemia, and arrhythmias necessitate aggressive therapy. Hyperthermia must also be addressed definitively.

The empiric administration of thiamine, naloxone, and glucose will cover the immediately reversible causes of altered consciousness. Thiamine should be administered before glucose to avoid exacerbation or precipitation of

Wernicke's encephalopathy, and if possible, a blood sample should be sent for a glucose level to avoid glucose administration in cases of hyperosmolar coma.

Sepsis and meningitis are always suspect in febrile patients with altered consciousness. Blood cultures should be drawn immediately, and broad-spectrum antibiotics and acyclovir (for the possibility of HSV infection) should be administered intravenously. Evaluation for possible central nervous system (CNS) infection requires a lumbar puncture, but this procedure is often deferred until after brain imaging to exclude mass lesions.

If signs of significantly elevated ICP or herniation are seen on initial presentation, empiric treatment should not be delayed to obtain brain imaging. Treatment should begin with elevation of the head. Hyperventilation should be initiated because reduction of PCO₂ to 30 to 35 mm Hg rapidly lowers ICP by 25% to 30% in most patients. In cases in which cerebral edema is the suspected cause of elevated ICP, intravenous mannitol is an effective therapy. In most instances, acute administration of steroids is not recommended. Once medical treatment has been initiated, emergent brain CT imaging is useful for determining what additional interventions are warranted.

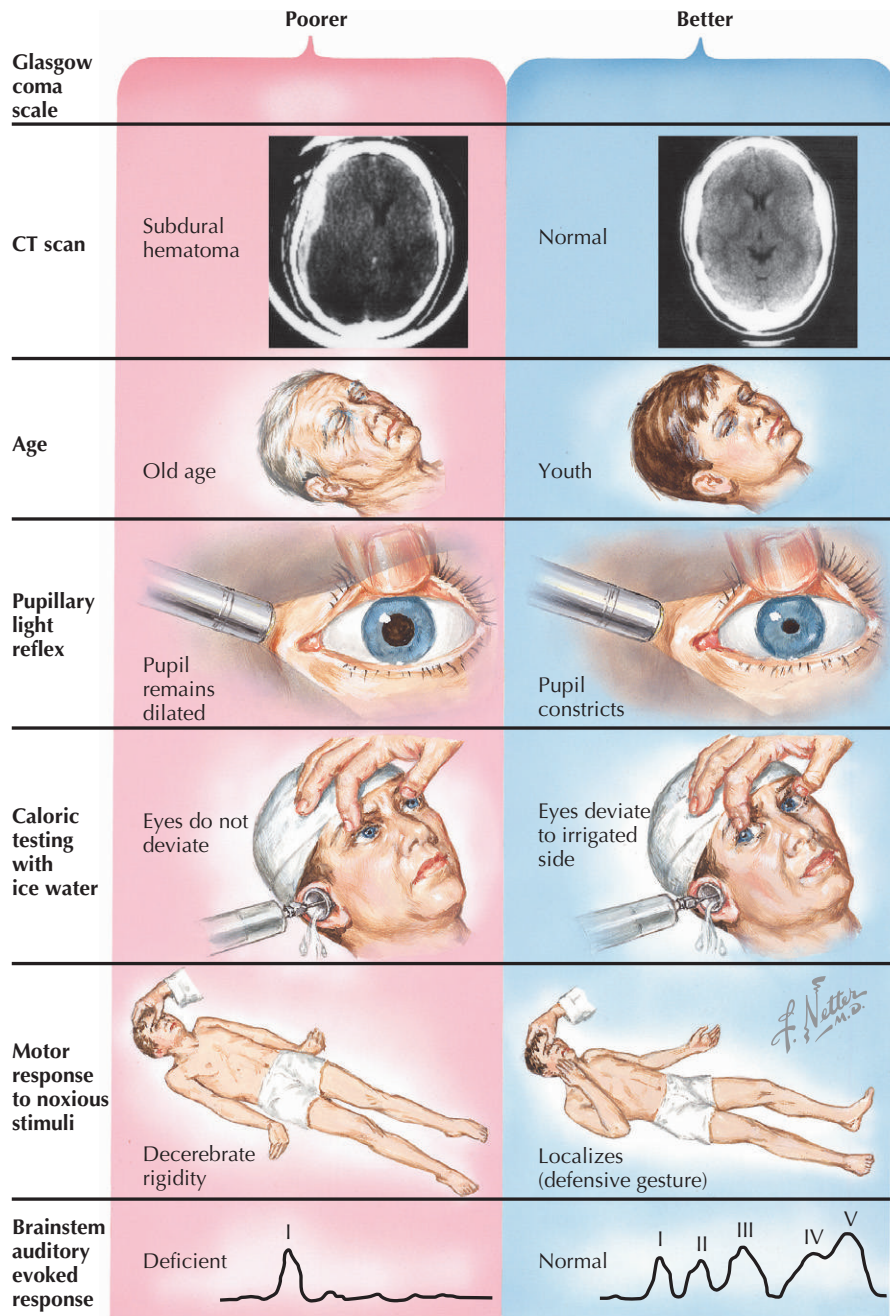

Other common interventions begun in the acute setting include placement of a urinary catheter and nasogastric tube. Arterial catheters and central venous access are useful in monitoring hemodynamic status. Invasive ICP monitors are helpful for patients who are at risk for elevated ICP but require sedatives that often make the neurologic exam difficult to follow.

Avoiding Treatment Errors

Delays in diagnosis and initiation of treatments are the most common and the most easily avoided errors. One should always keep in mind that even patients presenting with mild alterations in consciousness have the potential to deteriorate rapidly. Every patient should be evaluated emergently until life-threatening conditions have been excluded. The institution of critical care pathways for patients with depressed consciousness or coma facilitates rapid triage, evaluation, and treatment. Use of diagnostic algorithms may prevent omission of life-threatening conditions when generating the differential diagnosis.

Prognosis

In general, prognosis depends heavily on the degree of the disturbance and the underlying cause. Researchers have proposed various prognostic paradigms based on studies of patients with certain etiologies of coma. Paradigms and historical statistics exist for populations of patients with severe head trauma, nontraumatic coma, and hypoxic-ischemic coma. Although such studies provide a rough guide for clinicians, determining the prognosis for

Figure 121-3 Prognosis in Depressed Mental Status.

individual patients is much more difficult because other factors affect outcome and must be considered, including age and other comorbidities, severity of neurologic abnormalities on clinical exam, and findings on imaging or neurophysiologic testing (Fig. 121-3).

Patients presenting with low GCS score or with decreasing scores on subsequent examinations have a poorer prognosis. Most patients who are diagnosed with toxic or metabolic causes have a good likelihood of recovery, even if their neurologic illness is prolonged. Patients with

normal brain imaging have better outcomes than patients with identified lesions. Patients with focal lesions on imaging (e.g., subdural hematomas) generally do better than patients with diffuse abnormalities (e.g., shear injuries from trauma or injuries due to hypoxia-ischemia). On neurologic testing, pupillary defects, other brainstem findings (e.g., abnormal cold water caloric testing), and abnormal posturing are associated with poorer prognosis. Abnormalities on EEG and evoked potentials are also associated with a lower likelihood of recovery.

Future Directions

Therapeutic hypothermia as a neuroprotective means to reduce injury has been studied in patients with stroke, traumatic brain injury, and hypoxia-ischemia. The most promising results have been seen in studies of patients who have been resuscitated after cardiac arrest. However, application of this technology has been limited to centers with neurointensive specialists, for the most part.

Neuroprotective agents have also been studied in ischemic stroke. Unfortunately, most attempts at limiting the extent of neuronal injury with these agents have been disappointing. Attempts to use neuroprotective agents for treatment of traumatic brain injury are in early stages of development and testing.

Radiculopathies: Cervical, Lumbar, Spinal Stenosis

Introduction

Neck and low back pain are common symptoms leading patients to seek medical attention in the United States each year, with significant disability, loss of work, and medical expense. The estimated medical costs for patients with low back pain exceed \$8 billion annually by some estimates. Up to 80% of the population will have at least one episode of low back pain during their lives. Radiculopathy, or disease of the spinal nerve roots, is a major cause for neck and low back pain, and may be due to a variety of etiologies, most commonly degenerative disease of the spine. Spinal stenosis, or anatomical narrowing of the central spinal canal or neuroforamina through which exiting spinal nerves traverse, is caused by congenital or acquired disease of the spine and may result in radiculopathy or spinal cord compression. Spinal stenosis may occur in either the cervical or lumbosacral spinal regions, with lumbar stenosis being the most common.

Etiology and Pathogenesis

Spinal Anatomy

Spinal nerves are formed by the joining of the dorsal and ventral nerve roots at the level of the intervertebral foramina of the spine, which are formed lateral to the central spinal canal, as the facet joints of adjacent vertebrae are joined together. There are 31 pairs of spinal nerves (8 cervical, 12 thoracic, 5 lumbar, 5 sacral, 1 coccygeal), each named according to the corresponding vertebral level at which it originates. However, the relationship between individual spinal nerves and the corresponding vertebrae changes depending on the level of the spinal cord being considered. In the cervical spine, spinal nerve roots exit at a level cephalad to the corresponding vertebra (C5 root exits between the C4 and C5 vertebrae); however, the C8 root exits between C7 vertebra and T1 vertebrae, with subsequent roots exiting caudad to the vertebra for which the root is named (i.e., T1 root exits between T1 and T2 vertebrae). The spinal nerve immediately divides into dorsal and ventral primary rami or branches, with the ventral primary rami joining in the brachial and lumbosacral plexus at the appropriate levels to form the peripheral nerves innervating the limbs and in the trunk forming segmental innervation to the trunk muscles and cutaneous

structures. Cutaneous dermatomal innervation can be mapped according to this segmental innervation pattern based on the formation of the spinal nerve roots. The spinal cord itself ends typically at the L1-L2 vertebral level, and because of the differential growth of the spinal column relative to the spinal cord, the intrathecal lengths of spinal nerve roots progressively increase from cervical to lumbosacral levels. Above the C4 vertebral level, the spinal roots exit the spinal cord segment of their origin and enter the intervertebral foramen at a level basically perpendicular to the spinal cord level of origin; below C4, the distance from the spinal cord segment of origin and the intervertebral foramen of exit gradually increases, and below the L1 vertebral level, the nerve roots that exit at caudal intervertebral foramina extend for the greatest intrathecal distance and are together known as the cauda equina (Fig. 122-1).

Pathogenesis of Radiculopathy and Spinal Stenosis

Radiculopathy means injury or pathology affecting an individual spinal nerve or root and may involve any spinal nerve root, although certain nerve roots are more commonly involved clinically (Fig. 122-2). Pathophysiologic

Figure 122-1 Spinal Nerves and Sensory Dermatomes.

mechanisms include inflammation or immune-mediated mechanisms, ischemia, tumor, or mechanical compression due to altered spinal anatomy (either congenital or acquired), the latter being most commonly seen. Congenital alterations in spinal column anatomy include congenital spinal stenosis. Acquired changes in the vertebral anatomy that may lead to spinal nerve root compression and a clinical radiculopathy include protrusion or herniation of intervertebral disks; spondylosis or degenerative changes in the facet joints between vertebrae; hypertrophy of ligaments such as the ligamentum flavum, which is present posteriorly within the spinal canal; and spondylolisthesis, or slippage of adjacent vertebrae relative to each other due to degeneration of the intervertebral disk between them and loss of spine mobility due to chronic mechanical stress.

The vertebral level of the herniated or protruded disk has implications in terms of which spinal root may be compressed and the neurologic symptoms and signs that result. For example, a herniated disk between C4 and C5 vertebrae most likely will affect the C5 root at that level; likewise, because of the normal anatomic changes described previously, a herniated disk in the lumbar spine, at L4-L5 will affect the L5 nerve root because the L4 root exits cephalad to that disk level. Also, depending on whether the protruding disk is central or lateral in location within the spinal canal, other nerve roots may become involved, particularly in the lower lumbar spine with the cauda equina, because the nerve roots at this level have an intrathecal course close together, such that a large disk protrusion can affect up to three or more roots. Ultimately, with progres-

Figure 122-2 Spinal Nerve Origin: Cross Sections.

sive encroachment by disease of the structural elements of the vertebral column into the central spinal canal or the lateral recesses leading into the intervertebral foramen, polyradiculopathy and spinal stenosis may develop and lead to neurologic compromise and symptoms. Spinal stenosis implies abnormal narrowing of the anatomical spaces where the neural elements are present.

Clinical Presentation

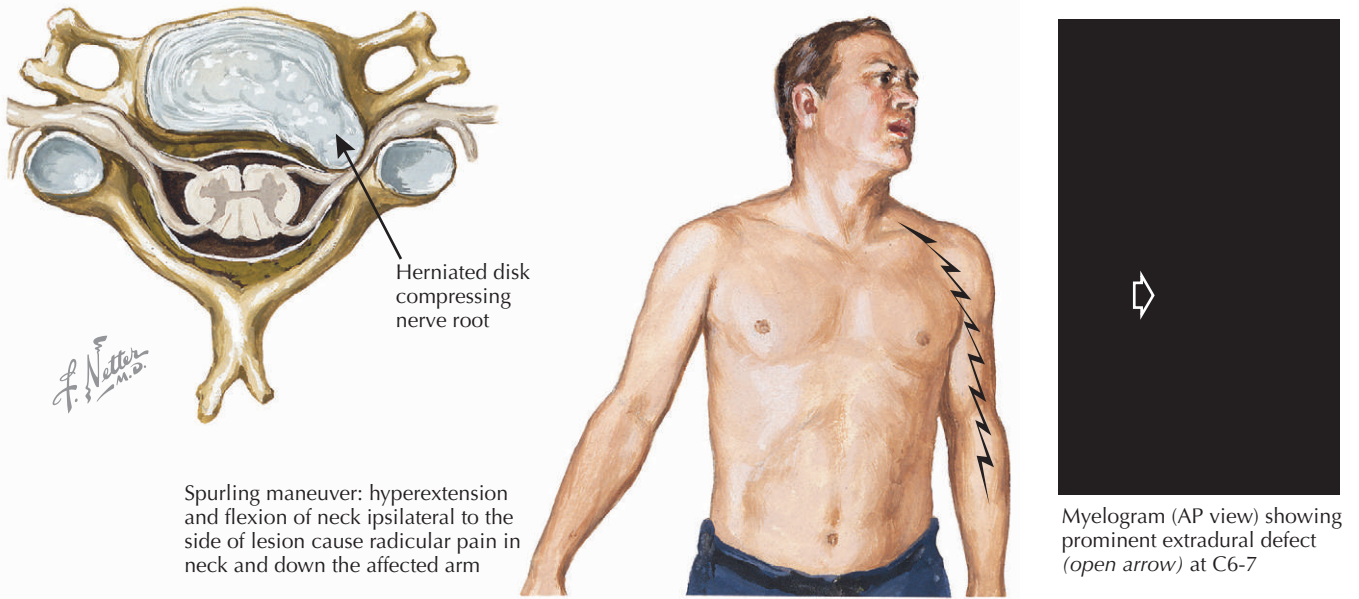

Radiculopathy

Cervical

Cervical radiculopathy most commonly involves the middle to lower cervical roots, from C5 to C8, usually due to

intervertebral disk herniation. Clinical manifestations of cervical radiculopathy include neck pain with radiation into the posterior shoulder or arm in a dermatomal pattern, numbness and weakness, and associated loss of deep tendon reflexes in the affected upper limb. Radiating pain into the limb may be triggered or worsened by movement of the head, neck, or limb itself, or by Valsalva maneuvers during coughing, sneezing, or straining. The muscle weakness and sensory loss may follow a myotomal or dermatomal pattern, but it also may be difficult to discern on routine clinical examination because of the overlapping pattern of innervation of muscles by individual nerve roots. Weakness of the proximal shoulder girdle and the abductors of the shoulder, with radiating pain into the posterior scapular region and lateral shoulder with associated paresthesias,

Figure 122-3 Cervical Disk Herniation: Clinical Manifestations.

Spurling maneuver: hyperextension and flexion of neck ipsilateral to the side of lesion cause radicular pain in neck and down the affected arm

Myelogram (AP view) showing prominent extradural defect (open arrow) at C6-7

Level	Motor signs (weakness)	Reflex signs	Sensory loss
C5	Deltoid	0	
C6	Biceps brachii	Biceps brachii Weak or absent reflex	
C7	Triceps brachii	Triceps brachii Weak or absent reflex	
C8	Interossei	0	

suggests C5 radiculopathy. C6 radiculopathy presents as weakness of the biceps and other forearm flexors with radiating pain into the lateral forearm to the thumb. Weakness of the triceps and extensors of the fingers, with pain and tingling paresthesias radiating into the second and third digits, suggests C7 radiculopathy. Weakness of the intrinsic hand muscles and painful paresthesias in the medial forearm and fourth and fifth digits indicates C8, T1

radiculopathy. Asymmetrically diminished biceps and brachioradialis reflexes point to C6 root lesion, and a triceps reflex abnormality suggests C7 pathology (Fig. 122-3).

Lumbar

Lumbar radiculopathy predominantly involves lower lumbar segments, including L4 and L5, with upper roots being much less commonly affected clinically by such processes

as disk herniation leading to single-level radiculopathy. Clinically, patients may have acute low back pain with radiation into the buttocks and posterior hip and into the posterolateral thigh and leg into the foot. Lumbar radicular pain is typically worse with flexion of the lumbar spine and relieved with lying down (lumbar extension). L5 radiculopathy presents with painful sensory symptoms in the dorsomedial foot to the great toe and associated muscle weakness involving ankle dorsiflexion, inversion and eversion, and extension of the toes, particularly of the great toe. L4 radiculopathy may involve weakness of knee extension and pain and tingling in the anteromedial thigh and medial leg into the medial foot. Upper lumbar radiculopathies (L1, L2, L3) may present with low back pain radiating into the anterior thigh and inguinal or groin regions, with muscle weakness of hip flexion and hip adduction. Sacral radiculopathy, specifically S1 radiculopathy, is frequently associated with L5 root lesions, and also presents with low back pain radiating into the posterior thigh and leg and distally into the lateral and plantar foot regions. Weakness with S1 radiculopathy involves plantar flexion of the ankle and toes, as well as hip extension and knee flexion. Deep tendon reflexes affected include the knee jerk or patellar response with L4 radiculopathy and the ankle jerk or Achilles reflex with S1 radiculopathy. Straight-leg-raise maneuvers, with the patient in the supine position with passive flexion of the leg at the hip to between 30 and 70 degrees above the horizontal, may be helpful in confirming intraspinal pathology involving lower lumbar nerve roots if the maneuver leads to radiating pain into the lower extremity. Straight-leg-raise testing with the patient in a prone position, with reproduction of radicular pain into the anterior thigh, is more useful for diagnosis of upper lumbar radiculopathies.

Spinal Stenosis

Cervical

Cervical spinal stenosis is most commonly due to spondylosis, in which degenerative facet joint changes with osteophyte formation, degenerative disk disease with protrusion, and ligamentous hypertrophy combine to narrow the spinal canal and lateral recesses leading to the intervertebral foramina. Stenosis in the cervical spine may lead to multilevel cervical radiculopathies and, if severe, may also cause cervical myelopathy, or compression of the cervical spinal cord itself. The midsagittal cervical canal diameter is normally 18 to 21 mm, with the spinal cord itself measuring 7 to 11 mm in diameter. Significant narrowing or stenosis of the diameter of the spinal canal (12 mm in diameter or less) may lead to intermittent compression of the spinal cord with subsequent damage to the neural parenchyma. These changes are typically degenerative or acquired in nature but may be accelerated in patients with congenitally stenotic spinal canals. If myelopathy occurs,

the clinical presentation may include upper motor neuron signs such as spasticity in addition to muscle weakness, hyperactive deep tendon reflexes with ankle clonus, and upgoing toes with plantar stimulation. These changes may involve both upper and lower extremities and may also lead to bowel and bladder dysfunction, including urinary retention and incontinence. Sensory changes may include not only those related to multiple cervical radiculopathies but also loss of vibratory and joint position sense in the distal lower extremities, as the myelopathy progresses (Fig. 122-4).

Lumbar

Lumbar spinal stenosis involves most commonly the lower lumbar spinal levels, and its incidence increases in patients older than 60 years. The most common cause is progressive degenerative spine disease with encroachment of the central spinal canal and resultant multiple lumbosacral radiculopathies. An important clinical feature of these patients is that they report worsening back and leg pain with extension of the spine, so that they experience pain with upright posture and ambulation, so-called neurogenic claudication or pseudoclaudication, to distinguish the syndrome from vascular claudication. If the patient's leg pain is due to a neurogenic lesion such as that observed in lumbar spinal stenosis, the leg pain is relieved with sitting and not with standing alone, as may occur with vascular claudication due to arterial insufficiency in the lower limbs. Patients may also note that the pain is worse when they lie down in a supine position at night, but improves if they lie in a lateral decubitus position with their knees flexed, which reduces the spinal stenosis and nerve root compression within the spinal canal. Patients with lumbar spinal stenosis may demonstrate a wide-based, antalgic gait with stooped posture and positive Romberg's sign.

A specific entity known as cauda equina syndrome occurs with compression of lumbosacral nerve roots within the spinal canal leading to bowel and bladder dysfunction. This is a rare condition (occurs in about 2% of cases of herniated lumbar disks) but requires immediate medical attention and treatment. Clinically, it may present with a gradual worsening over time of the chronic symptoms of lumbar spinal stenosis or, more typically, presents as an acute change in bowel or bladder function superimposed on a preceding history of symptoms of lumbar spinal stenosis. The latter clinical presentation is presumably due to an acute intervertebral disk herniation superimposed on lumbar spinal stenosis causing more severe narrowing of the spinal canal and compression of the sacral nerve roots. The earliest bladder symptom is usually urinary retention, which progresses to bladder incontinence. Patients with cauda equina syndrome also report altered sensation or anesthesia in the perineal or groin region (saddle anesthesia), corresponding to the lower sacral nerve roots being involved pathologically. Their leg pain and sensory symptoms, as well as motor weakness, may be asymmetric.

Differential Diagnosis

The differential diagnosis of cervical or lumbosacral radiculopathies includes peripheral neuropathy or multiple mononeuropathies of the limbs, which may also present with pain, sensory and motor symptoms, and signs. Peripheral neuropathy includes distal polyneuropathy as well as polyradiculopathies that may result from a wide range of underlying acquired etiologies, such as inflammatory or immune-mediated, nutritional, diabetes, toxins, infectious causes, or tumor or cancer related. Radiculopathy related to malignancy may be due to tumor metastasis to the vertebral structures leading to nerve root compression or infiltration, or due to conditions in which the primary lesion is cancer infiltrating the nerve roots directly, such as may occur with lymphoma or carcinomatous meningitis.

Cancer should be strongly considered as the underlying cause of the patient's symptoms in patients who have unremitting back pain that is not relieved at night or with change in body position and in those who do not respond to conservative therapy after 6 to 8 weeks, particularly patients with a history of cancer that is known to metastasize to the spine (breast, prostate, lung, colon, melanoma, multiple myeloma). Likewise, in patients with back pain unresponsive to conservative therapy who have fever, elevated erythrocyte sedimentation rate, and white blood cell count, infectious causes for their symptoms, such as osteomyelitis of the spine or epidural spinal abscess, should be considered strongly. The differential diagnosis of cervical spondylotic myelopathy includes motor neuron disease, multiple sclerosis, syrinx, spinal cord tumor, or vascular malformation leading to cord compression.

Diagnostic Approach

Obtaining a detailed history regarding the onset and type of symptoms, triggering and relieving factors, and progression of symptoms since onset, is the most important initial first step in diagnosis. History of trauma, previous spinal injuries or surgeries, and other medical conditions such as diabetes or cancer may also be helpful. A careful neurologic examination, with particular focus on the neuromuscular examination, is the next step in localization of the underlying process that is causing the patient's symptoms. This will include testing muscle strength and tone, deep tendon reflexes, sensory examination with specific effort to demonstrate dermatomal loss of sensation to various modalities, gait testing including Romberg testing, and mechanical tests of range of motion of the trunk at the hip, palpation of the spine, and inspection of the spine for scoliosis or other osseous deformities.

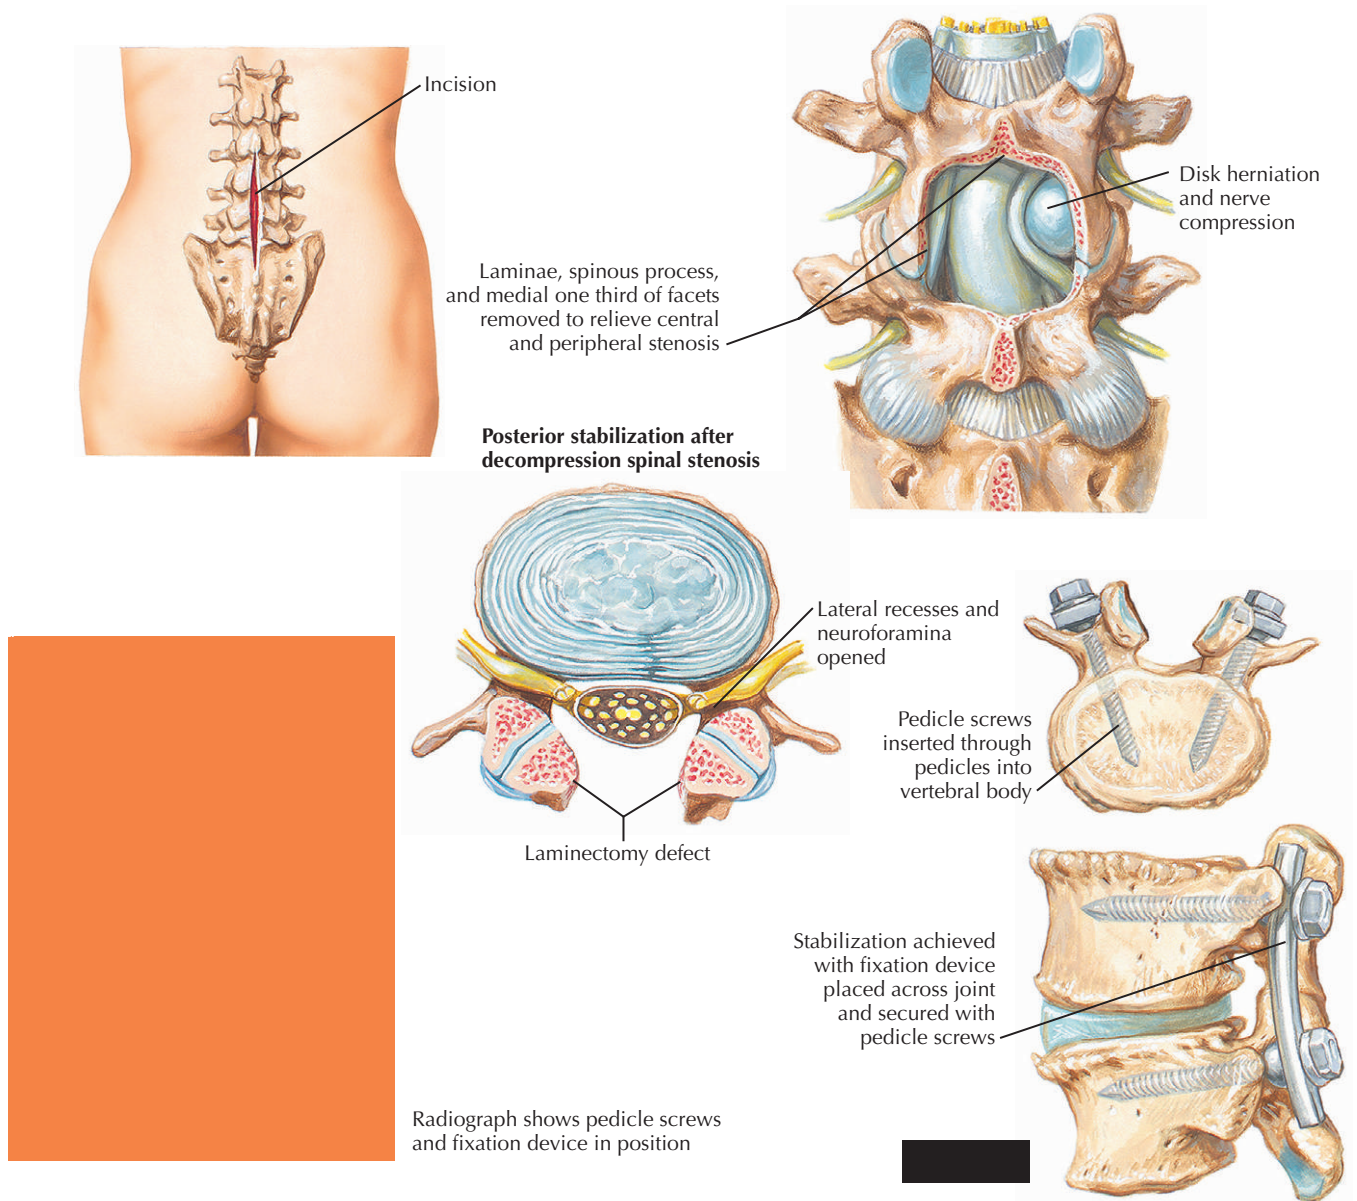

After an isolated nerve root lesion or radiculopathy or multiple nerve root lesions (e.g., due to spinal stenosis) is suspected, additional laboratory testing and imaging studies should be ordered depending on the examiner's judgment regarding the underlying cause of the condition. Electrodiagnostic testing, specifically nerve conduction studies and electromyography, can be used to confirm the presence of a radiculopathy and exclude other potential diagnoses such as peripheral neuropathy or mononeuropathies, localize the segmental root levels involved, and provide information regarding the chronicity of the lesion and whether active denervation and reinnervation are present. In patients in whom multiple pathologies may be present, such as a diabetic patient with radiculopathy superimposed on an underlying peripheral neuropathy, or in patients with symptoms but limited objective findings on neurologic examination, electrodiagnostic testing can be particularly useful. Blood tests, including complete blood count and erythrocyte sedimentation rate, should be done immediately in patients with a suspected infectious process causing their radiculopathy, such as those with history of recent fever, other systemic infections, immunosuppression, or localized tenderness to palpation over spinous processes associated with acute or subacute onset of back or neck pain. In patients with a history of cancer, unexplained weight loss, or unremitting back pain unresponsive to conservative measures, neuroimaging with magnetic resonance imaging (MRI) of the involved spinal region is important, with contrast administration if possible. Additional testing may include cerebrospinal fluid examination in patients with a question of leptomeningeal metastasis (cerebrospinal fluid cytology) or infection (cell count and cultures). Patients with a history of recent trauma before the onset of the symptoms should undergo plain x-ray imaging, including anteroposterior and lateral views, as well as flexion and extension views of the spine. Plain x-rays are of limited value in the patient with spinal pain without a history of trauma; however, it should be remem-

bered that in elderly patients with a history of osteoporosis, minimal or unsuspected trauma may lead to vertebral fracture. For those patients in whom degenerative spine disease is present, who have progressive or severe symptoms and neurologic deficits despite a reasonable course of conservative therapy, MRI and possibly computed tomographic myelography should be considered. However, because many abnormalities found on imaging studies are nonspecific and can also be found in asymptomatic individuals, any results should be taken in the clinical context of the patient's history, physical examination, and electrodiagnostic test results. For those patients with possible cauda equina syndrome, neuroimaging with MRI should be done on an emergent basis because confirmation of this condition and institution of early treatment are important in terms of clinical outcome.

Management and Therapy

Optimum Treatment

The management options in patients with radiculopathy and spinal stenosis range from conservative therapy with physical therapy, analgesics, epidural steroid injections, and intermittent rest and limitation of physical activities that may aggravate the symptoms to spinal surgery for decompression. The natural history of radiculopathy is in part dependent on the cause of the nerve root lesion. In patients with infection or malignancy as a cause for the radiculopathy, aggressive treatment with antibiotics and possibly surgical drainage of a spinal abscess for the former, and surgery and possibly chemotherapy or radiation therapy for the latter, are indicated. For patients with degenerative spine disease as a cause for their radiculopathy or in patients with multilevel radiculopathies due to spinal stenosis, the optimal treatment is less clear, except for those patients with severe disease, in which case surgical intervention seems most reasonable because there appears to be a clinical benefit early after surgery (Fig. 122-5). Certainly, in patients with cauda equina syndrome, surgical intervention within 48 hours of onset of symptoms has been shown to result in better clinical outcomes compared with surgery after 48 hours. However, in patients with mild or moderate radiculopathy or spinal stenosis, the natural history appears to be that of stable or slowly progressive disease, in which case surgical treatment is controversial and has been shown to be of limited benefit in the short-term only in patients with moderate to severe spinal stenosis, for example. Most authors would agree that in most patients with mild or moderate disease, a period of conservative therapy of a minimum of 6 to 8 weeks to determine whether the patient's symptoms are persistent or progressive would be advisable. Additionally, the patient's preferences and confounding medical conditions in terms of being a surgical candidate should always be taken into consideration in decision making in regard to

Figure 122-5 Surgical Management of Spinal Stenosis.

surgical intervention. Patients who develop signs of cervical myelopathy due to cervical spondylosis or canal stenosis should undergo surgical intervention to prevent further spinal cord damage.

Avoiding Treatment Errors

The most important management decisions regarding patients with possible radiculopathy or spinal stenosis are to evaluate the patient for potential “red flags” that would change dramatically the recommendations for the patient’s treatment. These include symptoms and signs of possible infection or cancer, myelopathy, or cauda equina syn-

drome. These conditions, as causes of radiculopathy or as a consequence of spinal stenosis, require further evaluation and intervention as soon as possible. The risks of delay of evaluation and treatment are paraplegia and permanent incontinence. Currently available medical literature does not provide clear guidelines as to the relative benefit of surgical versus conservative therapy for radiculopathy or spinal stenosis that is mild or moderate because confounding factors exist such as nonspecific MRI abnormalities and the natural history of the disease, which may favor conservative therapy. According to the literature available currently, there does not seem to be a disadvantage to delaying surgical intervention in patients without red flags.

Future Directions

Improving the accuracy of the diagnosis of radiculopathy and spinal stenosis and determining optimal treatment protocols by means of prospective, blinded, randomized clinical trials are what is needed in the future to improve evaluation and treatment for patients with these conditions. Advances in imaging techniques, such as the ability to perform MRIs in patients in an upright position or posture that may be functionally significant for their disease process, will be helpful and are hopefully forthcoming. Likewise, expansion of currently available electrophysiologic testing, to include possibly magnetic nerve root stimulation, will also aid in diagnosis and localization of pathology. Increased understanding of the natural history of these diseases, relative risks and benefits of various surgical and conservative therapies, and predictors of outcome measures will help clinicians in the future make more informed recommendations to their patients about how to treat their condition.

Peripheral Neuropathy

Introduction

Peripheral neuropathy is a condition that results from abnormalities in the structure and function of motor, sensory, or autonomic neurons or their peripheral processes. Neuropathies can be broadly classified into disorders that primarily affect myelin sheaths (demyelinating), those that affect the axonal process (axonopathies), and those that affect the neuronal cell body (neuronopathies or ganglionopathies). There are numerous hereditary and acquired causes of peripheral neuropathy within each subgroup. Neuropathies can also be classified based on their etiology and encompass those secondary to hereditary, toxic-metabolic, traumatic, entrapment, and systemic disease causes.

Etiology and Pathogenesis

The causes of neuropathy are diverse, and numerous pathogenic mechanisms exist. For both diagnostic and therapeutic purposes, neuropathies are usually categorized as either acquired or hereditary in origin.

There are many potential causes for acquired neuropathies. These include (1) metabolic disorders (e.g., critical illness polyneuropathy, diabetes mellitus, uremia, vitamin B₁₂ deficiency, hypothyroidism) (Fig. 123-1); (2) toxic exposures (e.g., heavy metals, industrial toxins) (Fig. 123-2); (3) infectious causes (e.g., leprosy, herpes zoster, HIV disease, West Nile virus, hepatitis C); (4) pharmaceutical agents (e.g., vinca alkaloids, ddC, ddI, pyridoxine, amiodarone, cisplatin, allopurinol); (5) vasculitic and connective tissue disorders (e.g., lupus; rheumatoid arthritis; non-systemic vasculitis affecting peripheral nerve; Sjögren's syndrome); (6) immune system aberrations (e.g., Landry-Guillain-Barré syndrome [GBS], chronic inflammatory demyelinating polyradiculoneuropathy [CIDP], brachial plexitis [Parsonage-Turner syndrome], neurosarcoidosis, amyloidosis); (7) underlying malignancy (e.g., paraproteinemias, lymphoma, a variety of solid cell tumors with paraneoplastic neuropathy); and (8) compressive-entrapment mononeuropathies (e.g., carpal tunnel and cubital tunnel syndromes, peroneal nerve compression at the fibular head).

Hereditary neuropathies are less common. Autosomal dominant, recessive, and X-linked inheritances have all been described. In some instances, the neuropathy is the

major feature of the illness (e.g., Charcot-Marie-Tooth [CMT] disease or hereditary motor and sensory neuropathy). In other hereditary diseases, the neuropathy is only one manifestation of a more widespread disorder (e.g., metachromatic leukodystrophy, adrenoleukodystrophy, Fabry's disease, Refsum's disease).

Autonomic neuropathies are a special category in that they may also result from acquired (diabetes mellitus, Sjögren's syndrome, autoimmune autonomic neuropathy) or inherited (hereditary sensory and autonomic neuropathy [HSAN]) causes, which may or may not be associated with involvement of the somatic nervous system.

Clinical Presentation

The prototypical peripheral neuropathy is a distal, symmetrical process affecting motor and sensory nerves that produces a stocking more than glove distribution of sensory disturbance and muscle weakness. The clinical presentations of neuropathy are varied but often follow characteristic patterns of nerve involvement and fall under the broad categories of motor weakness, sensory disturbance, and autonomic dysfunction. The pattern of nerve involvement may be distal and symmetrical, proximal, or asymmetrical (Fig. 123-3).

The predominant motor symptom is muscle weakness and muscle atrophy, frequently with fasciculations. The pattern of distribution and severity depends on the cause of the neuropathy. Symptoms of weakness typically begin

Figure 123-1 Peripheral Neuropathies: Metabolic, Toxic, and Nutritional.

distally with foot drop, which may cause the patient to trip, particularly when walking on uneven terrain, across door thresholds, or on rugs. There may be difficulties with fine motor movements of the fingers such as opening jars and manipulating small objects. More proximal motor nerve involvement often presents with trouble climbing up and down stairs or performance of motor tasks requiring the arms to be raised over the patient's head, such as combing the hair or reaching for objects from a high shelf.

Sensory symptoms can be quite varied. Positive symptoms include tingling, paresthesias (pins and needles),

neuropathic pain, and dysesthesias (unpleasant painful or uncomfortable symptoms). These symptoms may also include burning pains, especially in the feet or hands, or sharp, shooting, electrical shock-type pains in affected limbs. Negative symptoms include numbness or loss of sensation.

Autonomic dysfunction may present with subtle symptoms such as dry eyes or dry mouth, change in sweating, vasomotor skin changes, bowel and bladder dysfunction such as alternating diarrhea and constipation or incontinence, and erectile dysfunction, or more commonly with

Figure 123-2 Peripheral Neuropathy Caused by Heavy-Metal Poisoning.

History of nausea and vomiting may suggest arsenic poisoning in patient with peripheral neuropathy

Antique copper utensils (e.g., still for bootleg liquor) and runoff waste from copper smelting plant may be sources of arsenic poisoning

Although 24-hour urinalysis is the best diagnostic test for arsenic, hair and nail analysis may also be helpful

Mees' lines on fingernails are characteristic of arsenic poisoning

symptoms of orthostatic intolerance or orthostatic hypotension leading to dizziness with standing and even syncope.

A distal symmetrical abnormality of motor and sensory function with associated diminution of muscle stretch reflexes is the most common pattern of involvement for a distal polyneuropathy. Weakness and muscle wasting predominate in the distal muscles of the hands and feet. Sensory loss follows the classic distal symmetrical (glove-stocking) distribution, and reflex loss follows a similar pattern. Other disorders have a proximal pattern of muscle weakness. GBS is the most well known, and it can be seen also in porphyric neuropathy or CIDP. Sensory loss is less

common in this pattern of abnormality, and the motor weakness is generally symmetric.

A predominant pattern of sensory involvement may occur with certain sensory neuropathies or ganglionopathies associated with occult malignancies, as in paraneoplastic syndrome, but may also be seen in diabetes, vitamin B₆ deficiency, leprosy, HIV, Sjögren's syndrome, and HSAN. Neuropathies that have motor involvement predominantly include GBS, multifocal motor neuropathy, diphtheria, and lead intoxication. Autonomic dysfunction is a feature of HSANs, diabetic polyneuropathy, amyloidosis, Sjögren's syndrome, and autoimmune autonomic neuropathy (Fig. 123-4). A multifocal pattern of

Figure 123-3 Signs and Symptoms Consistent with Neuropathy.

involvement may occur in mononeuritis multiplex that implies vasculitic or inflammatory and immune etiology, multiple entrapment mononeuropathies, hereditary neuropathy with liability to pressure palsy (HNPP), diabetic amyotrophy, or inherited brachial plexopathy (Fig. 123-5).

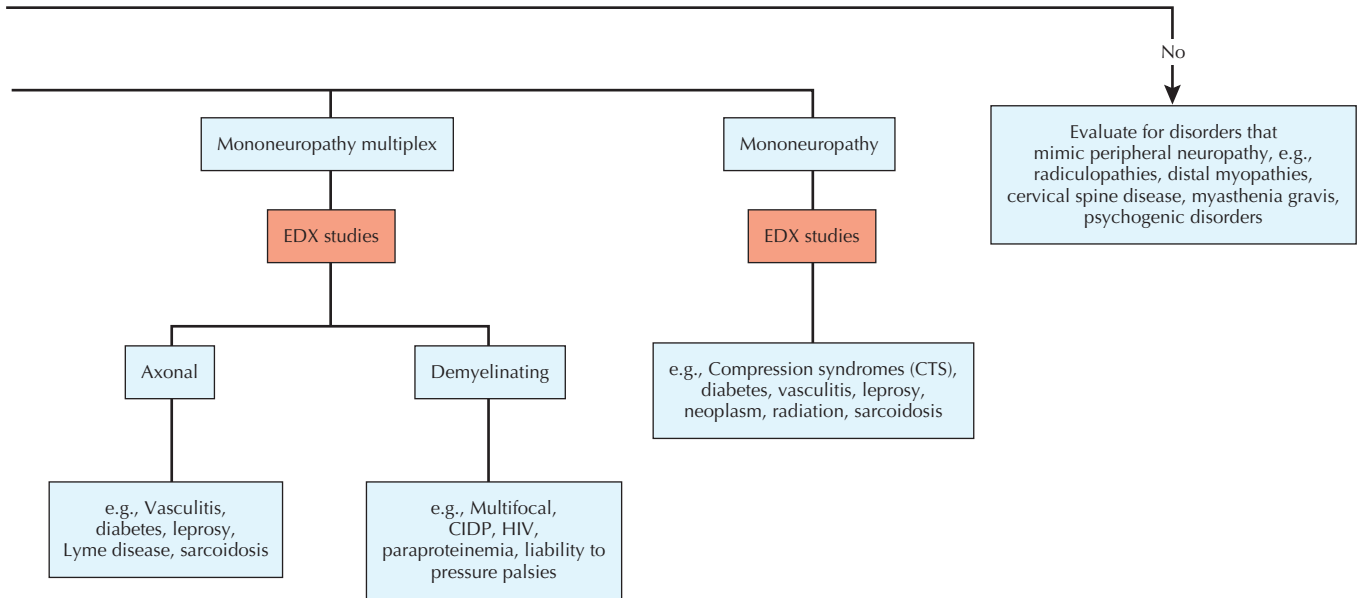

Some neuropathies progress very rapidly with a dramatic clinical course. These include GBS, vasculitic or ischemic neuropathies, and acute heavy metal intoxication (arsenic) typically. Rapidly evolving neuropathies may also follow acute compression resulting from hemorrhage (e.g., within the carpal tunnel or anterior compartment syndrome), direct trauma, or exposure to extreme cold. Subacute neuropathies, evolving over many days to a few weeks, are characteristic of chronic toxin or drug exposure, critical illness, Lyme disease, HIV, and nutritional disorders. A chronic time course is also typical of hereditary disorders, nutritional deficiencies, paraproteinemias, and some forms of inflammatory and HIV neuropathies.

Differential Diagnosis

The differential diagnosis is made easier once the neuropathy has been localized and characterized within the peripheral nervous system. This requires a carefully elicited history and a thorough neurologic examination to determine the pattern of nerve involvement, the population of

nerve fibers affected, and the portion of the nerve that is involved in the neuropathic process. The presence of sensory loss and diminished or absent muscle stretch reflexes is the sine qua non of peripheral nerve disease. A neuropathy of childhood onset and insidious progression is likely to be of genetic origin. Similar progression in late adult life suggests a paraproteinemic disorder, although an inherited process should always be considered. Acute or subacute demyelinating neuropathies suggest an inflammatory process. Marked disturbances of sensation suggest diabetes, heavy metal intoxication, pyridoxine or vitamin B₁₂ imbalance, paraneoplastic syndrome, or alcohol as the probable cause. Pure sensory neuropathies in an age-appropriate individual suggest a paraneoplastic disorder or connective tissue disease such as sicca or Sjögren's syndrome. A rapidly progressive painful sensory neuropathy with prominent autonomic features in an adult should raise the possibility of amyloidosis.

There are situations in which it may be difficult to distinguish primary sensory neuropathy from motor neuron diseases. For instance, spinal muscular atrophy, polio or postpolio syndrome, amyotrophic lateral sclerosis, and West Nile virus infection may be difficult to distinguish from axonal motor neuropathies. Likewise, diffuse motor polyradiculopathies due to cervical and lumbosacral spinal stenosis or degenerative disk disease with neuroforaminal

AIDP, acute inflammatory demyelinating polyneuropathy; CIDP, chronic inflammatory demyelinating polyneuropathy; CTS, carpal tunnel syndrome; EDX, electrodiagnostic; GBS, Guillain-Barré syndrome; HIV, human immunodeficiency virus; MLD, metachromatic leukodystrophy; RA, rheumatoid arthritis

stenosis may be difficult to distinguish from a motor neuropathy.

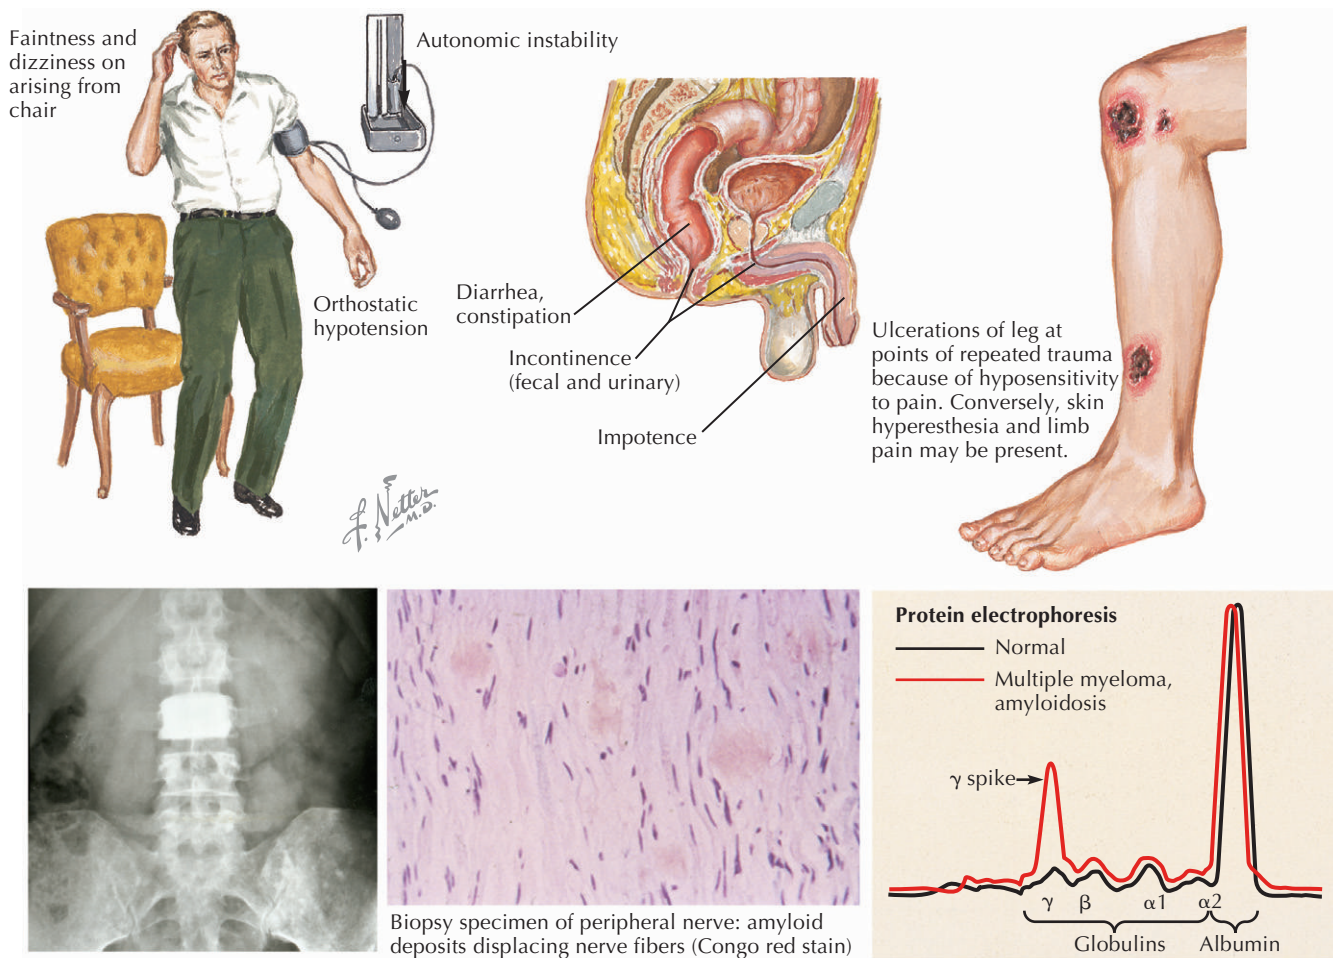

A careful history and electrodiagnostic and laboratory examination can help to differentiate these disorders. The initial presentation of a spinal cord syndrome may be confused for a sensory neuropathy because of the distal paresthesias. The presence of a definable truncal sensory limit and the presence of corticospinal tract involvement on careful examination can differentiate these entities. On rare occasions, isolated motor cranial neuropathies may be confused with myasthenia gravis. However, the tendency of the symptoms to worsen toward the end of the day in myasthenia gravis as well as electrodiagnostic and laboratory testing should aid in the proper diagnosis. Rarely, myopathies may present with a distal pattern of weakness. The preservation of muscle stretch reflexes, the absence of sensory abnormalities, and the typical laboratory (increased creatine kinase) and electrodiagnostic findings should clarify the problem. Autonomic neuropathies may be confused with primary cardiac disease as a cause for syncope or orthostatic intolerance. They may also be difficult to differentiate from central degenerative diseases of the autonomic nervous system, such as multisystem atrophy or Shy-Drager syndrome. However, careful history of autonomic symptoms and neurologic examina-

tion to detect central nervous system findings, as well as electrodiagnostic testing of autonomic nervous system reflex functioning, should allow for differentiation of these entities.

Diagnostic Approach

Nearly 75% of patients with neuropathic symptoms have a specific diagnosis if evaluated by physicians with experience in evaluation of patients with neuromuscular disease. Establishing a correct diagnosis is based on the optimal utilization of clinical, electrodiagnostic, and laboratory data. In some situations, pathologic examination of a peripheral nerve is necessary, or cerebrospinal fluid analysis is required.

The role of routine screening blood laboratory studies has not been established. The most useful studies include measurement of the vitamin B₁₂ level, serum protein electrophoresis with immunofixation, complete blood count with differential, renal function tests, and glycosylated hemoglobin. Other routine studies may be of benefit in carefully screened patients to confirm a diagnosis, for example, thyroid function studies, vitamin B₆ levels, Lyme titer, 24-hour urine heavy metals, and collagen vascular studies such as erythrocyte sedimentation rate, antinuclear

POEMS, polyneuropathy-organomegaly-endocrinopathy-monoclonal gammopathy, skin changes.

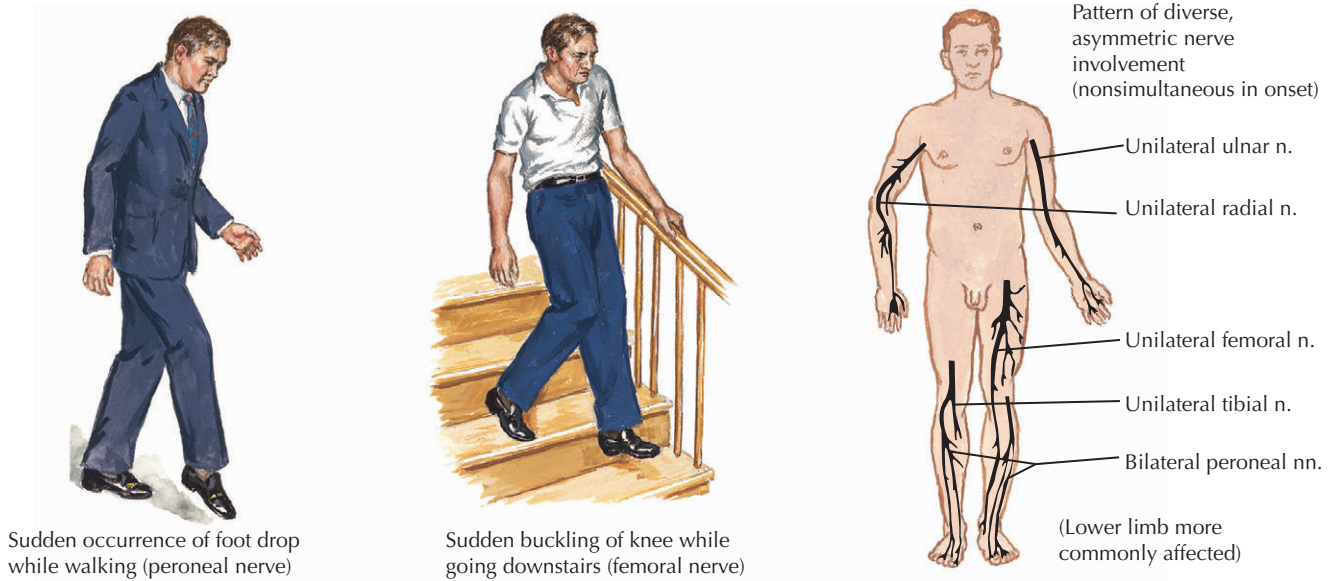

antibody, extractable nuclear antigen, rheumatoid factor, and C-reactive protein. Other studies to consider include HIV and hepatitis C viral serologies. Finding of a serum monoclonal protein should lead to consideration of urine protein electrophoresis with immunofixation, myeloma bone survey, and possible bone marrow biopsy to rule out multiple myeloma.

Specific serum antibodies directed toward gangliosides and glycoproteins have been implicated in several motor and sensory neuropathies. These include antimyelin-associated glycoprotein (MAG), anti-GM1, anti-GM2, anti-GD1a and b, anti-GQ1b, antisulfatide, and paraneoplastic antibodies. Unfortunately, the diagnostic and prognostic value of these antibodies remains unclear. Although their presence enhances the likelihood of an immune-mediated or paraneoplastic neuropathy, many patients with identical clinical syndromes are seronegative, and some individuals with no clinical findings of neuropathy express low levels of these antibodies. Anti-GM1 antibody

is useful in situations of suspected treatable motor neuropathy that cannot be distinguished from amyotrophic lateral sclerosis, or in those patients in whom pure motor neuropathies are associated with a paucity of upper motor neuron findings and multifocal conduction block is demonstrated on electrodiagnostic studies of motor nerves. Anti-GQ1b antibodies may be helpful in confirming the suspected Miller-Fisher variant of GBS. Anti-Hu antibody is useful in patients with asymmetrical proximal sensory findings or in those patients with a predominantly sensory neuropathy and strong smoking history because this may be the earliest manifestation of an underlying malignancy. Anti-MAG antibodies may be associated with an immune-mediated sensory neuropathy.

Genetic testing should be considered in patients with a positive family history of peripheral neuropathy, as may be seen in patients with CMT disease or HNPP. Most currently known mutations for CMT involve the form of the disease that causes a demyelinating sensorimotor periph-

eral neuropathy (CMT type IA) (Fig. 123-6). A common genetic abnormality found in patients with CMT type IA involves duplication of the gene for PMP 22 protein, which is localized to chromosome 17. Interestingly, the genetic mutation seen most commonly in HNPP, which also has demyelinating features with superimposed compressive neuropathies at common entrapment sites, is a deletion in the same gene.

The electrophysiologic examination involves nerve conduction studies, needle electromyography (EMG), and in selected situations, autonomic reflex function testing. Electrodiagnostic studies provide information about the distribution of neuropathy and the elements involved (e.g., motor, sensory, autonomic, or combinations thereof). Electrodiagnostic testing can also help to determine whether the neuropathy primarily involves disease of

Figure 123-6 Hereditary Motor-Sensory Neuropathy Type I: Motor Nerve Conduction Velocity.

myelination, nerve axons, or nerve cell bodies. Electrodiagnostic studies may also help distinguish between acquired and hereditary diseases. Disorders characterized by disease of myelin typically have modest to marked slowing of conduction velocities, whereas those of predominantly axonal origin preserve conduction velocity; or it is only minimally slowed but the amplitudes of the responses elicited by nerve stimulation are reduced. Needle EMG examination typically is relatively preserved in demyelinating disorders and demonstrates the findings of denervation and reinnervation in axonal processes. Autonomic reflex function testing examines reproducible autonomic pathways includ-

ing postganglionic sympathetic sudomotor axon reflexes to produce sweating, cardiovagal responses including heart rate response to deep breathing and Valsalva maneuver, and adrenergic nerve fiber function with beat-to-beat blood pressure responses during Valsalva maneuver and during head-up tilt-table testing. Some or all of these reflex pathways may be impaired in an autonomic neuropathy.

Nerve biopsy is useful in determining the underlying pathophysiology of neuropathy in selected circumstances. It is most helpful in acquired disorders such as vasculitis, sarcoidosis, and amyloidosis; in instances of tumor infiltra-

tion of the nerve sheath; and in small-fiber neuropathy in which electrodiagnostic studies are usually normal, as well as in the hereditary disorder of polyglucosan body neuropathy. The role of nerve biopsy in hereditary disorders will likely become less important as the molecular genetics of these disorders are elucidated. The sural nerve is the most common nerve biopsied, although in specialized centers, other nerves can undergo biopsy if needed. Because the sural nerve is a cutaneous sensory nerve, it may not be as useful in disorders that only affect motor or autonomic function.

Management and Therapy

Optimum Treatment

The treatment of neuropathy depends on its cause and can be directed either toward the underlying disease process or a specific symptom. Therapy directed toward the improvement of a particular symptom, usually pain or a skilled function that is impaired leading to disability, such as ankle-foot orthotic devices for patients with gait imbalance due to foot drop, can be very helpful for an affected patient. The symptomatic treatment of pain control is evolving and is also of importance. Many of the newer anticonvulsant agents have been shown to be beneficial in treating neuropathic pain in addition to the more common use of tricyclic antidepressants and certain topical anesthetic agents.

Entrapment neuropathies are best treated through discontinuation of those activities that worsen or precipitate symptoms. In some situations, surgical intervention is necessary. Many of the metabolic and toxic neuropathies require correction of the underlying problem (e.g., B₁₂ replacement, control of diabetes mellitus or thyroid function status, treatment of collagen vascular disease, or removal or avoidance of the toxic agent or drug. Inflammatory (e.g., CIDP, GBS), vasculitic, or paraproteinemic neuropathies can be successfully treated with corticosteroids, intravenous immunoglobulin, immunosuppressive medications such as azathioprine or mycophenolate mofetil, or therapeutic apheresis. Physical and occupational therapies and the use of adaptive equipment are of benefit in more severe forms of neuropathies. Similarly, these modalities are all that are available in the management of hereditary neuropathies.

Patients with significant sensory loss as the result of their neuropathy are at risk for orthopedic and dermatologic injury of their limbs. The foot is most likely to be affected because patients are not able to perceive painful stimuli and their feet are subjected to repetitive trauma. The resulting painless, often overlooked, ulcers that develop may become secondarily infected resulting in cellulitis and osteomyelitis. Charcot's joints may develop in the most severe cases. These situations typically occur in patients with diabetic neuropathy or

HSAN, and patient and care provider vigilance is of critical importance.

Avoiding Treatment Errors

Careful diagnosis—confirmation of the presence of peripheral neuropathy as a cause for the patient's symptoms and findings, and its underlying cause—allows the clinician to provide the most appropriate treatment for each patient. Symptomatic treatment, such as medications for neuropathic pain and supportive care such as physical and occupational therapies, should be instituted in all patients with peripheral neuropathy as needed. However, a decision regarding appropriate treatment directed at the underlying cause of the peripheral neuropathy requires a careful and thorough investigation of each patient. Misdiagnosis of the underlying cause of the peripheral neuropathy can lead to administration of treatments that could be potentially dangerous to the patient, such as immunosuppressive therapies. Therefore, such treatments should only be considered in patients with a known immune-mediated neuropathy of a severity to justify such a therapeutic approach.

Future Directions

Advances in the treatment of neuropathy are evolving on three broad fronts: the identification of the gene mutations involved in hereditary neuropathies, which will hopefully lead to better diagnosis and ultimately gene therapy; the elucidation of the immunopathology in several immune-mediated acquired neuropathies; and the control of pain.

As understanding of the immune-mediated basis for several of the neuropathic disorders evolves, newer immunosuppressive regimens will be developed. The goal is to develop specific or targeted therapies that are nontoxic and that quickly and permanently remove the abnormal immune response in order to allow regeneration of the peripheral nerve and return of its normal function. The role of interferons and cytokines and the ability to interfere with antigen presentation or co-stimulatory processes are being studied. Because pain is a prominent feature of many neuropathies, extensive work is being carried out on the role of neural growth factors to modulate pain perception and to promote neuronal survival.

Report of the American Academy of Neurology, the American Association of Electrodiagnostic Medicine, and the American Academy of Physical Medicine and Rehabilitation. *Neurology* 64(2):199-207, 2005.

This seminal article establishes the definition of a distal symmetrical polyneuropathy based on the available evidence and, where adequate evidence was not available, consensus of more than a dozen leading experts in the field of peripheral neuropathy. This definition will serve as the basis for defining patient populations for further clinical research studies.

2. Hughes RA, Bouche P, Cornblath DR, et al: European Federation of Neurological Societies/Peripheral Nerve Society guideline on management of chronic inflammatory demyelinating polyradiculoneuropathy. Report of a joint task force of the European Federation of Neurological Societies and the Peripheral Nerve Society. *Eur J Neurol* 13(4):326-332, 2006.

This article establishes guidelines for the definition, diagnosis, and treatment of chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) based on the available evidence and, where adequate evidence was not available, consensus.

Migraine Headache

Introduction

Migraine is a prevalent disorder that has been documented throughout the record of human history. Neolithic humans (7000 BC) bore holes (trepanation) into the skulls of presumed headache sufferers, and the Egyptians (1200 BC) wrapped a clay crocodile around the heads of headache patients with cloth bearing the names of the gods. It was Arateus of Cappadocia (2nd century AD) who is given credit for first identifying many of the features of migraine described in later history. Galen (200 AD) named the illness using the Greek, *hemicrania*, from which the term *migraine* derives its name.

Today, we know migraine to be a disabling disorder with a lifetime prevalence of 18% among females and of 6% among all males in the United States. In 1988, the International Headache Society published guidelines for classification of all recognized headache types. Shortly thereafter, Stewart and Lipton published the American Migraine Study, recognized for its generalizability and reproducibility in other countries throughout the world.

Migraine disability has been estimated to cost the United States between \$5 and \$17 billion annually. Fifty percent of migraineurs miss work 2 days per month and have reduced work efficiency for 6 days per month. Two thirds of migraineurs recognize that the disease has adversely affected their family life. Classifiable migraine is physician diagnosed in only 52% of sufferers. These facts underscore the importance of the physician in recognizing, diagnosing, and treating migraine in the workplace and home.

Etiology and Pathogenesis

Migraine was considered a purely vascular disorder until the mid-1980s when Moskowitz proposed the *Trigeminovascular Theory* of migraine. Using animal models, he demonstrated that electrical stimulation of the trigeminal nucleus caudalis in the pons causes plasma protein extravasation from dural blood vessels. He concluded that the generation of migraine depended on serotonin-mediated increases in neuronal excitation, not on primary vascular reactivity. Thus the pain results in inflammation of blood vessels, although its source is a *neurogenic* cause localizable to trigeminal nuclear centers. In humans, trigeminal stimulation during neurosurgery has resulted in the expression of recognized inflammatory and pronociceptive substances (calcitonin gene-related peptide, neurokinin-A, substance P) within the extracranial circulation similar to that produced in the animal studies (Fig. 124-1).

Migraine aura occurs consistently in 15% to 25% of migraineurs (Figs. 124-2 and 124-3). Aura is a localizable

and fully reversible neurologic deficit preceding head pain, which results from progressive, neuronal dysfunction spreading across the cerebral cortex. A similar spreading cortical depression occurs in experimental animals after chemical or electrical irritation of the brain surface. Studies including single-photon emission computed tomography, positron emission tomography, functional magnetic resonance imaging, phosphorous magnetic spectroscopy, and magnetoencephalography have bolstered this hypothesis. Decreased blood flow does not reach levels severe enough to qualify as ischemia. Other systems including serotonergic, noradrenergic, and dopaminergic pathways; hormones (e.g., estrogen); and hypothalamic and deep brainstem structures are involved in the ultimate expression of migraine. Thus, migraine can be described as neuronal sensitization and neurogenic inflammation in a milieu of multiple neurochemical influences. The goal of migraine treatment is to attenuate neuronal irritability and neurogenic inflammation while keeping in mind the importance of the contributions of these other central mechanisms.

Figure 124-1 Mechanisms in Migraine.

Clinical Presentation

Migraine presents in a variable fashion, but it can be divided into two groups: with aura (classic migraine) and without aura (common migraine) (Fig. 124-4). A prodrome may occur up to 24 hours preceding headache. Prodromal features may include hunger, thirst, euphoria, mania, depression, drowsiness, psychomotor slowing, or irritability. Aura is present in only 15% to 25% of migraineurs. Aura symptoms may

include visual scotomas (dark spots), photopsias (bright spots), fortification spectra (jagged bright lines), numbness, tingling, weakness, confusion, or aphasia. Triggers include environmental stimuli such as intense light, sound, and odors; certain foods (nitrates, sulfites, monosodium glutamate, alcohol); irregular sleep or nutrition; exercise; stress; and hormonal fluctuations (Fig. 124-5). The International Headache Society proposed guidelines in 1988 to diagnose migraine, shown in Boxes 124-1 and 124-2.

Figure 124-2 Migraine Prodromes and Attack.

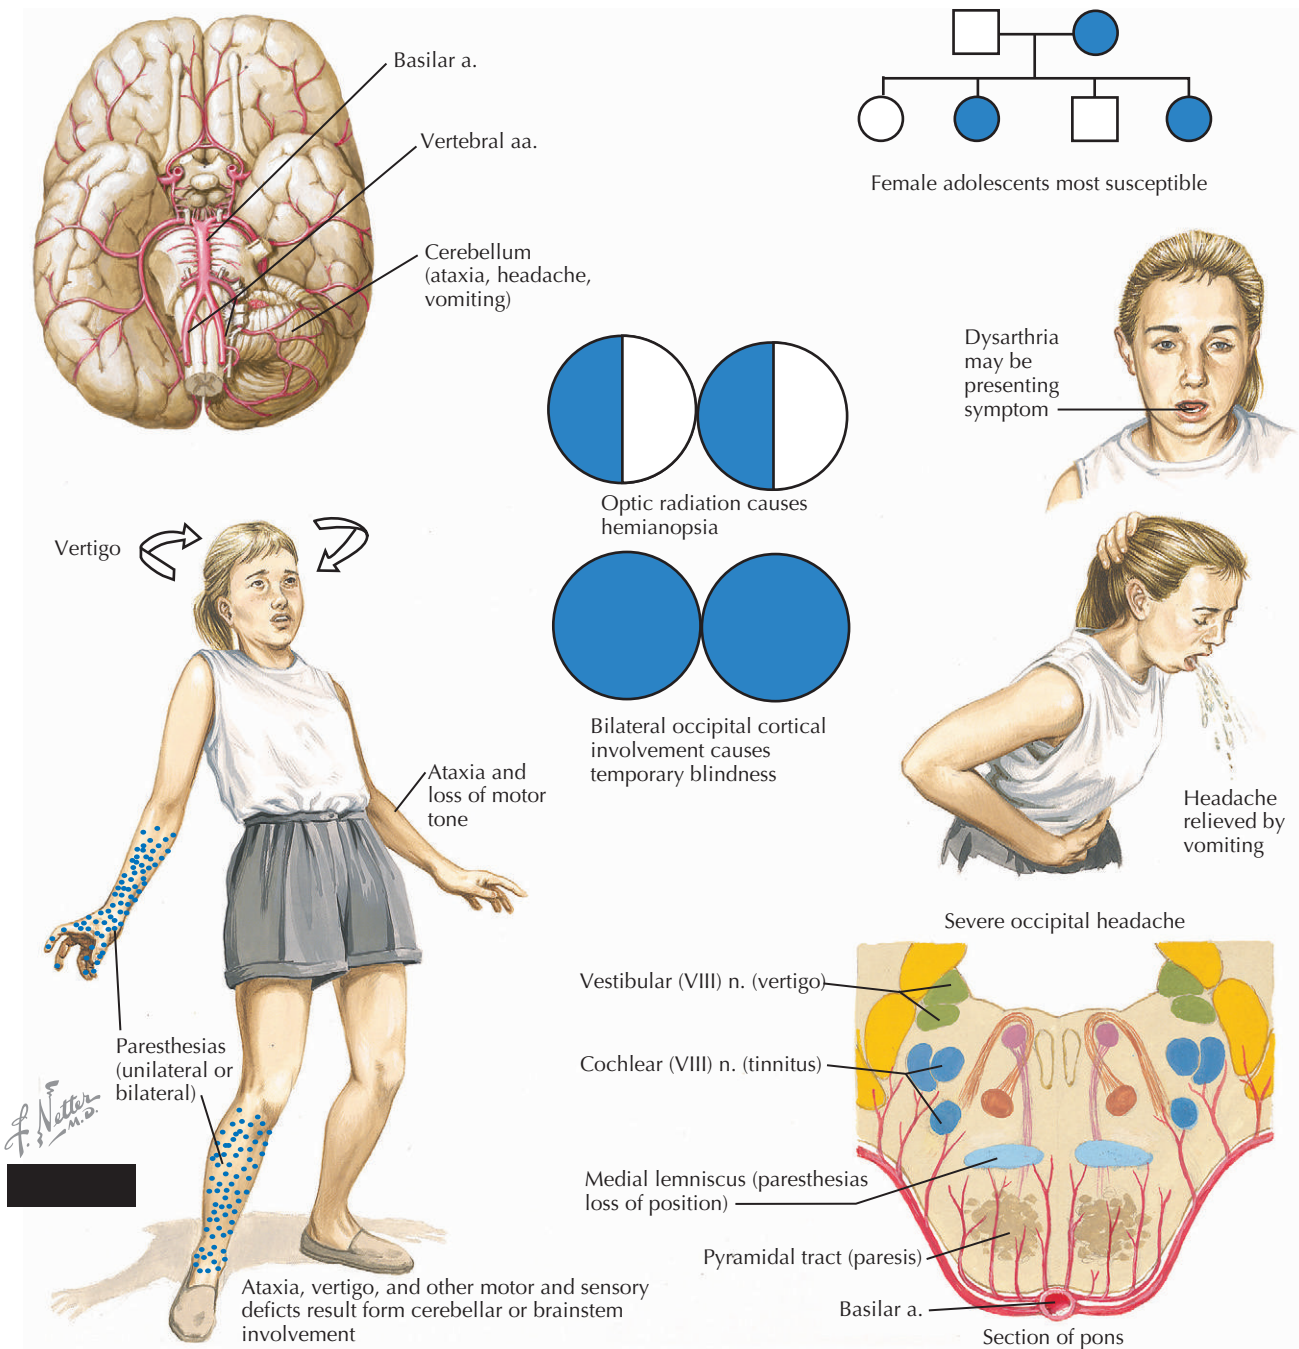

Box 124-1 Diagnostic Criteria for Migraine without Aura (Common Migraine)

- No single feature required or sufficient for diagnosis
 - At least five attacks lasting 4-72 hours
 - Headache has at least two of the following characteristics:
 - Unilateral location
 - Pulsating quality
 - Moderate or severe intensity (inhibits or prohibits daily activities)
 - Aggravation by routine physical activity
 - At least one of the following during headache:
 - Nausea or vomiting
 - Photophobia (light sensitivity)
 - Phonophobia (sound sensitivity)
- History and exam do not support evidence of organic disease that could cause headaches, or if disease is present, then headaches should not have originated in close temporal relation to the disease.

Box 124-2 Diagnostic Criteria for Migraine with Aura (Classic Migraine)

- At least two attacks
 - Aura must exhibit at least three of the following characteristics:
 - Fully reversible and indicative of focal cerebral cortical or brainstem dysfunction
 - Gradual onset
 - Lasts less than 60 minutes
 - Followed by headache with a free interval of less than 60 minutes
 - Headache may begin before or simultaneously with the aura
- History and exam do not support evidence of organic disease that could cause headaches, or if disease is present, then headaches should not have originated in close temporal relation to the disease.

Figure 124-3 Basilar Artery Migraine.

Differential Diagnosis

Migraine must be differentiated from secondary causes of headache to rule out more lethal causes of severe head pain. Other primary headache disorders, tension-type headache, cluster headache, and cluster variants are often confused with migraine. Tension-type headache typically does not cause nausea and does not present with *both* photophobia and phonophobia. There is considerable debate about whether tension-type headache is an independent

disorder or represents a part of a migraine continuum. Nevertheless, tension-type headache may coexist with migraine, and the presence of a tension headache does not preclude the possibility of migraine. Cluster headache derives its name from the pattern of recurrent groups of headaches within a finite period of days to months. It is characterized as an excruciating, typically retro-orbital or temporal pain with duration of 15 to 180 minutes and typically affects males more than females. The headache attack may recur at specific times of the day with remark-

Figure 124-4 Triggers of Migraine.

able consistency. It is differentiated from migraine by its short duration and difference in behavior of the patient during the attack: the cluster patient cannot be still during the event, whereas the migraine patient prefers immobility and hibernation. In addition, it must present with at least one of the following features: lacrimation, rhinorrhea, ptosis, miosis, nasal congestion, conjunctival injection, eyelid edema, and forehead or facial sweating abnormalities. Cluster variants include those headaches with similar features to cluster but with shorter duration. Chronic par-

oxysmal hemicrania, a cluster variant, affects women more than men and has an absolute response to indomethacin.

Secondary causes of headache disorders include head trauma, vascular disorders (e.g., hemorrhage, stroke, vasculitis), intracranial disorders (e.g., neoplasm, increased or decreased intracranial pressure), substance withdrawal, infection, metabolic disorders (e.g., hypoxia, hypercapnia, hypoglycemia, dialysis), and disorders of other structures of the head and neck (e.g., cervical spine, eyes, ears, nose and sinuses, temporomandibular joints). Most of these can

be elucidated by a careful history and exam; however, sometimes it is necessary to perform diagnostic procedures if suspicion for these disorders is raised.

Diagnostic Approach

There is no specific diagnostic test for migraine, but investigations are mandated if secondary causes of headache are of concern. Secondary headaches should be suspected when the patient reports a “worst headache,” has an abnormal neurologic exam, has developed a new-onset headache, or when there has been a dramatic change in headache

Figure 124-5 Migraine Aura.

Visual disturbances, most common element of migraine aura: blurred cloudy vision, scotomas, scintillating zigzag lines (fortification spectrum), flashes of light, etc.

pattern. To rule out an acute hemorrhage, noncontrasted computed tomography scan is preferred because of speed of the procedure and sensitivity. Lumbar puncture may be necessary to detect xanthochromia in patients with negative computed tomography scans and high index of suspicion for bleed (worst headache of life). Lumbar puncture may also be helpful in assessing causes of headache related to pressure (position affects headache) or infection (nuchal rigidity plus photophobia or altered mental status). However, if intracranial masses are suspected, then magnetic resonance imaging with contrast is preferred. Abnormalities in the posterior fossae are associated with headaches with coughing, straining, bending, and so forth. Contrast-enhanced magnetic resonance angiogram may be helpful in assessing vasculitis or the presence of an aneurysm, but consider traditional angiography if suspicion is high and magnetic resonance angiogram is negative. Carotid Doppler assessment may be helpful in acute-onset headache with Horner's syndrome to rule out carotid dissection. Electroencephalography should be performed in those patients with paroxysmal headache with cognitive or behavioral changes to rule out epilepsy.

Management and Therapy

Optimum Treatment

Treatment of migraine begins with clear diagnosis and knowledge of its pathophysiology (Fig. 124-6). Acute treatment of headache should be stratified to the level of disability in the patient. Nonspecific therapies (Table 124-1) include nonsteroidal anti-inflammatory drugs, sympathomimetics (e.g., caffeine), or analgesics (acetamino-

Table 124-1 Nonspecific Acute Therapy for Migraine and Tension Headache*

Medication	Dose	Regimen	Comments
Aspirin	325 mg	1-2 PO every 6 hr PRN with food	
Acetaminophen	325 or 500 mg	1-2 PO every 6 hr PRN	Category B agent in pregnancy
Aspirin/caffeine	250 mg/65 mg	1-2 PO every 6 hr PRN with food	
Acetaminophen/caffeine	250 mg/65 mg	1-2 PO every 6 hr PRN	
Isometheptene/ dichloralphenazone/ acetaminophen	65 mg/100 mg/325 mg (1 capsule)	2 at headache onset; 1 every hour until headache remits	Maximum dose 5 capsules daily
Ergotamine/caffeine	1 mg/100 mg	2 at headache onset; 1 every 30 min until headache remits	Maximum dose 6 daily; category X agent in pregnancy
Ibuprofen	400, 600, or 800 mg	1 PO every 4-6 hr PRN with food	Category B agent in pregnancy
Indomethacin	25 or 50 mg	1 PO every 8 hr PRN with food	Category B agent in pregnancy
Ketoprofen	25 or 50 mg	1 PO every 8 hr PRN with food	Category B agent in pregnancy
Naproxen sodium	375 or 500 mg	1 PO every 8-12 h PRN with food	Category B agent in pregnancy
Lidocaine 4%	1 mL	0.5 mL per nostril every 4 hr PRN	Tilt head back during administration; supine position preferred; category B agent in pregnancy
Metoclopramide	10 mg	1 PO every 6 hr PRN	Use with other acute medications; category B agent in pregnancy
Prochlorperazine	5 or 10 mg	1 PO every 8 hr PRN	Use with other acute medications
Promethazine	25-50 mg	1 PO every 8 hr PRN	Use with other acute medications

* All nonsteroidal anti-inflammatory drugs are contraindicated during the third trimester of pregnancy.

phen, opiates). Frequent use of many of these has been associated with substance withdrawal headache and analgesic rebound. For moderate to severely disabling headache, specific medication should be used (Table 124-2). The most specific of these are triptans. They bind specifically to serotonin receptors on trigeminal nerve endings to halt neurogenic inflammation in addition to binding to dural blood vessels to reduce painful swelling. There is no class effect of triptans, and if one is not effective, another may be tried. They are contraindicated in patients with uncontrolled hypertension and a history of coronary artery disease but are generally safe and effective. Triptans are more costly than nonspecific therapy, but economic analyses point to cost savings and decreased disability when triptans are used in patients with moderate to severe headache.

Patients should be offered preventive treatment if untreatable headaches occur more than twice per month or if the patient is willing to use a daily medication to prevent headache. Preventive medication usually provides benefit after 2 to 3 months of administration. U.S. Food and Drug Administration–approved preventive treatment for migraine includes valproic acid, propranolol, and methysergide. There is evidence (Table 124-3) to support the use of other agents, including other anticonvulsants (decrease neuronal irritability), other β blockers (modulate noradrenergic system and vascular system), tricyclic antidepressants (modulate serotonin and norepinephrine), calcium channel blockers (vascular and central factors), and hormonal manipulation. Oral chelated magnesium, high-dose (400 mg/day) oral riboflavin, and coenzyme Q₁₀ have been reported to be effective in double-blinded studies.

Nonpharmacologic approaches include the avoidance of migraine triggers (e.g., foods, missed meals), biofeed-

back and self-hypnosis, psychological counseling to improve stress management skills, regular exercise, good sleep hygiene, and a balanced diet. All these measures serve to decrease neuronal irritability and thereby reduce the frequency of migraine.

Avoiding Treatment Errors

Acute Treatment Errors

Treatment errors are common among headache specialists and general practitioners alike. One common error is to treat migraine as a general pain disorder for which a step-based approach is often used. In this approach, a less-specific and often cheaper therapy is used followed by more sophisticated therapies if the initial therapy fails. It has been shown that a stratified approach to treatment is more effective for both reduction of disability and reduction of cost. In such an approach, patients with moderate to severe headache history are given migraine-specific therapy (triptans) first rather than waiting for them to fail nonspecific therapies (e.g., aspirin, caffeine, nonsteroidal anti-inflammatory drugs).

Another common error is to attempt to use acute treatment as a diagnostic tool. Although triptans are specific to the treatment of migraine, they do not have a class effect, so if one drug fails, another may still be effective. Thus, failure to respond to a given triptan does not exclude migraine as the underlying diagnosis.

Timing of therapy is a frequent pitfall in migraine acute treatment. Several studies have demonstrated that migraine is best treated within 1 to 2 hours of headache onset. Patients must be educated to treat their headaches when the first symptoms occur before the headache has a chance

Table 124-2 Migraine-Specific Acute Therapy

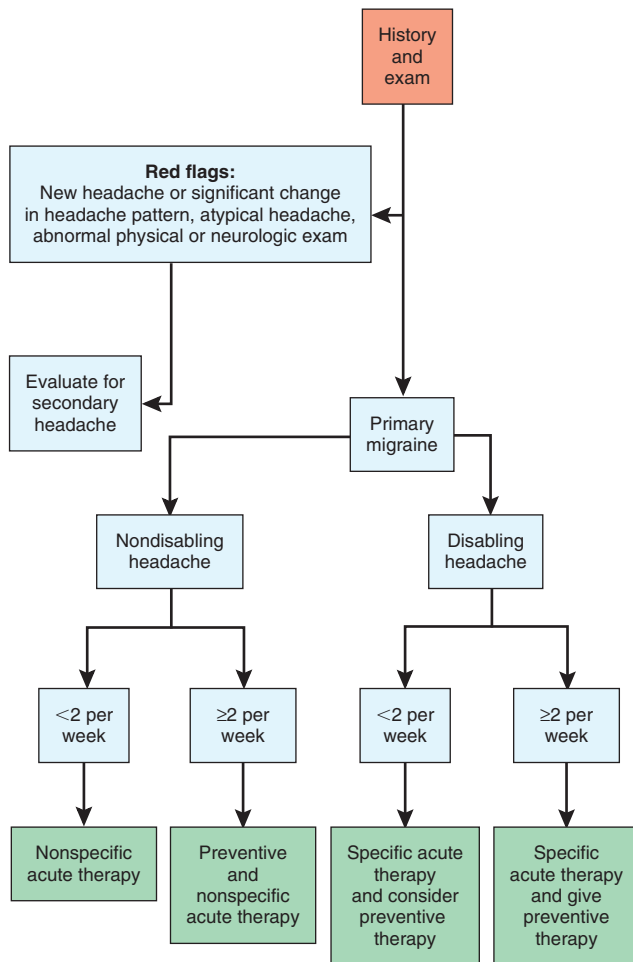

Medication	Dose	Regimen	Comments
Ergot Derivatives			
Dihydroergotamine IV	1 mg	IV every 8 hr PRN	Administer antiemetic/antihistamine therapy before using this agent; category X agent in pregnancy
Dihydroergotamine intranasal spray	1 mg	1 spray in each nostril and repeat in 15 min every 2 hr PRN	FDA maximum dose 2 vials daily; must prime pump before administration; category X agent in pregnancy
Triptans			
Almotriptan	12.5 mg	1 PO every 2 hr PRN	FDA maximum dose 25 mg/d
Eletriptan	20 or 40 mg	1-2 PO every 2 hr PRN	FDA maximum dose 80 mg/d
Naratriptan	1 or 2.5 mg	1 PO every 4 hr PRN	FDA maximum dose 5 mg/d
Rizatriptan	5 or 10 mg	1 PO every 2 hr PRN	FDA maximum dose 30 mg/d
Sumatriptan PO	25, 50, or 100 mg	1 PO every 2 hr PRN	FDA maximum dose 200 mg/d
Sumatriptan intranasal spray	5 or 20 mg	1 spray to 1 nostril every 2 hr PRN	FDA maximum dose 40 mg/d
Sumatriptan injection	4 or 6 mg	1 injection SC every 2 hr PRN	FDA maximum dose 12 mg/d
Zolmitriptan PO	2.5 or 5 mg	2.5-5 mg PO every 2 hr	FDA maximum dose 10 mg/d
Zolmitriptan intranasal spray	5 mg	1 spray to 1 nostril every 2 hr	FDA maximum dose 10 mg/d

Table 124-3 Medications for Migraine Prevention (FDA Approved and Nonapproved)			
Medication	Dose	Regimen	Comments
Tricyclic Antidepressants			
Amitriptyline; nortriptyline	10, 25, 50, 100, or 150 mg	10-150 mg PO qhs*	Titrate \leq 25 mg per week; may cause dry mouth, blurred vision, drowsiness, and urinary retention
Ergot Derivatives			
Methysergide	2 or 4 mg	2-4 mg tid	<i>FDA-approved</i> ; however, no longer available in the United States; titrate \leq 2 mg every 2 days; taper after 4-6 months because of risk for retroperitoneal fibrosis; category D agent in pregnancy
Mitochondrial-Enhancing Agents			
Coenzyme Q ₁₀	50, 100, 120, 200, or 300 mg	150-300 mg in 2 divided doses	Effective in about 50% of patients with migraine
Riboflavin	50 or 100 mg	400 mg PO qd with food	Effective in about 50% of patients with migraine
Miscellaneous			
Cyproheptadine	4 mg	1-6 tabs PO qhs*	Children with migraine should take low doses; adults with migraine with concurrent allergies should take higher doses
Magnesium oxide	200-250 or 400-500 mg	1 tab PO bid with food	Effective in menstrual migraine; 400 mg bid is preferred, but dose may be decreased to 200-250 mg bid if diarrhea occurs
β Blockers			
Atenolol	25-100 mg	qd or bid	Titrate slowly; contraindicated in patients with diabetes, asthma, and heart block; category D agent in pregnancy
Nadolol	40-120 mg	qd	<i>FDA-approved</i> . Titrate slowly; contraindicated in patients with diabetes, asthma, and heart block
Pindolol	5 mg	bid; titrate to 10-60 mg total daily	Titrate slowly; contraindicated in patients with diabetes, asthma, and heart block; category B agent in pregnancy
Propranolol LA	30-160 mg	qd or bid	<i>FDA-approved</i> . Titrate slowly; contraindicated in patients with diabetes, asthma, and heart block
Calcium Channel Blockers			
Verapamil	120-720 mg	qd or tid depending on total dose	High dose is often necessary; side effects may occur; titrate slowly; contraindicated in patients with congestive heart failure
Amlodipine	5-15 mg	qd or bid	Titrate slowly (every 2 wk) from 5 mg
Felodipine	5-15 mg	qd or bid	Titrate slowly from 5 mg
Nisoldipine	10-40 mg	qd or bid	Titrate slowly from 10 mg
Anticonvulsants			
Gabapentin	300, 400, 600, or 800 mg	1800-4800 mg/d in 3 divided doses	Titrate by 900-1200 mg every 2 wk; may cause fatigue or edema
Lamotrigine	25 or 100 mg	25-200 mg qhs* or divided bid	Titrate by 25 mg/wk; rapid titration may increase risk for rash
Levetiracetam	250, 500, or 750 mg	1000-4000 mg in 2 divided doses	Titrate by 250-500 mg/wk; may cause somnolence
Sodium valproate, sodium valproate ER	125, 250, or 500 mg (250 and 500 mg ER formulation)	500 mg bid; 1000 mg qhs* in ER formulation	<i>FDA-approved</i> . Begin at 250 mg total daily; titrate slowly over 2-4 weeks; women at risk for pregnancy should take folate supplements; category D agent in pregnancy; causes hair thinning in about 5% of patients; take selenium at a mealtime when sodium valproate is not administered; liver function testing is recommended after 1 and 3 months
Topiramate	15, 25, 50, or 100 mg	50-100 mg bid or 100- 200 mg total qhs*	<i>FDA-approved</i> . May cause weight loss; reversible/transient side effects include tingling and drowsiness; contraindicated in patients with nephrolithiasis and glaucoma
Zonisamide	25, 50, or 100 mg	100-400 mg qhs*	Titrate extremely slowly by 25 mg/wk; may cause weight loss; reversible/transient side effects include tingling and drowsiness; contraindicated in patients with nephrolithiasis and glaucoma

to progress. This approach will increase the likelihood of drug efficacy and the chance for sustained headache relief. Early treatment decreases disability and decreases the cost of treating each headache.

Preventive Treatment Pitfalls

Patients who present with a long list of failed therapies often suffer the pitfall of attempting treatment without addressing causative or aggravating factors. In the setting of medication overuse headache (medication used on a near daily basis), the medication must be completely removed in order for prevention to be effective. The removal of caffeine is especially important if it is present in the offending medication or if it is a frequent component of the patient's diet. Other factors include the identification and treatment of sleep disorders such as sleep apnea or restless legs syndrome. Environmental sensitivities and dietary sensitivities are also issues that may perpetuate headache. The relationship of menstrual and ovulatory withdrawal of estrogen to headache must be considered. The presence of structural changes in the cervical spine secondary to degenerative arthritis or degenera-

tive disk disease must be considered in refractory headache as well. If any one or any combination of these underlying problems is present, both acute and preventive medications will be less effective, and the patient will falsely conclude that potentially effective therapies have failed.

Future Directions

The future of migraine management lies in the development of pharmacologic and nonpharmacologic strategies that follow advances in migraine pathophysiology. Genetic studies have linked hemiplegic migraine (aura of reversible hemiplegia) to a defect on chromosome 19p13, which encodes voltage-gated P/Q type calcium channel. Genetic polymorphism studies have implicated alterations in the gene for serotonin receptors in migraine without aura and in dopamine receptors with migraine with aura. Such studies may provide clues to why migraineurs are predisposed to central sensitization and neurogenic inflammation. Neuroimaging studies may continue to provide links between the animal and human models. Nonpharmacologic therapies are just beginning to be subjected to evidence-based medicine trials. Pending such studies there will likely be a place in migraine therapy for neurohypnosis, acupuncture, music therapy, and other complementary medical approaches. Education of health care professionals is an important part of management of migraine because nearly half of all migraineurs remain undiagnosed. Proactive and educated health care providers will serve to improve the quality of life in migraineurs and will lessen the impact of this prevalent and disabling disease.

Stroke and Transient Ischemic Attacks

Introduction

Stroke is an illness of sudden onset causing brain injury as a result of occlusion or rupture of a cerebral blood vessel. Strokes can be further characterized as ischemic or hemorrhagic (Fig. 125-1). Transient ischemic attacks (TIAs) are brief episodes of neurologic dysfunction of vascular origin, with clinical symptoms typically lasting less than 1 hour, and without evidence of infarction. TIAs are strong predictors of future ischemic events, and the risk for having a stroke within 48 hours of a TIA is nearly 5%. This chapter will focus on ischemic strokes and TIAs, which account for nearly 85% of all strokes.

Etiology and Pathogenesis

Most ischemic strokes are thrombotic or embolic in origin, usually resulting from underlying atherosclerotic disease of extracranial or intracranial cerebral vessels or underlying cardiac disease. Lacunar strokes result from thrombosis of the small subcortical penetrating arteries of the brain and are most often associated with hypertension.

Well-documented, common stroke risk factors include hypertension, smoking, diabetes mellitus, atrial fibrillation, cardiac disease, carotid artery stenosis, dyslipidemia, physical inactivity, postmenopausal hormonal replacement therapy, and obesity. Other risk factors include alcohol and drug abuse, metabolic syndrome, hyperhomocysteinemia, hypercoagulability, and oral contraceptive use. A number of medical conditions (e.g., sickle cell disease, polycythemia vera, meningovascular syphilis, bacterial endocarditis) are much less commonly associated with stroke; however, such etiologies should be considered in patients when other risk factors are not present or when suggested by the medical history (Fig. 125-2).

Clinical Presentation

Symptoms and signs are a reflection of the cerebrovascular distribution of ischemia.

Carotid Artery Territory

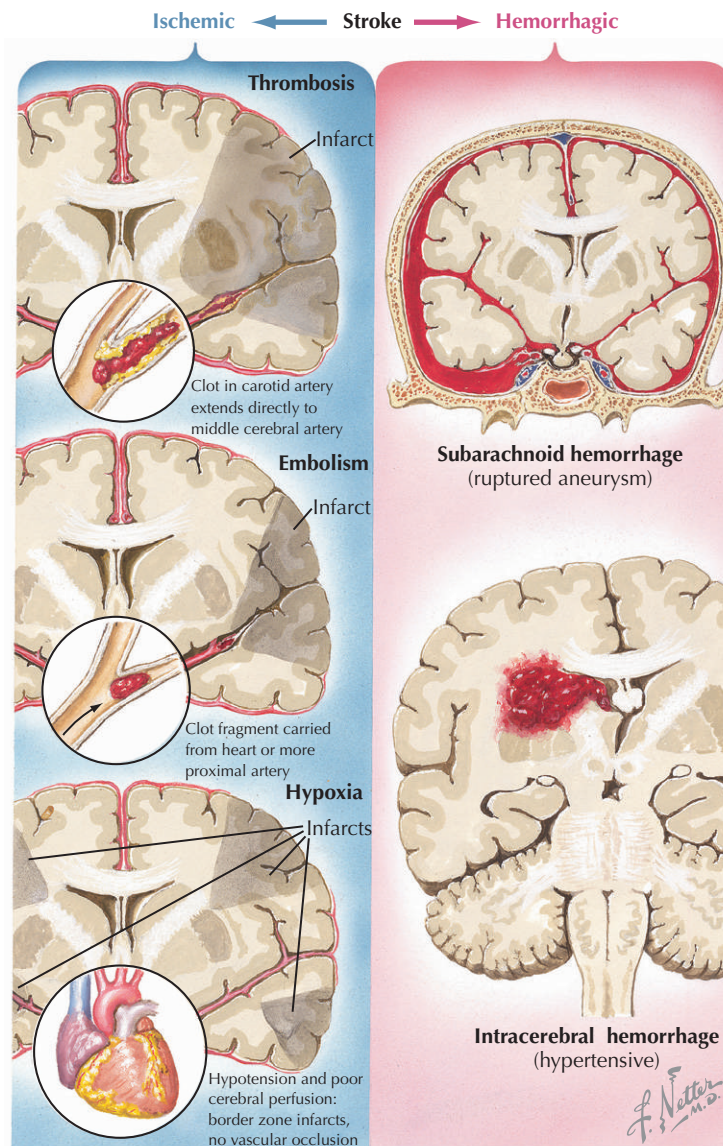

Common symptoms and findings are monocular visual loss (amaurosis fugax), contralateral weakness or sensory disturbance, dysarthria, language impairment with dominant hemisphere involvement, neglect with nondominant hemisphere involvement, other higher cortical deficits, and contralateral homonymous visual loss (Fig. 125-3).

Vertebrobasilar Artery Territory

Common symptoms and findings are unilateral or bilateral weakness or sensory disturbance, crossed motor or sensory findings, dysarthria, pupil abnormalities, ophthalmoplegia, other cranial nerve deficits, Horner's syndrome, ataxia, various visual field deficits, and altered level of consciousness (Fig. 125-4). Several brainstem syndromes describe the findings seen with specific vascular distributions and are best understood in terms of the specific nuclei and anatomical pathways involved by the event.

Lacunar Strokes

A number of lacunar syndromes have been described, including pure motor hemiplegia, pure sensory stroke, clumsy hand–dysarthria syndrome, and ataxic hemiparesis.

Figure 125-1 Classification of Stroke Subtypes.

Differential Diagnosis

Many medical conditions may be confused for cerebrovascular events: partial seizures; migrainous auras; cardiac syncope and near-syncope; peripheral vestibulopathies; hypoglycemia; brain tumors, subdural hematomas, and other intracranial mass lesions; demyelinating diseases; spinal cord injuries or lesions; and somatoform disorders. One should also consider systemic infection, metabolic disorders, and medication intoxication or overdose in the patient with primarily generalized weakness or altered consciousness.

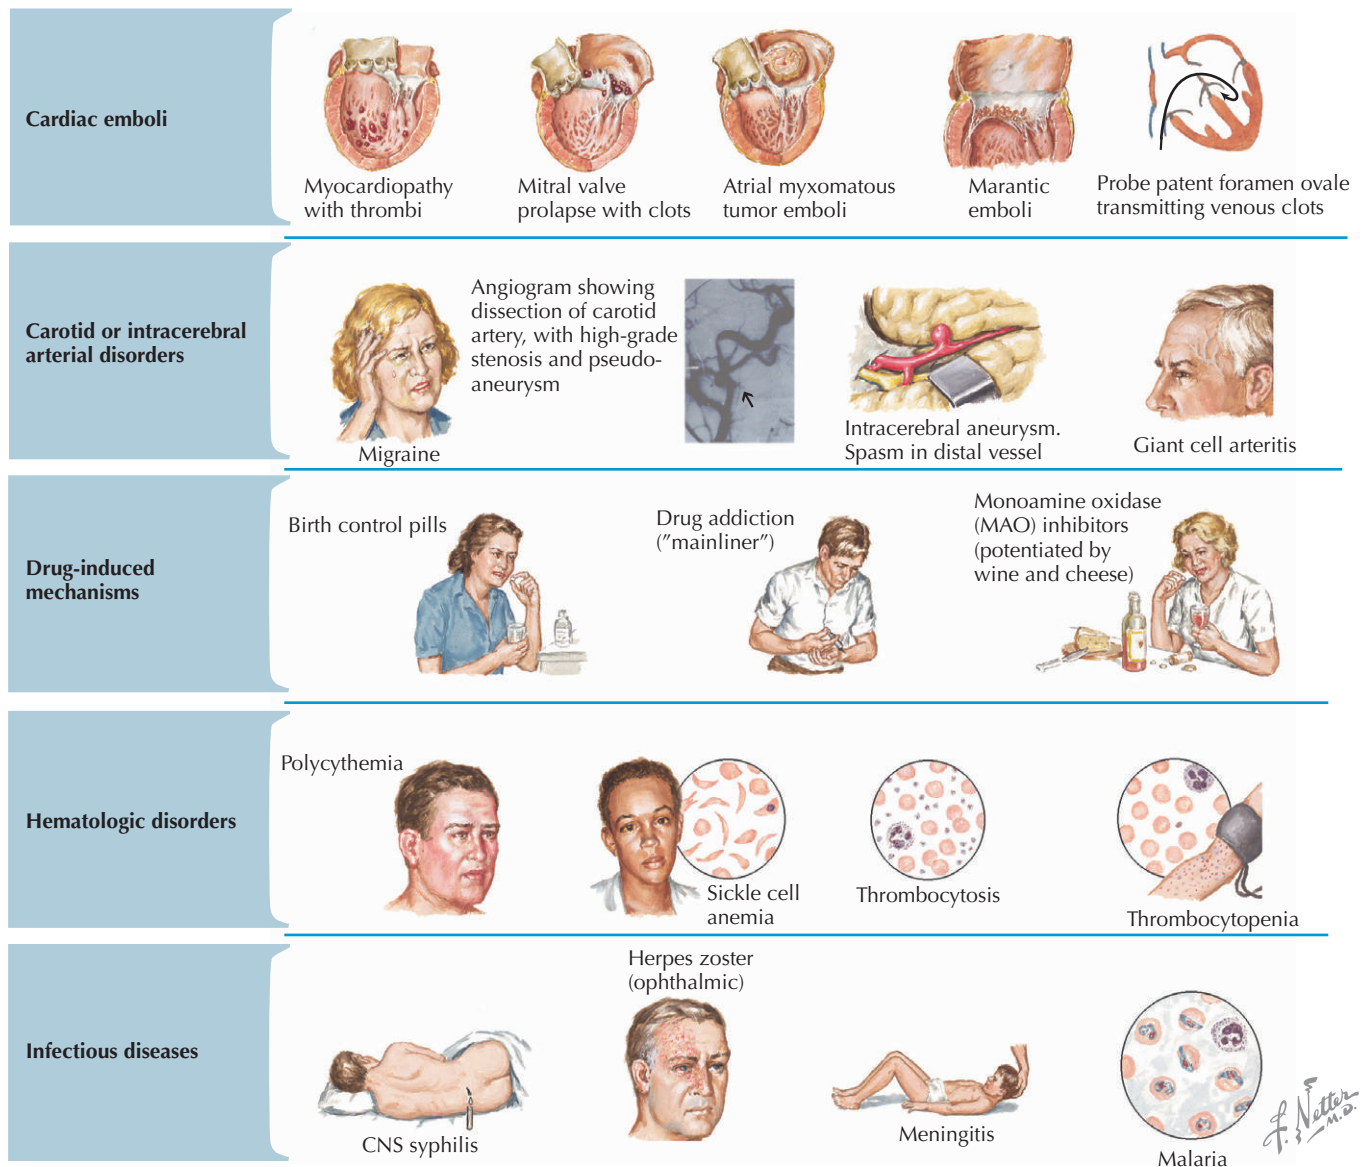

Diagnostic Approach

Rapid recognition and diagnosis are essential for treatment of acute strokes. Obtaining a time of symptom onset and

a careful history are critical. Onset of symptoms is defined as the time since the patient was last known to be symptom free. For patients awakening with deficits, one must use the time they were last awake and without symptoms. Initial evaluation should include a careful history and neurologic examination. Many centers use the National Institutes of Health Stroke Scale to grade stroke severity.

Blood samples should be drawn for glucose, serum electrolytes, renal function tests, complete blood counts, coagulation studies, and sedimentation rate. Additional laboratory tests may be indicated to rule out systemic infection and medication intoxication or overdose. Emergent imaging of the brain is indicated because of the potential for therapeutic intervention. In general, computed tomography (CT) is the preferred modality for acute strokes, particularly if the patient is eligible for

Figure 125-2 Less Common Etiologic Mechanisms of Stroke.

treatment with thrombolytic therapy. Magnetic resonance imaging with diffusion-weighted images is very useful in demonstrating acute infarcts, but logistical issues, such as longer acquisition times and limited availability of scanners and specialists needed to interpret the images, often make use of this modality difficult in the acute setting. At certain centers, CT or magnetic resonance angiography is performed acutely, if neurointerventionalists are available to provide endovascular therapies (see “Future Directions”).

Following the initial acute assessment and treatment, or for patients presenting in the subacute period, the evaluation is focused on determining etiology and risk factors for secondary stroke prevention. Magnetic resonance imaging of the brain is most often performed in this period to

confirm the diagnosis of stroke. Evaluation of cerebral vessels should be performed; carotid ultrasound, CT, or magnetic resonance angiography and conventional angiography are all acceptable studies. A cardiac evaluation should also be performed, including 12-lead electrocardiogram and echocardiography looking for sources of emboli or shunting. Electrocardiogram telemetry monitoring can be useful, particularly if concerns exist about undetected cardiac arrhythmias. Lipid and cholesterol panels, syphilis screening, homocysteine level, and high-sensitivity C-reactive protein level should be checked. In the young stroke patient, evaluation for hypercoagulable states may be indicated, including antithrombin III activity, protein C and S activity, sickle cell screen, lupus inhibitor, anti-nuclear antibody, and anticardiolipin antibody.

Figure 125-3 Ischemia in Internal Carotid Artery Territory: Clinical Manifestations.**A. Ocular**

Transient blindness in one eye from temporary occlusion by platelet-fibrin or cholesterol emboli (on side of involved artery)

Partial blindness may be detected by covering one eye at a time to determine if defect is monocular or binocular

B. Cerebral hemisphere

Occasional headache (usually supraorbital or temporal)

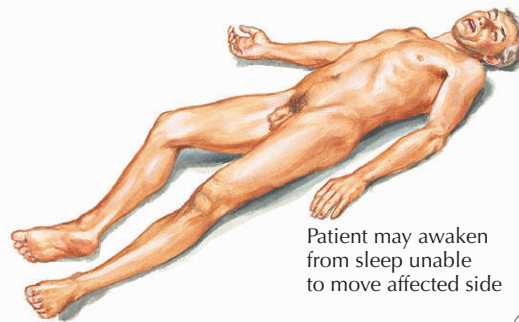

Homonymous (partial) visual field defects

Language defect (partial or complete) only when dominant hemisphere is involved

Hemiparesis or hemiplegia (only arm or leg may be affected); may be fleeting, transient, or permanent and may appear with or without sensory deficits

On side opposite involved artery

Patient may awaken from sleep unable to move affected side

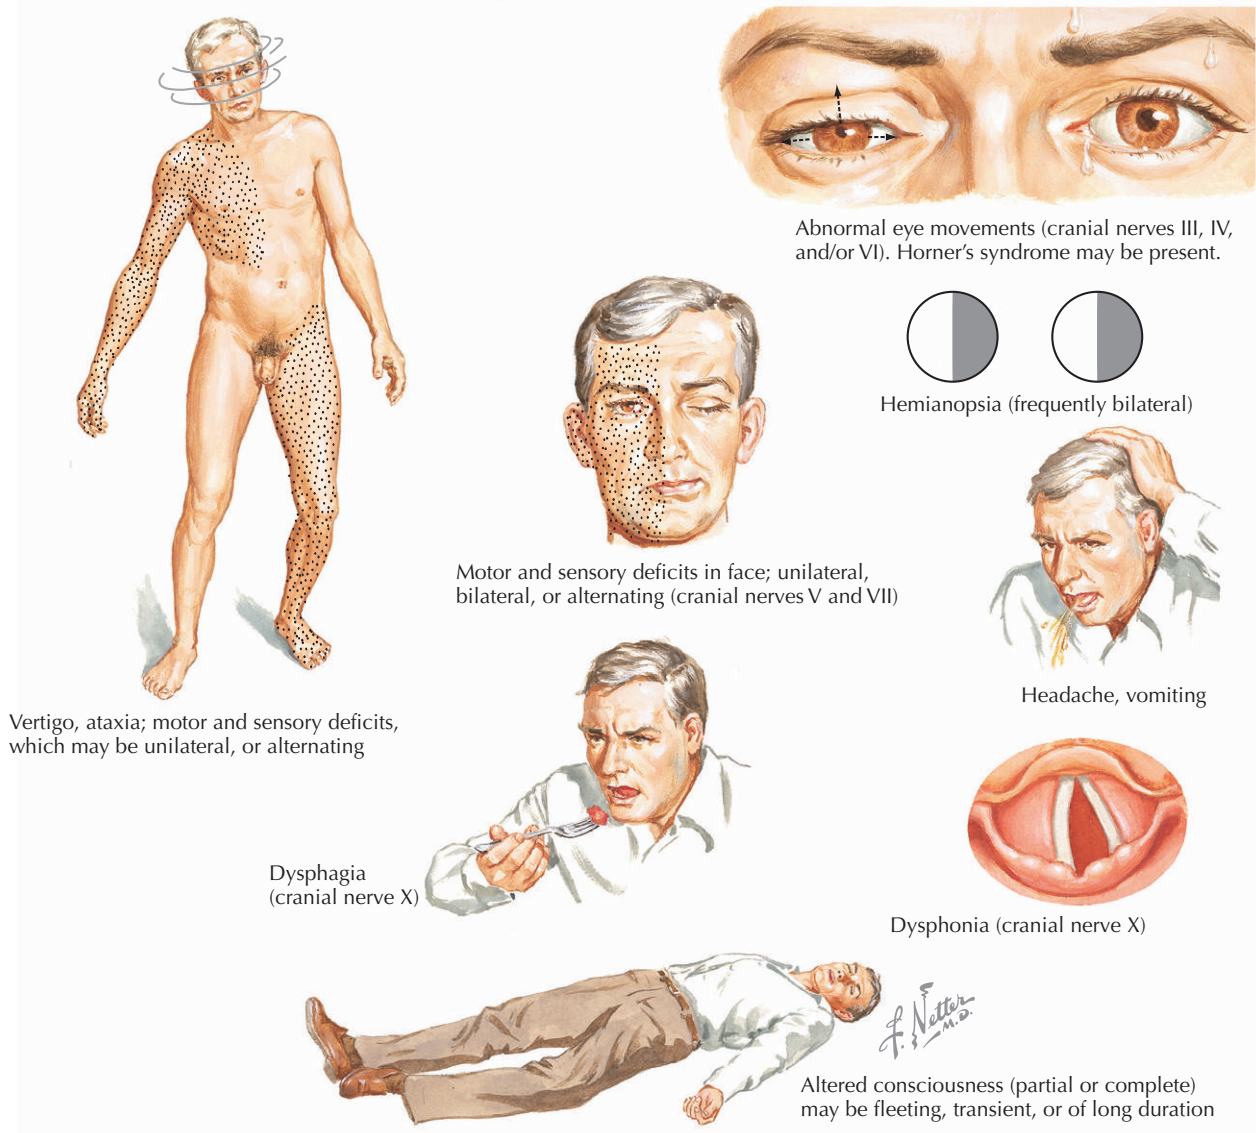

F. Netter M.D.

Management and Therapy**Optimum Treatment for Acute Strokes**

In the acute setting, initial attention should be given to cardiopulmonary stabilization, and this stabilization should be achieved as rapidly as possible because all unnecessary delays to stroke treatment should be avoided. Currently, acute stroke therapy is centered on the use of intravenous thrombolytic therapy with recombinant tissue plasminogen activator (rt-PA), the only therapy approved by the U.S. Food and Drug Administration for the treatment of acute ischemic stroke. The National Institute of Neurological Disorders and Stroke study documented an approximately 30% relative and 12% absolute increase in patients having a good outcome with minimal to no disability at 3 months, when compared with the placebo group. This was

despite an absolute increase of 6% in the occurrence of symptomatic intracerebral hemorrhage in the rt-PA treated patients. Treatment must be initiated within 3 hours after the onset of stroke symptoms and after careful consideration of the patient's eligibility (see Box 125-1 for guidelines). The recommended dose of rt-PA is 0.9 mg/kg (maximum of 90 mg) infused over 60 minutes with 10% of the total dose administered as an initial intravenous bolus over 1 minute.

Patients treated with rt-PA should be closely monitored for at least 24 hours. Neurologic examinations should focus on any signs of acute deterioration (e.g., progressing weakness and alterations in consciousness), which might suggest extension of the stroke or the development of an intracranial hemorrhage (ICH). If ICH is suspected, an emergency head CT scan should be obtained, and rt-PA

Figure 125-4 Ischemia in Vertebrobasilar Territory: Clinical Manifestations.

should be discontinued immediately. Blood should be drawn for complete blood counts, coagulation studies, fibrinogen level, and type and cross-match. If ICH is confirmed by CT, the administration of cryoprecipitate containing fibrinogen and factor VIII or fresh frozen plasma is suggested. Platelets and packed red blood cells should be transfused, if required. Neurosurgery should be consulted for possible hematoma evacuation.

After rt-PA administration, significant elevations in blood pressure should be actively controlled. The recommended upper limits for patients receiving thrombolytics are a diastolic blood pressure of 110 mm Hg and a systolic blood pressure of 185 mm Hg. Patients receiving rt-PA should not receive antiplatelet agents (e.g., aspirin, dipyridamole, clopidogrel, and abciximab) or anticoagulants (e.g., heparin and warfarin) during the first 24 hours.

In the event that rt-PA is not administered, most stroke and TIA patients should still be admitted to the hospital for further monitoring and evaluation and treatment of short- and long-term stroke risks. In general, aspirin should be given to patients within 24 to 48 hours of stroke onset. Aspirin should not be used as a substitute for other acute interventions, especially not in place of intravenous rt-PA. There are insufficient data with regard to the use of other antiplatelet agents, such as dipyridamole, clopidogrel, or abciximab, in the acute setting.

Although anticoagulation with heparin has been used in the past for patients presenting with an acute ischemic stroke—especially for patients with progressing symptoms (so-called strokes in evolution)—there is no significant evidence for a clinical benefit and much evidence for an elevated bleeding risk from such an approach. It is possible

Box 125-1 Recombinant Tissue Plasminogen Activator Eligibility Guidelines

- Diagnosis of ischemic stroke causing measurable neurologic deficit
- The neurologic signs should not be clearing spontaneously
- The neurologic signs should not be minor and isolated
- Caution should be exercised in treating a patient with major deficits
- The symptoms of stroke should not be suggestive of subarachnoid hemorrhage
- Onset of symptoms <3 hours before beginning treatment
- No head trauma or prior stroke in previous 3 months
- No myocardial infarction in the previous 3 months
- No gastrointestinal or urinary tract hemorrhage in previous 21 days
- No major surgery in the previous 14 days
- No arterial puncture at a noncompressible site in the previous 7 days
- No history of previous intracranial hemorrhage
- Blood pressure not elevated (systolic <185 mm Hg and diastolic <110 mm Hg)
- No evidence of active bleeding or acute trauma (fracture) on examination
- Not taking an oral anticoagulant or if anticoagulant being taken, INR \leq 1.7
- If receiving heparin in previous 48 hours, activated partial thromboplastin time must be in normal range
- Platelet count \geq 100,000 mm^3
- Blood glucose concentration \geq 50 mg/dL (2.7 mmol/L)
- No seizure with postictal residual neurologic impairments
- Computed tomography does not show a multilobar infarction (hypodensity greater than one third of cerebral hemisphere)
- The patient or family understand the potential risks and benefits of treatment

From Adams H, Adams R, Del Zoppo G, Goldstein LB: *Guidelines for the early management of patients with ischemic stroke: 2005 Guidelines update. A Scientific Statement from the Stroke Council of the American Heart Association/American Stroke Association. Stroke* 36:916-921, 2005.

that certain subsets of patients (e.g., patients with severe large vessel atherosclerosis or those perceived to be at high risk for recurrent embolism) might benefit from early anticoagulation, but additional research is needed.

An elevated blood pressure is commonly found in patients with acute and subacute strokes. If necessary, doses of outpatient antihypertensive drugs are reduced acutely to maintain perfusion to the ischemic penumbra. For patients not eligible for thrombolytic therapy, acute treatment of elevated blood pressures is generally only recommended for diastolic blood pressures greater than 120 mm Hg and systolic pressures greater than 220 mm Hg.

Deep venous thrombosis and pulmonary embolism can occur as a complication of immobility associated with strokes. For this reason, prophylaxis for deep venous thrombosis and pulmonary embolism is recommended in

all stroke patients with immobility. Early mobilization of the patient is another important measure in preventing medical complications of acute stroke. The involvement of speech therapy, physical therapy, occupational therapy, and rehabilitative medicine are all important in preventing complications and maximizing recovery of the stroke patient. A rehabilitation plan is vital for reducing long-term morbidity and mortality after a patient is discharged from the acute care setting.

Avoiding Treatment Errors in Acute Stroke

Early recognition and treatment of stroke have been shown to improve functional outcome and reduce long-term morbidity and mortality after stroke. Delays in emergency transport should be minimized. Any suspected stroke should be given high triage priority at the treating facility, and initial evaluation and brain imaging should be performed as quickly as possible.

However, the pressures to treat quickly must also be balanced by a thorough review of the presenting history and a careful neurologic evaluation to exclude stroke mimics. Establishing a reliable time of onset is crucial to avoid treating a patient outside of the recommended time window. Familiarity with published guidelines for administering rt-PA in acute stroke will also reduce the likelihood of protocol deviations, and it is recommended that all treating facilities develop acute stroke care pathways based on these guidelines.

Secondary Stroke Prevention

Prevention of recurrent strokes should begin with risk factor modification. Hypertension and diabetes should be aggressively controlled. Statins are reasonable for all patients with stroke or TIA due to atherosclerotic disease and are recommended for all patients with dyslipidemia. All patients should be advised not to smoke, and smoking cessation should be recommended for current smokers.

Most patients with noncardioembolic strokes or TIAs should be placed on antiplatelet therapy. Aspirin, 50 to 325 mg once daily, the combination agent of aspirin, 25 mg and extended-release dipyridamole, 200 mg administered twice daily, and clopidogrel, 75 mg once daily are all acceptable initial options. The combination of clopidogrel and aspirin is frequently used for acute coronary syndrome; however, trials of this combination have not shown a significant benefit for stroke over the use of clopidogrel alone. One recent trial (the MATCH [Management of ATtherosclerosis with Clopidogrel in High-risk patients with recent transient ischemic attacks or ischemic stroke] trial) reported a 1.3% absolute increase in life-threatening bleeding with clopidogrel plus aspirin compared with clopidogrel alone.

In treating stroke and TIA patients with cardiogenic embolic infarcts, anticoagulation with warfarin is effective,

with a goal of an international normalized ratio in the range of 2.0 to 3.0. For patients with atrial fibrillation or paroxysmal atrial fibrillation, long-term anticoagulation with warfarin is generally recommended, and aspirin, 325 mg once daily, is recommended for patients unable to take warfarin. Other indications for anticoagulation include rheumatic mitral valve disease and prosthetic mechanical heart valves. For patients with acute myocardial infarction with left ventricular thrombus, anticoagulation for at least 3 months and up to a year is reasonable.

Surgical intervention may be indicated for patients found to have large-artery cerebrovascular disease. Carotid endarterectomy is recommended for stroke and TIA patients with severe (70% to 99%) ipsilateral carotid stenosis. A more moderate risk reduction is seen in patients with stenosis of 50% to 69%, and treatment decisions must take into consideration factors such as age, gender, comorbidities, and severity of the initial stroke or TIA. Carotid artery stenting may be considered for patients with severe stenosis who are considered high surgical risks.

Future Directions

Diagnostically, newer brain imaging modalities such as CT and magnetic resonance perfusion are being used to rapidly define the areas of cerebral perfusion abnormality and the degree of ischemic injury. These modalities will allow physicians to better define which patients might benefit from specific acute stroke therapies.

Acute interventional procedures for treating major vessel occlusions are being developed and evaluated. The Merci Retriever is an endovascular embolectomy system cleared by the U.S. Food and Drug Administration in 2005 for removal of blood clots from patients with ischemic stroke. The wire-based system was shown in a trial to be more successful in restoring the patency of occluded large intracranial vessels within 8 hours of stroke onset, at a rate of 46%, compared with a 18% spontaneous recanalization rate seen in a previous interventional study. However, use of this device is currently limited to centers with interventional facilities and trained operators. Interventional procedures involving intraarterial delivery rt-PA have been reported in case series and small trials, and larger trials are underway. Combination intravenous plus intra-arterial rt-PA strategies are also being tested.

Most attempts at limiting the extent of neuronal injury with neuroprotective agents have been disappointing.

Some newer agents are in various stages of development and testing.

Vertigo

Introduction

Dizziness is one of the most common patient complaints. It represents 10% of all complaints in primary care practice and 20% in otolaryngology and neurology practices. Patients often group a wide array of sensations under the term *dizziness*. True vertigo, however, is a subtype of dizziness defined as an illusory perception of movement relative to the environment. Although classically described as rotatory, the movement itself can be in any direction. Vertigo is not a disease but rather a symptom reflecting a disturbance of one of the balance systems. The visual, somatosensory, proprioceptive, and vestibular systems all contribute to postural stability. A dysfunction in any of these systems can result in a feeling of imbalance. Vertigo reflects a disturbance in the vestibular system, either peripherally or in the central nervous system connections.

This chapter focuses on vertigo, with a description of the most common entities encountered in clinical practice.

Etiology and Pathogenesis

The peripheral vestibular system is formed by the semicircular canals and the utricle and saccule (Figs. 126-1 and 126-2). The canals detect angular acceleration. They are positioned at right angles to each other and are paired with canals in the contralateral ear. A certain movement will therefore cause an increase in firing on one side with a corresponding decrease on the contralateral side. The saccule and utricle, on the other hand, detect linear movement.

These signals are then carried centrally to the brainstem, where they are integrated with input from the other balance systems and result in overall balance and posture as well as stability of the visual field. The vestibular system also has connections with the visceral system signals in the brainstem, which explains the autonomic and affective manifestations associated with vertigo. Irritation or suppression of one vestibular apparatus results in an imbalance of input to the central balance centers, which reflects in a sensation of movement with associated symptoms.

Vertigo, as mentioned, can be due to disturbances in either the peripheral or central vestibular apparatus. It can be due to infectious, inflammatory, autoimmune, traumatic, or neoplastic etiologies (Fig. 126-3). The more common conditions causing vertigo are listed in Box 126-1 and are considered in this chapter.

Clinical Presentation

History

A thorough patient history is essential to the evaluation of the vertiginous patient. The most important element in the history is the duration of vertigo. Ask the patient to describe the episode in detail, including the typical onset, duration, resolution, and exacerbating or alleviating factors. An association with position or movement is also critical to ascertain. The overall course of the disease, with a focus on the initial episode and frequency of subsequent episodes, is very informative. A history of associated symptoms, either otologic (hearing, tinnitus, otalgia, fullness) or neurologic (headache, visual changes, weakness, numbness), is also helpful in diagnosis. A complete medical history and review of systems can also yield helpful information, particularly when focusing on cardiovascular, autoimmune, and psychiatric conditions. Review all the patient's medications, especially the most recent ones.

Physical Examination

The physical examination must include complete head and neck, as well as neurologic, evaluations. This includes pneumatic otoscopy, cranial nerve testing, fundoscopic exam, assessment of ocular reflexes, eye movements and

the presence of nystagmus, cerebellar examination including Romberg's and gait testing, and auscultation of the neck and heart. Additional examinations may include orthostatic vital signs, muscle strength, proprioception, and visual acuity. The presence of nystagmus, whether spontaneous or related to eye movement or body position, is extremely important (Fig. 126-4). The direction of the nystagmus, duration, and fatigability help differentiate peripheral from central etiologies. The middle ear should be examined and hearing tested using a tuning fork. The Dix-Hallpike maneuver is virtually diagnostic for benign paroxysmal positional vertigo (BPPV). Dysmetria, dysdiadochokinesia, Romberg's testing, and gait ataxia help in differentiating central from peripheral causes.

Figure 126-4 Test for Positional Vertigo.

Differential Diagnosis

A long differential diagnosis must be considered in patients with vertigo. However, it is possible to narrow the list of potential etiologies considerably based on the history and physical examination. Distinguishing factors are listed subsequently (Table 126-1; see Box 126-1).

Diagnostic Approach

Diagnostic testing is often required to distinguish between one of several possible clinical diagnoses. A pure tone audiogram should be performed to assess patients for related hearing loss. Electronystagmography can frequently identify unilateral vestibular weakness and help

distinguish nystagmus of peripheral and central origin. Electrocochleography can be performed to aid in the diagnosis of Meniere's disease. Dynamic posturography may aid in localizing balance disorders when multiple systems are involved. Laboratory evaluation usually has a limited role in the diagnostic approach to vertigo and may include complete blood count, erythrocyte sedimentation rate, antinuclear antibody titers, rapid plasma reagin or VDRL screening, and evaluation of thyroid function. Cerebrospinal fluid analysis may aid in the diagnosis of multiple sclerosis (MS).

Radiographic imaging in patients with vertigo is sometimes useful. For middle ear disease and temporal bone pathology or trauma, computed tomography scan highlights bony anatomy and helps detect pathologies such as

Table 126-1 Clinical Features of the Most Common Causes of Vertigo

Clinical Features	Migraine	Vestibular Neuritis	Labyrinthitis	Menière's Disease	Perilymph Fistula	BPPV	Vestibular Schwannoma	Chronic Otitis Media

cholesteatoma or middle ear tumors. For soft tissue examination (e.g., cerebellopontine angle masses, vestibular schwannoma, MS plaques) magnetic resonance imaging is the study of choice. For suspected vascular disease, transcranial Doppler, magnetic resonance angiography, or selected arterial angiography may be diagnostic.

Management and Therapy

General Principles

The management of vertigo depends on the etiology and associated pathology. In general, however, acute control of symptoms is the same in all patients. The most commonly used class of medications includes the older antihistamines, such as meclizine, dimenhydrinate, and promethazine. These drugs help reduce the feeling of movement and instability as well as the associated gastrointestinal symptoms. Side effects are mostly limited to drowsiness. The newer generation antihistamines do not penetrate the central nervous system and are therefore not helpful in the management of vertigo. Other medications include anticholinergics such as scopolamine for motion sickness, antidopaminergics, and monoaminergics. Antidopaminergics help control the chemoreceptor trigger zone, whereas monoaminergics potentiate the effects of the antihistamines and can be used in severe cases.

Benzodiazepines, such as diazepam, are powerful vestibular suppressants that are very effective in the acute management of vertigo. Long-term use, however, can affect the natural compensatory processes that occur with the loss of one vestibular system and is therefore discouraged.

Vestibular rehabilitation therapy is usually performed on an outpatient basis. These exercises are designed to facilitate habituation and central compensation.

Optimum Treatment of the Most Common Entities

The following is a brief description of the most common etiologies of vertigo, both peripheral and central. These are also summarized in Table 126-1.

Acute vestibulopathy is the sudden failure of the balance system. A viral etiology has been postulated based on several lines of evidence. When associated with hearing loss, *labyrinthitis* is the commonly used term. When hearing is preserved, *vestibular neuritis* is the common terminology. Acute vestibulopathy typically presents as an attack of prolonged, incapacitating vertigo with nausea and vomiting that can persist for greater than 24 hours, gradually subsiding over the following days to weeks. Patients often describe a history of antecedent upper respiratory infection. In cases of vestibular neuritis, hearing is unaffected; however, in acute labyrinthitis, sensorineural hearing loss and tinnitus accompany the episode. About 20% of patients experience

recurrent episodes that are often less severe than the initial presentation. Management is typically focused on control of the acute symptoms, in addition to bed rest and hydration. Corticosteroids have been shown to improve the recovery, whereas antivirals have shown no clear benefit. Vestibular suppressants should be withdrawn as soon as possible to allow effective central adaptation. Vestibular rehabilitation exercises and early mobilization improve final outcomes. One particular form of viral labyrinthitis, herpes zoster oticus or Ramsay Hunt syndrome, is due to a reactivation of the varicella-zoster virus. This has a unique clinical course that starts with a burning pain followed by a vesicular eruption; hearing loss, vertigo, and facial weakness can then follow. In addition to steroids, acyclovir can have a role in the treatment of this specific entity. Aggressive eye care in the presence of the facial paralysis is also warranted.

Endolymphatic hydrops (Meniere's disease) is believed to be caused by excessive accumulation of endolymph in the endolymphatic sac secondary to impaired resorption. The exact pathophysiologic mechanism in Meniere's disease remains unknown. Endolymphatic hydrops episodes are typically described as lasting for several hours and are characterized by fluctuating sensorineural hearing loss, vertigo, and tinnitus. Many patients report a sensation of aural fullness during or before an attack. Episodes occur at irregular intervals for many years and may become bilateral as the disease progresses. Late Meniere's disease is characterized by permanent severe sensorineural hearing loss and less severe vertiginous attacks. Treatment is again symptomatic during the acute attacks. Prevention starts with a low-salt (1 to 2 g/day) diet and a diuretic. Advanced cases can be treated with intratympanic gentamicin, shunting procedures, vestibular neurectomy, or labyrinthectomy depending on the progression, hearing, and status of the contralateral ear.

Episodic vertigo associated with perilymph fistula is believed to be caused by a leak of perilymph from the otic capsule, typically from a damaged oval or round window. The intermittent nature of the vertigo and associated sensorineural hearing loss reflects the intermittent leak from the defect and the subsequent exposure of the inner ear to ambient pressure changes. The recently described disorder of superior semicircular canal dehiscence is consistent with the findings of a perilymph fistula and may be considered together for the purposes of this text. The most common etiology for perilymph fistula is trauma to the ear—either direct, surgical, or barometric. Often the vertigo is least noticeable early in the morning or after lying down, then progresses with upright posture and activities through the day. Symptoms are exacerbated by Valsalva maneuvers (nose blowing, heavy lifting, straining, vomiting) and can often be reproduced with pneumatic otoscopy. An inciting traumatic event can often be elicited with a careful history (e.g., diving, head injury, direct ear trauma, childbirth, extreme straining or lifting). Initial management is conser-

vative with bed rest, elevation of the head of the bed, and stool softeners. Many consider perilymph fistula a surgical entity which requires middle ear exploration and patching.

BPPV results from canalolithiasis, an accumulation of otoconial debris displaced into the semicircular canal system (typically the posterior canal), resulting in limited-duration gravity-dependent stimulation with changes in head position. BPPV typically presents as short-duration (seconds) vertiginous episodes associated with changes in head position. Careful questioning may reveal a latency in the onset of vertigo of up to 1 minute after head movement and that predictable changes in head position may routinely precipitate the symptom (e.g., rolling over in bed, looking up to the top shelf). Usually there is no hearing loss. Fatigable horizontal or torsional nystagmus with latency in onset may be reproduced by Dix-Hallpike positioning maneuvers. The Epley or Semont maneuvers can help relocate the debris from the semicircular canal. Patients are instructed to remain upright while sleeping for several days to avoid reaccumulation of displaced particles. In severe cases of BPPV unrelieved by repeated positioning maneuvers, posterior canal occlusion or singular neurectomy may be effective in controlling symptoms.

Chronic middle ear disease, either chronic infection or cholesteatoma, can cause vertigo by local destruction and erosion into the otic capsule, creating a fistula into the perilymph-filled system. The pathophysiology is similar to that of perilymph fistula described earlier. Additionally, serous labyrinthitis associated with the chronic suppurative process may exacerbate vertigo. Chronic middle ear disease classically presents as a persistently draining and painful ear, resistant to multiple courses of topical and systemic antibiotics. The otorrhea is often malodorous in the chronic state. The tympanic membrane is commonly heavily scarred with visible perforation. Pearly-white cholesteatoma matrix may be seen deep to the tympanic membrane remnant. As with perilymph fistula, pneumatic otoscopy may reproduce associated vertigo. Chronic middle ear disease treatment typically involves surgery to remove erosive cholesteatoma or infected tissue, repairing hearing loss and preventing further intratemporal or intracranial complications.

MS flares are often associated with vertigo. The etiology of MS-related vertigo may be plaque formation in the pontine region of the brainstem or proximal eighth nerve. Central vertigo may result from interruption of the medial longitudinal fasciculus, which causes disconjugate eye movements (internuclear ophthalmoplegia). MS is characterized by the episodic development of neurologic deficits. Vertigo and sensorineural hearing loss may fluctuate over time as plaques are formed. Nearly half of patients with MS present with vertigo at some point, and careful examination often reveals internuclear ophthalmoplegia, an ipsilateral adducting extraocular muscle deficit with

contralateral abducting nystagmus. An MS flare involving vertigo typically persists for days to weeks before adequate central compensation is achieved. MS often responds to high-dose pulse of corticosteroids with shortened duration of symptoms. Additionally, gabapentin may reduce resulting nystagmus and vertigo.

Migraine may produce vertigo through poorly understood mechanisms. Vertigo may precede the headache (aura equivalent) or replace it (migraine equivalent). Recent genetic discoveries in migraine research have implicated ion channel mutations as a potential link with the vestibular system; however, the definitive pathophysiologic explanation remains elusive. Vertigo associated with migraine is difficult to categorize. It may replace the aura of the migraine or the headache itself, or it may happen in the interval between headaches. The duration of migraine-associated vertigo is highly variable, lasting from hours to days and, in women, may show correlation to menstrual cycle. Severe cases may awaken the patient from sleep and are often associated with nausea and vomiting. There is usually a strong family history of migraines and no other neurologic deficits are typically noted during an episode. Migraine therapy involves behavioral as well as pharmacologic interventions. Serotonin receptor antagonists have proved effective as aborting agents and prophylaxis has been demonstrated for β -blockers, tricyclic antidepressants, valproic acid, and calcium channel blockers (see Chapter 124).

Vascular disease in the vertebrobasilar system may induce vertigo by compromising posterior circulation through occlusive or embolic processes. The most commonly affected arteries are the anterior-inferior cerebellar artery, posterior-inferior cerebellar artery, and superior cerebellar artery. Severe arthritic changes to the cervical spine are thought to be related to vascular insufficiency in the vertebrobasilar system. Additionally, there is evidence that aberrant vessel anatomy may compress the eighth nerve complex, resulting in vertigo and pulsatile tinnitus. Occlusive or embolic vascular disease affecting the posterior circulation often results in severe postural instability, direction-shifting nystagmus without suppression by visual fixation, and multiple neurologic findings, particularly if the brainstem is involved. Vascular insufficiency is typically associated with a lightheaded or presyncopal sensation exacerbated by neck extension with no related hearing loss. By contrast, vascular compression or impingement of the eighth nerve complex presents typically as pulsatile tinnitus with hypacusis, often exacerbated by head position. Vertigo in this case is a result of progressive functional loss and is usually less severe because of central compensation. Vertigo attributed to vascular disease requires addressing risk factors as well as instituting antiplatelet therapy. For significant stenosis, anticoagulation with warfarin may be considered.

Vestibular schwannomas (incorrectly called acoustic neuromas) are benign tumors arising from the vestibular

nerve that eventually encroach on other structures in the internal auditory canal and cerebellopontine angle. Typically, there is increased vestibular deficit and sensorineural hearing loss with increasing tumor size and local compression. Vestibular schwannomas most often present as progressive unilateral sensorineural hearing loss with symptoms of imbalance and tinnitus. The vestibular system often is able to compensate over time for the tumor growth, and thus, vertigo is often absent. The hearing loss may be sudden in up to 20% of patients. With large tumors, ipsilateral facial nerve function may be compromised. Vestibular schwannoma may be treated with surgical resection. Stereotactic radiotherapy is an alternative mode of treatment and may be considered if surgery is not desired or the patient would be at high risk for a general anesthetic.

Other brainstem neoplasms involving the cerebellopontine angle (meningiomas, epidermoids, lipomas, gliomas, astrocytomas) may cause vertigo. The etiology of the vertigo is usually compression of adjacent structures, either by direct extension of the neoplasm on the eighth nerve complex and brainstem or resulting hydrocephalus. Brainstem neoplasms presenting with vertigo tend to be large and have symptoms of cerebellar compression and hydrocephalus. Hearing loss is often associated, and patients may complain of otalgia, diplopia, and headaches. Brainstem neoplasms causing vertigo usually require resection and adjunctive therapy, the details of which depend on the histopathology of the neoplasm.

Avoiding Treatment Errors

The most important elements in the evaluation of the patient with dizziness are the clinical history and a thorough physical examination. Accurately distinguishing true vertigo from other types of dizziness such as unsteadiness, imbalance, or lightheadedness is the most critical aspect of the history and the most effective way to avoid an error in diagnosis and treatment. Once true vertigo is confirmed, it is important to have a detailed description of the episodes, most importantly the time course of the actual spinning sensation. When the neurotologic evaluation is negative, the patient should be evaluated for potential cardiovascular, metabolic, or neurologic pathologies.

Future Directions

A detailed understanding of the vestibular system and its pathophysiology is essential for the treatment of the vertiginous patient. The diagnosis still hinges heavily on the history of symptoms, but several areas show promise for future research. Reliable objective testing for

perilymph fistula could streamline its diagnosis and treatment. Improved imaging modalities could pinpoint vascular lesions without the present risks of invasive angiography. Research into the underlying pathophysiology of Meniere's disease continues and may one day explain its constellation of findings. Even as more discoveries are made, patients with vertigo will continue to challenge the clinician's knowledge and skills.

Sleep Disorders

Introduction

Sleep is the reversible physiologic state of decreased responsiveness to the environment that is achieved by neuronal networks of the brain. Although the underlying purpose remains a mystery, sleep promotes higher levels of wakefulness and cognition, and sleep loss increases the likelihood of accidents, increases health costs, and lowers workplace productivity and quality of life.

One-in-three individuals will present with a sleep-related complaint to their physician. In the second edition of the International Classification of Sleep Disorders, sleep disorders are categorized into insomnias, hypersomnias, sleep-related breathing disorders, circadian rhythm disorders, parasomnias, sleep-related movement disorders, and other sleep disorders, including medical and psychiatric disorders. These disorders result in complaints of excessive daytime sleepiness and difficulty initiating or maintaining sleep or events associated with sleep (Boxes 127-1 and 127-2).

Etiology and Pathogenesis

The state of sleep is determined by symphony of neuronal processes. Sleep is typically divided into stages based on electroencephalogram (EEG) features, eye movements (electro-oculography), and muscle tone (electromyogram). Stages N1 to N3 are called collectively *non-rapid eye movement* (NREM) sleep. Stage N1 sleep is frequently associated with the perception of drowsiness and is characterized by EEG features of mild slowing and Vertex sharp waves. Stage N2 (light sleep) is characterized by the presence of K complexes or sleep spindles. In stage N3 (deep sleep), high-amplitude slow waves predominate the EEG activity. *Rapid eye movement* (REM) sleep or stage R is characterized by a low-amplitude, mixed-frequency pattern on EEG, absence of muscle tone in voluntary muscles, and intermittent REM. Dreams can occur in all stages of sleep but are more vividly recalled from REM sleep. All these stages have other physiologic correlates; NREM sleep has relatively constant respiration, cardiac rhythm, and autonomic function, whereas REM sleep demonstrates variation in respiration, cardiac function, and an absence of thermal regulation.

Healthy adults display a reproducible pattern of sleep organization. They enter sleep through stage N1, progress to stage N2, and after 20 to 30 minutes progress to stage N3, followed by reemergence of stage N2 sleep. The first

REM sleep period occurs after 90 minutes. This pattern repeats about every 90 minutes throughout the sleep period with progressively less stage N3 sleep and longer periods of REM sleep in each cycle.

Both extrinsic and intrinsic factors may contribute to disordered sleep. Extrinsic factors disrupting sleep include environmental disturbances such as noise, uncomfortable setting, or bright light. Intrinsic disorders are prompted by an internal disruption associated with sleep. Obstructive sleep apnea (OSA) and periodic limb movements of sleep are excellent examples of disorders that become evident once the central nervous system (CNS) has entered the sleep state. OSA is associated with narrowing of the upper airway related to either a structural issue or relaxation of airway dilator muscles. Periodic limb movements of sleep appear to be related to unsuppressed excitation of spinal cord processes causing repetitive limb movement occurring every 10 to 120 seconds during sleep. Other sleep disorders such as narcolepsy are abnormalities in the mechanism of sleep-wake differentiation. Narcolepsy with cataplexy has a strong linkage to HLA DQB1*0602 and DR2 (DR15) major histocompatibility complex and is linked to a depletion of orexin-hypocretin-producing neurons in the hypothalamus.

Alteration of the circadian rhythm can also disrupt sleep-wake determination. This internal clock allows for the body to anticipate periods that are likely to be active

Box 127-1 Sleep Disorders**Intrinsic Sleep Disorders**

Obstructive sleep apnea
 Primary central sleep apnea

or inactive; thus, certain times of the day, such as 4:00 AM, are associated with a greater circadian pressure to sleep. A complex interaction of genes and proteins produce this chemical rhythm, which can be influenced by many external stimuli, including bright light, activity level, and social interactions.

Clinical Presentation

Typically, patients with sleep issues present with one of three major complaints: excessive daytime sleepiness; difficulty initiating or maintaining sleep; or unusual events occurring during the night. Patients may focus on one symptom yet have features that suggest several underlying processes. The following are commonly recognized sleep disorders.

Sleep Deprivation

Chronic reduction in total sleep time interferes with normal daytime function. Most commonly, sleep deprivation

tion is voluntary and a result of societal pressures for adults to perform more with less time for sleep. Sleep debt may accumulate over years. This unmet sleep need increases the likelihood for an individual to fall asleep at inappropriate times such as during work or driving, decreasing productivity and increasing risk for accidents. The physiologic effects of sleep deprivation also increase appetite, promote weight gain, and worsen mood.

Sleep Apnea

Sleep apnea is characterized by repetitive stoppage of breathing and sleep fragmentation. Typically, sleep apnea appears in two forms: obstructive and central. OSA is associated with narrowing of the upper airway, which causes turbulent air flow that results in snoring, loud snorts, or gasps during sleep. Typically, these patients are overweight, but many patients with OSA can have relatively normal body habitus. These patients may have large necks or crowded airways. The disorder is associated with increased risk for hypertension, diabetes, and recurrence of vascular events. Central sleep apnea, characterized by repetitive episodes of the absence of movement of the lower respiratory muscles, is associated with a pause in breathing. Both disorders may cause the patient to have

Figure 127-1 Sleep Disorders.

hundreds of brief arousals per night, which lead to insomnia or excessive daytime sleepiness.

Narcolepsy

Narcolepsy is a disorder of the on/off control of NREM and REM sleep. This disorder is nonprogressive and typically appears in early adolescence. Patients have bouts of irresistible intrusions of sleep throughout the day. The traditional tetrad of symptoms is excessive daytime sleepi-

ness, cataplexy, sleep paralysis, and hypnagogic hallucinations (Fig. 127-1); however, insomnia and sleep disruption are common complaints. Excessive daytime sleepiness occurs despite a relatively normal total sleep time and may be described as uncontrollable bouts of sleep (“sleep attacks”). Cataplexy is an abrupt decrease in muscle tone without loss of consciousness and is provoked by strong emotional stimuli or exercise. Individuals may fall, or experience mild to severe degree of weakness. Sleep paralysis occurs in the transition from sleep to wakefulness with the

retention of the atonia of REM sleep. These events can be accompanied with the feeling of impending doom and hallucinations. Hypnagogic hallucinations are visual imagery just before the onset of sleep that may be difficult to distinguish from reality. Most patients do not exhibit the complete tetrad.

Restless Legs Syndrome

Restless legs syndrome is a disorder associated with discomfort in the legs (less often, the arms) and includes sensations of crawling, wiggling, and electrical features. These symptoms must be worse with rest and improve with movement and are more prevalent during the evening. This disorder is sometimes associated with periodic limb movements. Periodic limb movements of sleep are repetitive stereotyped movements of the upper or lower extremities lasting 0.5 to 4.0 seconds, occurring at 20- to 120-second intervals, and sometimes associated with arousals. Patients may be unaware of the movements and have no sleep complaints, but bed partners may note the movements. Iron-deficiency anemia, uremia, peripheral vascular disease, arthritis, peripheral neuropathy, and spinal cord lesions have been associated with both disorders. The use of tricyclic antidepressants, selective serotonin reuptake inhibitors, dopamine antagonists, and caffeine may exacerbate sensory and motor phenomena.

Circadian Rhythm Disorders

The desynchronization of behavioral and neural sleep cycles may result in excessive daytime sleepiness or disrupted nocturnal sleep. Most individuals experience some of these symptoms with abruptly changing time zones or work schedule, but others have chronic desynchronization of the body clock with their surrounding environment. Delayed sleep phase type, characterized by an inability to fall asleep until past midnight and trouble waking in the morning, is seen commonly in adolescents. Advanced sleep phase type is more common among elderly individuals who fall asleep early in the evening and awake in the early morning hours. Individuals with a free running schedule have a lack of entrainment of the endogenous 24.3-hour circadian clock. This is most common in patients who are blind. Other patients with hypothalamic dysfunction may have an irregular sleep wake schedule owing to a loss of the rhythm generators.

Primary Disorders of Initiation or Maintenance of Sleep

Insomnia is the difficulty initiating or maintaining sleep, combined with daytime sleepiness, fatigue, or impairment of daytime performance. Most adults have occasional nights of poor sleep, which are often linked to daytime

events or sudden changes in medical condition. For a smaller group of patients, insomnia persists for weeks, months, or years and leads to significant psychological and medical symptoms. Primary insomnias account for more than one third of insomnia cases. Psychophysiological insomnia is characterized by somatized tension and learned sleep-preventing associations; individuals typically sleep well in a new environment away from associations that remind them of the difficulty of sleeping. Paradoxical insomnia is the inability to recognize the occurrence of sleep. Patients have normal sleep as measured by polysomnography, but report being unaware that they have slept. Idiopathic insomnia, an abnormality in the neuronal ability to attain adequate sleep, typically starts in childhood and persists as fragmented and unrefreshing sleep.

Nocturnal Events

Nocturnal events occur in about 3% of the adult population. Not all nocturnal events are parasomnias; some can be related to other non-sleep-related disorders. Parasomnias, however, present either as disorders of arousals from NREM sleep (sleep walking, sleep terrors, or confusional arousals) or REM-related events (REM sleep behavior disorder). The disorders of arousal typically occur as partial arousals from the deeper stages of NREM sleep. REM sleep behavior disorder is related to the loss of atonia during REM sleep. This disorder is associated with a higher risk for developing Parkinson's disease, Lewy body dementia, or multisystem atrophy. Other parasomnias can occur as events that are present during the transition from wake to sleep. Other disorders such as epilepsy or psychological events can occur at night as a result of changes in neurophysiology, which make those pathologic events more likely to appear.

Differential Diagnosis

The differential diagnosis is divided into intrinsic sleep disorders, extrinsic sleep disorders, and medical and psychiatric disorders (see Boxes 127-1 and 127-2). Patients with sleep apnea, periodic leg movements of sleep, and circadian rhythm disorders may or may not complain of sleepiness despite severe sleep disruption. Patients with medical disorders such as congestive heart failure, renal failure, arthritis, and pain syndromes may complain of poor sleep or fatigue. Psychiatric disorders are often preceded by insomnia; frequently, sleep disturbance outlasts the mood disturbance of affective disorders.

Nocturnal events may be difficult to distinguish. Key features such as time of the events, memory for the events, and stereotypic behavior help distinguish the events and allow for the clinician to guide the evaluation (Table 127-1). Clinicians should always be careful to screen these patients for other sleep disorders that may provoke nocturnal events.

Table 127-1 Distinguishing Features of Nocturnal Events

Feature	NREM Parasomnia	REM Behavior Disorder	Nocturnal Seizures	Psychogenic Events
Time of occurrence	First third of the night	During REM	Anytime	Anytime
Memory of event	Usually none	Dream recall	Usually none; may have memory	Usually none
Stereotypical movements	No	No	Yes	No
Polysomnographic findings	Arousals from deep NREM sleep	Excessive EMG tone during REM	Potentially epileptiform activity	Occur from awake state

EMG, electromyogram; NREM, non-rapid eye movement; REM, rapid eye movement.

Diagnostic Approach

The diagnostic evaluation should focus on several key points. Complaints should be separated into categories of excessive daytime sleepiness, insomnia, or unusual events at night. A detailed history is crucial, including information regarding the clinical course, the degree of impact, the sleep-wake pattern, perception of sleep quality, report from bed partner, dietary habits (especially caffeine and alcohol intake), activity changes, drug use (including over-the-counter agents, herbal and home remedies), and medical conditions. Clinicians should look for potential causes of sleep disturbance from four groups—intrinsic sleep disorder, extrinsic sleep disturbance, circadian rhythm disorder, and other medical, neurologic, or psychiatric disorders—and should consider the potential for multiple participating etiologies.

To sleep well, one needs a conducive environment, psychological preparedness for sleep, an adequate sleep period, and the neurophysiologic mechanisms for sleep. Most patients with chronic insomnia have a set of factors that predispose, initiate, and perpetuate insomnia. Gender, age, and coping mechanisms may predispose one to insomnia, whereas poor sleep hygiene, substance abuse, and performance anxiety may perpetuate it. Patients must be questioned for cardinal symptoms of sleep disorders, such as snoring, leg kicking, or sleep-related activities.

Many disorders can be elucidated with objective evaluation. Clinicians should consider referring patients with sleep complaints for polysomnography at a qualified sleep laboratory when they have symptoms suggestive of sleep-related breathing disorder (snoring, gasping), movement disorder, narcolepsy, paroxysmal arousals, or behaviors that are potentially injurious or atypical for parasomnia (Box 127-3). Patients being evaluated for excessive daytime sleepiness may require a multiple sleep latency test (MSLT) to measure the degree of daytime sleepiness and the potential to enter REM sleep inappropriately during the day such as in narcolepsy. Other tests such as the maintenance of wakefulness test (MWT) can measure the degree to which a subject can stay awake. This test is required for individuals with sleep disorders and certain occupations

Box 127-3 Primary Indications for Polysomnography

1. Snoring with complaint of excessive daytime sleepiness, insomnia, or nocturnal events
2. Snoring with history of vascular disease
3. Excessive daytime sleepiness despite adequate sleep time
4. Disruptive or potentially injurious nocturnal events
5. Intractable insomnia

(truck drivers, pilots). Although the MSLT and MWT are very similar tests, patients may have significant different abilities in falling asleep and remaining awake. Therefore, each test should be used to obtain specific information.

Management and Therapy

Optimum Treatment

The management of patients with sleep disorders requires close follow-up and clearly established therapeutic goals. Clinicians should identify and resolve issues of extrinsic sleep disruption before proceeding with expensive polysomnographic investigations. Through identification of underlying causes, directed therapeutic interventions are more likely to result in success. For example, OSA is traditionally treated with continuous positive airway pressure (CPAP) or, in more difficult cases, bilevel positive airway pressure. These therapies are dependent on the patient wearing the mask every night; thus, mask comfort is very important. Alternative therapies include oral devices and surgeries. These require identification of patients with characteristics favorable for each of these therapies but provide options for those patients unable to tolerate CPAP therapy. Patients with restless legs syndrome may be treated with an array of medications, including dopamine agonists, gabapentin, opiates, and benzodiazepines, but require close observation for worsening symptoms. CNS-active medications should be used to affect specific neurochemical processes. Stimulants, such as caffeine,

methylphenidate, dextroamphetamine, and modafinil, have been used to treat the excessive sleepiness in narcolepsy or idiopathic hypersomnolence. Benzodiazepine receptor agonists (esopiclone, zolpidem, and zaleplon) and new melatonin agonists are approved for the treatment of insomnia with fewer psychomotor side effects and lower the chance of rebound insomnia compared with older hypnotics. For primary insomnia, behavioral modification and cognitive therapies show the greatest long-term success. Additionally, patients with circadian issues may augment or alter the sleep-wake clock by using bright light exposure and exercise at specific times to reinforce the timing of wakefulness. Most patients need clinical monitoring and education to reinforce therapies and behaviors conducive to good sleep.

Avoiding Treatment Errors

Our current societal view places low emphasis on adequate sleep. For some physicians, this view extends into their treatment of sleep disorders. Clinicians should view sleep complaints as opportunities to explore issues that may have long-term social and health consequences. These complaints should be approached with a logical delineation of the underlying etiologies, and treatment should be focused on those etiologies. Frequently, physicians may treat the symptoms of the disorder without adequately investigating the cause. Although the patients may initially derive benefit, long-term benefit is more likely to develop from a directed therapeutic approach.

Future Directions

Our understanding of the mechanisms involved in determining the sleep-wake state is rapidly expanding. Application of molecular biologic techniques to determine novel neuroactive substances and receptors has opened new understanding of state determination. Understanding these mechanisms provides opportunities for molecularly targeted therapies to manipulate sleep and wake states.

Epilepsy

Introduction

Epilepsy has been described for more than 2500 years. Hippocrates, in his manuscript “On the Sacred Disease,” described detailed seizure types and localized seizures as a disorder of the brain. The term *epilepsy* is a derivative of the Greek word for “to take hold of”: *epilepsia*. Throughout time, individuals with epilepsy have been regarded as having special powers or being possessed. Yet historical figures such as Julius Caesar, van Gogh, Napoleon, and Dostoyevsky, who lived with epilepsy, demonstrate that individuals with epilepsy can make tremendous contributions.

Etiology and Pathogenesis

The broad definition of seizure includes any sudden onset of morbid symptoms. This includes syncope, cataplexy, and even psychogenic events. However, epileptic seizures, a more narrowly defined paroxysmal form of seizures, are events resulting from excessive pathologic synchronous neuronal activity in a large population of neurons. Epileptic seizures are one of the most common symptoms of disturbed brain function. About 10% of the population will have a seizure by age 80 years. Some seizures are self-limited as part of an acute medical condition, illness, or exposure to epileptogenic substances, whereas other epileptic seizures are a sign of abnormal neuronal physiology and networks.

Epilepsy is a chronic disorder that is hallmarked by recurrent, unprovoked seizures. Thus, the diagnosis of epilepsy is based on historical features and can be made after the second unprovoked epileptic seizure. The patient with epilepsy may have multiple seizure types. A patient with juvenile myoclonic epilepsy, for example, may display absence, generalized tonic-clonic, and myoclonic seizures. Yet, all of these seizure types occur in one type of epilepsy.

Classification of Seizures

Seizures are classified by behavioral symptomatology (semiology) and electroencephalographic data (Box 128-1). Seizures are fundamentally of two types: focal onset

(partial) and diffuse onset (primary generalized). About two thirds of epilepsy patients have partial seizures. Partial seizures are further divided into simple partial and complex partial. Simple partial seizures are defined by the retention of consciousness or memory. Complex partial seizures are defined by the impairment of consciousness or the loss of memory during the seizure. Focal-onset seizures may also evolve into generalized seizures, and these secondarily generalized seizures are the most common generalized seizures in adults.

Primary generalized seizures begin simultaneously across the whole brain and may comprise various types of behavior. Behavioral pauses associated with a three-per-second generalized spike-and-wave discharge characterize absence seizures. These seizures typically occur in children, last less than 20 seconds, and are associated with no postictal confusion. A sudden loss of muscle tone characterizes atonic seizures. An atonic seizure often causes patients to fall and sustain injuries. Tonic seizures are seizures that produce generalized stiffening. Patients with tonic seizures also frequently fall. The behaviors observed during clonic seizures are repetitive quick jerks with a slow relaxation phase. Tonic seizures may develop into clonic seizures, and clonic seizures may progress into tonic and then clonic seizures. Single quick jerks of the whole or a portion of the body characterize myoclonic seizures. The minority of myoclonus is of cortical origin, so that myoclonus often does not have an electroencephalogram (EEG) correlate. Only myoclonus with an EEG correlate is considered epileptic.

Classification of Epilepsy

The classification of the epilepsies is based on age, family history, the seizure types, associated clinical findings, and laboratory abnormalities, especially the EEG characteristics and neuroimaging abnormalities. Etiology, anatomic correlates, age at onset, associated neurologic signs, precipitating factors, prognosis, circadian cycles, and seizure type are important features used in the classification of epilepsy. The epilepsies are divided into two principle groups: localization-related and generalized events. Box 128-2 shows the current epilepsy classification. Plans are underway to revise this classification.

Causes of Seizures and Epilepsy

Focal seizures begin as an autonomous electrochemical discharge of a group of neurons that recruit surrounding neurons into a rhythmical firing pattern. Although many theories have been postulated about how focal seizures begin, most likely multiple factors are responsible. At the cellular level, the characteristic interictal abnormality of an epileptic focus is the paroxysmal depolarization shift (PDS). The PDS is an abnormal cellular event characterized intracellularly by a large membrane depolarization, which produces a burst of action potentials followed by hyperpolarization of the neuron. On the surface of the brain or scalp, the PDS is seen as a spike followed by a

slow wave. With the occurrence of a seizure, the intracellular depolarization and bursting persist, and no hyperpolarization occurs. A clinical seizure occurs only when a large number of neurons synchronously display this activity. The spread of seizures from the focus is usually prevented by a surround inhibition manifested intracellularly by hyperpolarization of the neurons. This inhibition is mediated predominately by γ -aminobutyric acid. The mechanisms of the generalized epilepsies involve many neurons in a large portion of the brain.

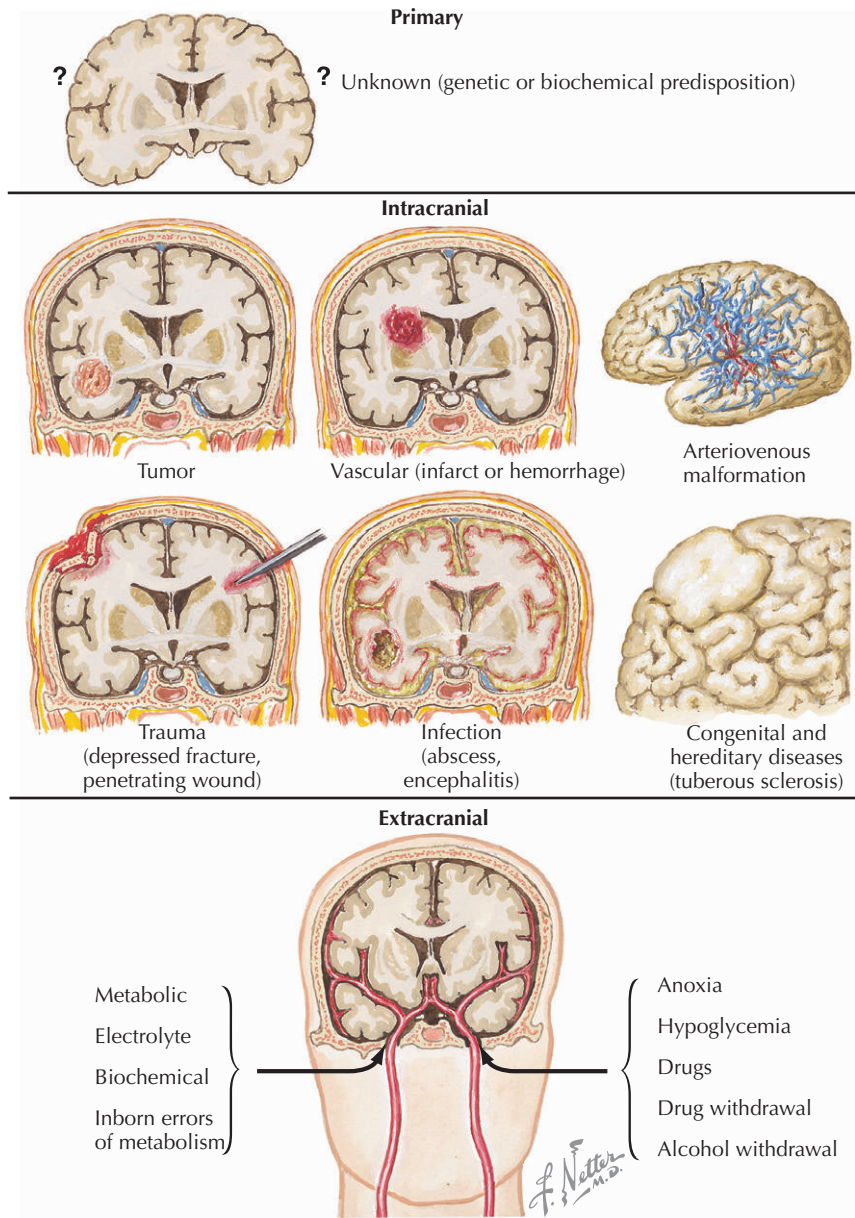

Potential causes that lead to these epileptic changes can be potentially age dependent. The age of onset may give clues to the underlying cause of the seizures and epilepsy. Yet, any significant injury to cortical structures can produce seizures. These injuries may come in the form of tumor, stroke, hemorrhage, infection, or trauma (Fig. 128-1). More than two thirds of patients have no clear cause of their seizures. The most common identifiable causes are listed below by age (Box 128-3).

Most of the epilepsies with defined gene abnormalities have abnormalities of membrane channels. Only a few of the known genetic causes of epilepsy are abnormalities of neurotransmitters (Table 128-1).

Clinical Presentation

Individuals with epilepsy present with a wide variety of symptoms. The key clinical feature of a seizure is the paroxysmal nature of discrete stereotypic symptoms or signs. An accurate description of a seizure may require reports from many sources and at times even a videotape of the events because the patient may be unaware of the events and most seizures last less than 5 minutes.

Figure 128-1 Causes of Seizures.

Partial Seizures

The behavior exhibited during a seizure is determined by the pathophysiologic events in the region of affected brain (Fig. 128-2). Nearly any function performed by the brain may occur as part of a seizure. These symptoms range from motor and sensory involvement to complex automatisms or hallucinations. The symptoms or behaviors associated with the seizures are a manifestation of the area of brain being excited by the seizure. Thus, a patient with occipital lobe seizures may have visual symptoms, or a patient with temporal lobe seizures may smell something burning or

have a rising sensation in their chest. Patients with frontal lobe seizures may have unusual motor manifestations such as turning or bicycling movements. Patients frequently may have automatisms. Automatisms are repetitive motor activities that are purposeless, undirected, and inappropriate and that can be done without awareness. Patients may exhibit lip smacking, sucking, swallowing, chewing, repetitive hand movement, picking at clothes, or fidgeting. Following the seizure, patients are frequently confused and disoriented; this is called the *postictal period*. These symptoms and behaviors are important in helping to define the seizure type and subsequent therapy.

Primary Generalized Seizure

Generalized seizures involve both cerebral hemispheres from the onset. The expression of generalized seizures requires the interaction of cerebral hemispheres, thalamus, and possibly the brainstem.

Generalized seizures are subcategorized into several specific types. The most common form is generalized

tonic-clonic convulsion (previously called grand mal) (Fig. 128-3). These seizures begin as tonic stiffening of the limbs in the extended position, followed by synchronous clonic jerking of the muscles. Occasionally, patients have pure tonic or pure clonic seizures. After the seizure, the patient is very lethargic, confused, and disoriented.

Absence seizures (previously called petit mal) are characterized by staring spells lasting less than 20 seconds and often associated with eye blinking (Fig. 128-4). Patients have no warning of oncoming seizures and also have no postictal period. Frequently, they have no memory of the event but may note a brief loss of time. Patients usually have hundreds of these per day. These seizures usually occur in children and many times are first noticed in school. Hyperventilation frequently can be used to provoke absence seizures. The characteristic generalized three-per-second spike-and-wave pattern on EEG is the hallmark for this seizure type.

Atonic seizures are composed of drop attacks or brief periods of loss of postural body tone. Patients may have clusters of atonic seizures causing injury from the falls. These patients frequently have to wear helmets to avoid serious head injury.

Myoclonic seizures are rapid, brief, usually bisynchronous contractions of the musculature. Patients may have frequent jerks occurring in bursts and have minimal impairment of consciousness.

Differential Diagnosis

The differential diagnosis for paroxysmal events can be divided into several categories: vasculature, endocrine, metabolic, neurologic, and psychiatric events (Table 128-2). The clinician should use a relatively wide differential before presuming the diagnosis. Frequently, nonepileptic paroxysmal events can be misinterpreted as epileptic seizures.

Diagnostic Approach

The goals of the evaluation of the patient with seizures are to identify the type of seizure that occurred, look for potential causes, elucidate possible risk factors that may promote recurrence, review the previous therapies, define the psychological and psychosocial impact of seizures on the patient, and recognize the patient's goals. The history is the most important feature of the evaluation. A clear description of the events as witnessed by an observer increases the likelihood of obtaining a correct diagnosis. The physician should pay particular attention to events leading up to the seizures, during the seizures, and following the seizures. The patients may have certain risk factors such as significant head trauma, stroke, family history of seizures, febrile seizures, or developmental delay. The physical examination should focus on the cardiac and

vascular system, and a complete neurologic examination should be performed. Most patients with epilepsy have a normal neurologic examination, so the absence of neurologic deficits does not exclude the diagnosis.

All patients with epilepsy should have had an EEG. This study records the electrical fields generated over the scalp. Although about 40% of patients with epilepsy have a normal routine EEG, a second EEG performed with the subject asleep or sleep deprived increases the yield of abnormalities to 80%. The classic epileptiform abnormalities found on the EEG are spikes, sharp waves, or spike and slow wave complexes. These waveforms are the elec-

trical signature of epilepsy. Nevertheless, the incidence of these abnormalities in people without seizures may be as high as 2%.

Patients with possible focal-onset epilepsy should have an MRI study of the brain. This study can demonstrate the cortex in great detail and allow for the detection of small structural abnormalities.

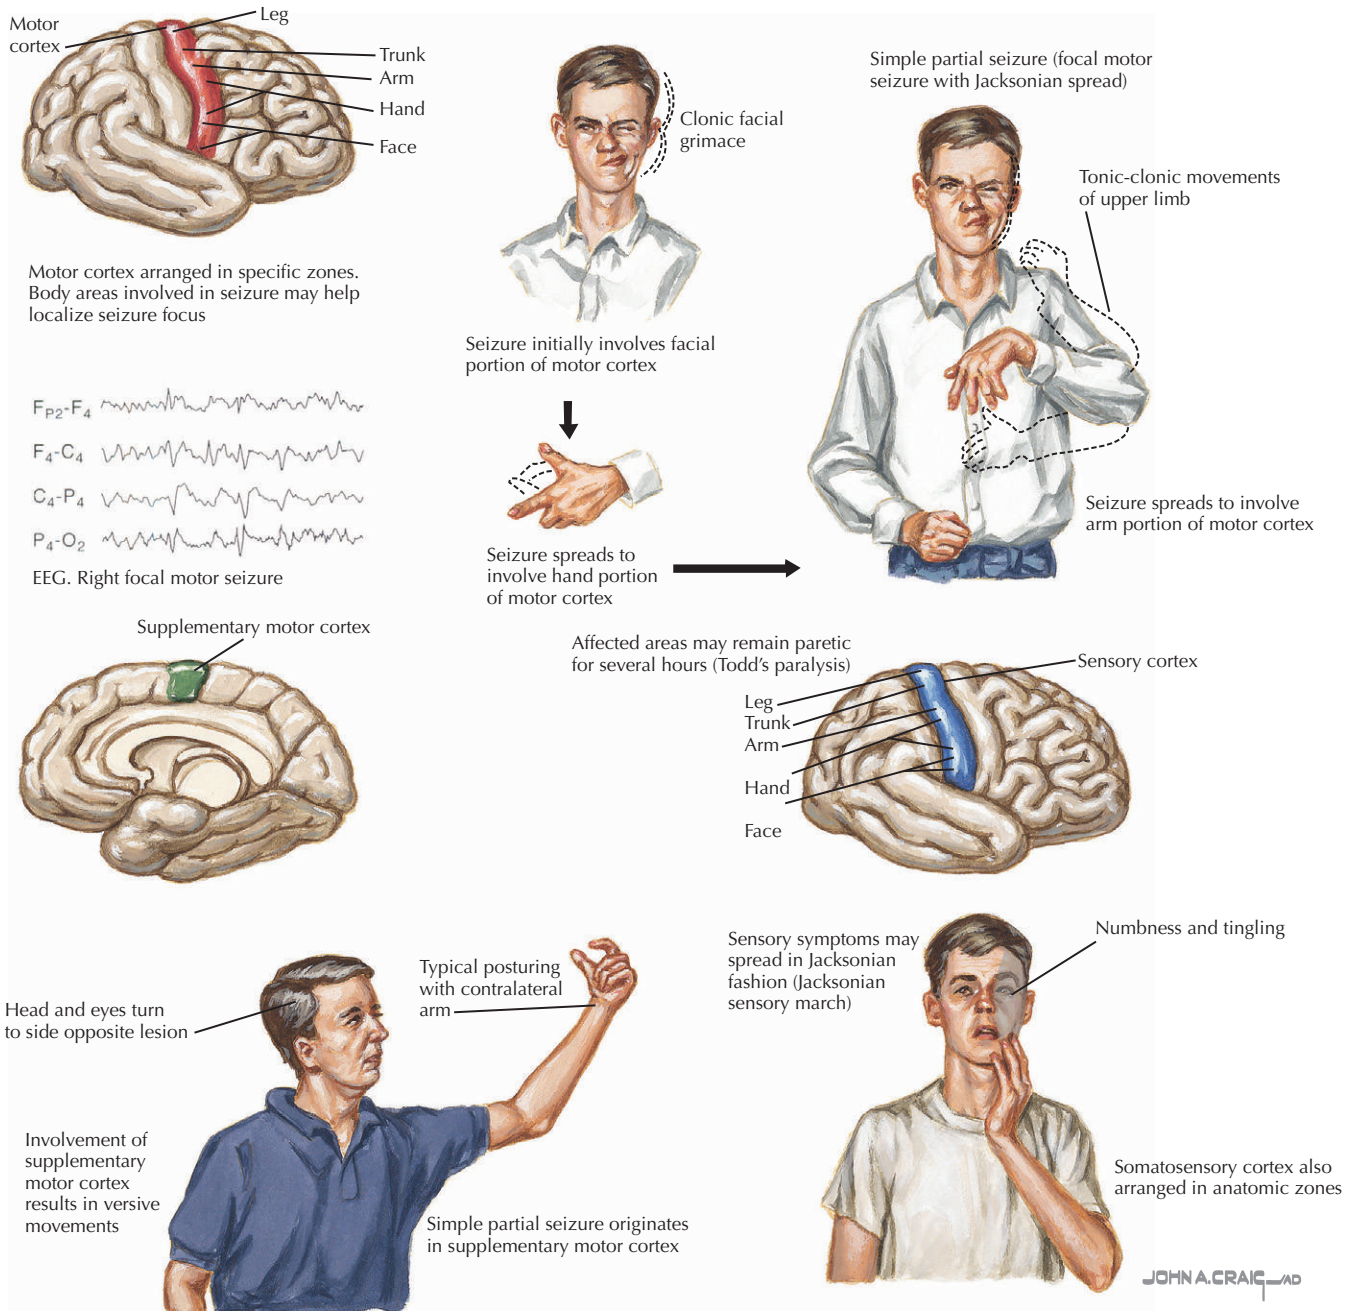

Management and Therapy

Optimum Treatment

The goals for managing a patient with epilepsy are to have the patient completely seizure free, with no side effects of therapy, and to reverse any untoward effects of the epilepsy. These goals are not obtainable in all patients but should be strived for. Between 20% to 44% of patients with epilepsy do not achieve complete control of their seizures with medication. The general principles of medication therapy are to start a single medication at a low dose, slowly titrating the medication till one of two end points is reached: either the patient is seizure free, or the patient has untoward side effects that do not abate with drug manipulation. If the first medication does not succeed, a second medication is added and titrated to an efficacious dose before the tapering off of the first medication. Medications should be given ample trial time especially to allow side effects to improve with time. A list of medications is provided in Box 128-4.

If medications do not prove helpful, the physician should consider reevaluating the patient. Confirmation

Figure 128-2 Partial Motor and Somatosensory Seizures.

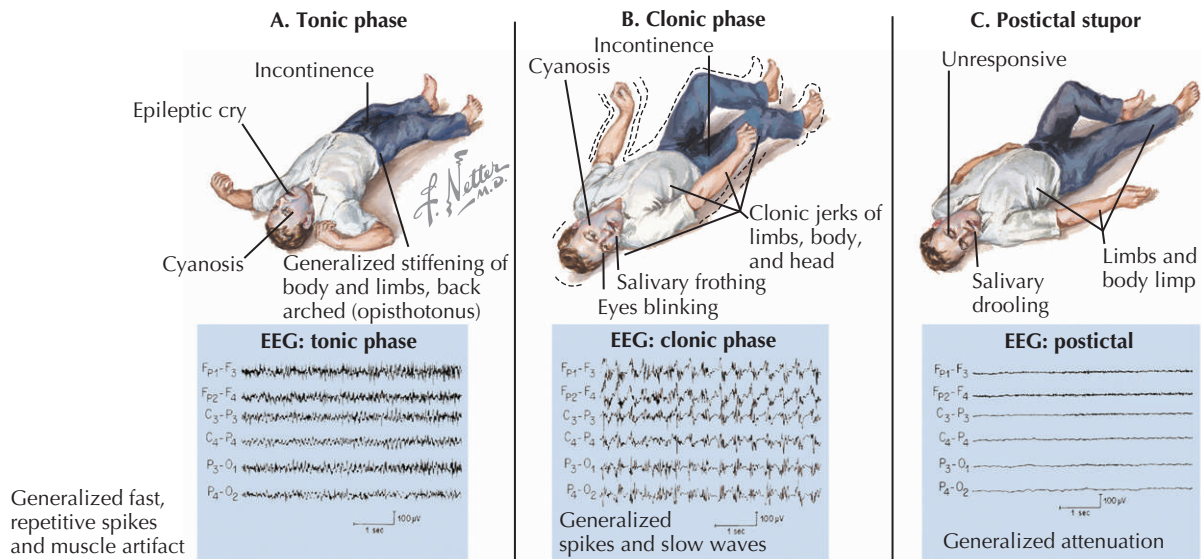

of the diagnosis with video EEG monitoring may prove helpful. Additionally, this monitoring may demonstrate whether the patient would be a candidate for potential evaluation for epilepsy surgery. Resection of the epileptic focus in some cases can cure the epilepsy. Success rates as high as 85% have been reported in resection of the seizure foci from the temporal lobes. Unfortunately, resections from other areas of the brain have not been as fruitful. Alternatively, neuronal stimulation therapy is available.

The vagus nerve stimulator is a proven therapy for patients with intractable epilepsy.

Avoiding Treatment Errors

The most common treatment error is that physicians fail to be aggressive enough to completely stop recurrent seizures. For patients to have a significant improvement in quality of life, they must be seizure free. Therefore, one

seizure per year still impairs one's life. Antiepileptic medication should be gradually increased until the patient is seizure free or incurs a side effect. Physicians must also realize that serum drug levels only reflect the amount of drug in the blood, not the amount of drug in the brain, which is the organ being treated. The therapeutic range is only a guideline, not an absolute. Patients may have seizures while in the lower therapeutic range but remain seizure free with a higher level. Conversely, patients may experience side effects at a serum level below the therapeutic range. Thus, the clinician must follow the patient's symptoms and the clinical exam to determine whether the drug dosage needs to be changed.

Future Directions

Epilepsy research is striving toward curing epilepsy and the epileptic process. Although seizures are the defining component of the epilepsies, further research is needed to completely characterize the effect the epileptic process has on the brain and body. Development of new therapies that selectively treat the neurons participating in the seizure focus, while not altering normal brain function, will ultimately provide a key for us to unlock the mysteries of neuronal networking and plasticity. Additional approaches of gene manipulation and selective brain stimulation of epileptic networks using closed-loop computer integrated processors offer novel mechanisms to alter brain dysfunction and augment brain restoration.

Tremor

Introduction

Tremor is defined as involuntary, rhythmical oscillations of a body part. The involved body part can be proximal (e.g., head tremor) or distal (e.g., hand tremors). The tremor may be fine or coarse, fast or slow; it may exist at rest, when maintaining a posture, or with movement. A unified clinical classification was lacking until the 1998 Movement Disorder Society consensus paper on clinical classification that serves as a guide for this chapter.

Etiology and Pathogenesis

Tremor is a nonspecific finding that can result from a variety of nervous system lesions and a number of underlying disease processes. Lesions in the basal ganglia, the cerebellum, or certain areas of the brainstem are particularly likely to result in tremor. Some fairly common tremors have no clear localization (see later) and a number have metabolic or toxic causes.

Clinical Presentation

Observation is a key to identify the etiology and should include a description of the body parts involved (e.g., upper or lower limbs, lips, tongue, neck, or voice), type of tremor (e.g., rest tremor, postural tremor, or action tremor), tremor frequency (e.g., low [<4 Hz], medium [4 to 7 Hz], or high [>7 Hz]), and the factors that exacerbate or suppress the tremor.

Phenomenology of Tremor

Physiologic Tremor

An 8- to 12-Hz tremor is inherent in the normal nervous system. It is the result of physiologic subtetanic recruitment of motor units and is not generally clinically obvious. When muscle contractions are maintained, as when the arms are held outstretched, especially with a paper on top, the physiologic tremor (PT) becomes visible to the naked eye. Enhanced PT involves more prominent responses in stressful situations (e.g., fatigue, anxiety, fever, and some

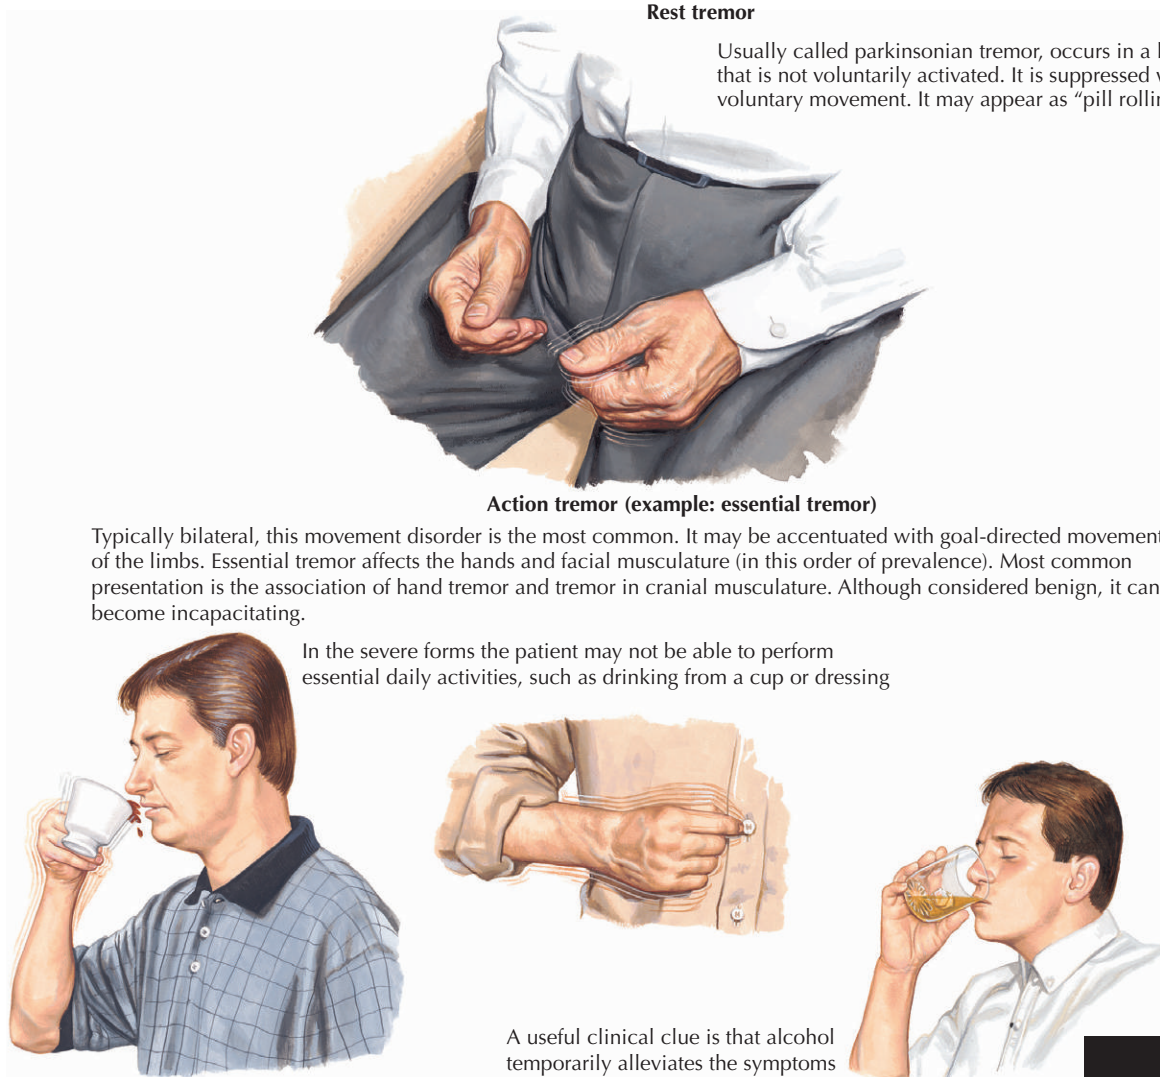

hypermetabolic states), as well as after certain medications (e.g., sympathomimetic drugs, lithium, sodium valproate, and caffeine). Enhanced PT is easily visible when arms are held outstretched, or during writing or drinking from a cup. The diagnosis of PT can be made when there is no evidence of underlying neurologic disease, and if the tremor is reversible with removal of the offending factor or agent.

Rest Tremor

Rest tremor (usually 4 to 5 Hz), often called *parkinsonian tremor*, occurs in a limb that is not voluntarily activated. It is suppressed with voluntary movement, and may appear as “pill rolling” (thumb rubbing across the palm or fingers) (Fig. 129-1, upper panel). In early Parkinson’s disease (PD), rest tremor can be intermittent and obvious only under emotional or physical stress. As with almost all movement disorders, it disappears with sleep.

Action Tremor

Accentuated by voluntary contraction of muscle, action tremors include postural, kinetic, and isometric tremors. Postural tremor is seen when maintaining a position, such as when the arms are held outstretched. Kinetic tremor occurs during voluntary movement and is subdivided into *simple kinetic tremor* (during non-target-directed movement), *intention tremor* (exacerbated as the hand or foot approaches the target of a voluntary movement, such as finger-to-nose), and *task-specific tremor*. Isometric tremor occurs with muscle contraction against a stationary object (squeezing the examiner’s fingers).

Figure 129-1 Tremor.

Localization and Etiology of Different Clinical Tremor Syndromes

The tremor elements (discussed earlier) can be combined into the following clinical syndromes with specific etiologies that are useful for clinical diagnosis and treatment.

Rest Tremor (Parkinsonian Tremor)

This occurs most commonly with diseases of the basal ganglia, typically with idiopathic PD. The diagnosis of PD is usually established by concomitant findings, such as bradykinesia (e.g., slow movement, facial masking), rigidity (including cogwheel phenomenon from tremor superimposed on rigidity), and gait disorder (e.g., shuffling, lack of arm swing on walking). Other causes for rest tremor include both primary parkinsonism (e.g., progressive supranuclear palsy, multiple system atrophy) and secondary

parkinsonism (e.g., stroke lesions of the basal ganglia, carbon monoxide intoxication, mitochondrial diseases). Recently, benign monosymptomatic resting tremor has been recognized as an entity associated with neither the typical symptoms, nor the progressive course, of PD. It has been given a variety of names such as *benign tremulous PD* and *benign tremulous parkinsonism*, and the exact neuropathology of the condition is unknown.

Action Tremor (Cerebellar Tremor)

Postural and kinetic tremor is a common feature of disease involving the deep cerebellar nuclei and the cerebellar tracts in the brainstem. There may be a striking intention component that is particularly incapacitating. Other findings such as nystagmus, scanning dysarthria, dysrhythmia, and truncal ataxia help in cerebellar localization. Accompanying cranial nerve and pyramidal tract involvement

also suggest brainstem disease. Many disease processes involving these structures may result in tremor, including neoplastic and paraneoplastic syndromes, hereditary and sporadic degenerative diseases, demyelinating diseases, trauma, infection, and cardiovascular disease. Alcohol is among the best-known toxicants causing this tremor.

Essential Tremor

Although of unknown etiology, essential tremor (ET) is the most common movement disorder (prevalence of 0.4% to 3.9%), presenting typically as bilateral, largely symmetric postural tremor that may be accentuated with goal-directed movement of the limbs. Severe ET also can manifest as rest tremor. ET most frequently affects the hands, and next most frequently, the cranial musculature. Although tongue, head, or voice may be affected in isolation, it is most common for the tremor in cranial musculature to occur in association with hand tremor. The legs and trunk are least affected, and usually only in the later stages of the illness. Our knowledge regarding the anatomic localization and pathologic mechanisms of ET is minimal. The cerebellum appears to be a prime candidate for the site of dysfunction based on animal model studies, and also the similarity in clinical signs and symptoms between advanced ET and patients with cerebellar disease. ET is currently thought to be a likely result of a central oscillator that can be enhanced or suppressed by reflex pathways.

ET may be sporadic or familial. It may appear at any age but is more frequent in early adulthood. The onset of ET may be earlier in the familial than the sporadic form. The course is unpredictable but may be static for many years or progress with a slow decline. Although usually considered benign, it can become incapacitating, particularly in occupations that require precise hand movements. In the severe form, patients may not be able to perform essential daily activities such as drinking from a cup or dressing. A family history will assist the diagnosis of ET, although the expression may be extremely varied in different members. A useful clinical clue in the diagnosis of ET is that alcohol may temporarily alleviate symptoms (Fig. 129-1, lower panel). As with most other tremors, ET remits during sleep.

Dystonic Tremor Syndrome

Dystonic tremor is described as postural, localized, and irregular, decreased during muscle relaxation, and accentuated by positioning the dystonic body part opposite to the direction of dystonia. The tremor caused by cervical dystonia is usually present as “no-no” kind of head shaking. The hand-and-head dystonic tremor can be difficult to differentiate from ET, but failure to respond to treatment for ET, or any dystonic feature in other body parts, may suggest the diagnosis. The etiology of dystonic tremor is unknown, however, but may be associated with basal ganglia dysfunction.

Primary Orthostatic Tremor

Primary orthostatic tremor (OT), also called *shaky leg syndrome*, is an uncommon condition that starts in late adulthood. The patient has a feeling of tremulousness in the legs when standing. This may lead to falls but generally disappears on movement and is not present when sitting or lying. The diagnosis is helped by specific surface electromyogram evaluation showing a 14- to 18-Hz oscillating tremor in the musculature of the legs when standing, disappearing with rest or movement. The etiology is unknown. Although suggested to be a variant of ET, it is probably a distinct entity because of the difference in age of onset, involvement of different parts (ET rarely affect legs), lack of family history, and lack of response to alcohol.

Holmes' Tremor

Holmes' tremor syndrome combines features of rest, intention, and postural tremor. The amplitude while resting may be small but may become uncontrollable while attempting to hold a posture, even worse when attempting a movement. In 1904, Holmes first described this as *rubral* tremor, but later it was called *midbrain* or *thalamic* tremor. Holmes' tremor is now preferred because the syndrome can occur with lesions affecting not only the red nucleus and rubral spinal tract in the brainstem but also the cerebellum and thalamus. The tremor may appear weeks to months after a known lesion (e.g., stroke), and some patients may have associated dystonia. Identifying this tremor always warrants evaluation for an underlying focal lesion.

Drug-Induced Tremor

A tremor is considered drug or toxicant induced if it occurs in a reasonable timeframe following ingestion or exposure. Drug-induced tremors can take any form, but the most common clinical manifestation is enhanced PT that can be caused by drugs such as sympathomimetic agents including bronchodilators, xanthines (e.g., caffeine), and epinephrine; centrally acting agents (e.g., valproate, lithium, tricyclic and other antidepressants, cocaine); antiarrhythmics (e.g., mexiletine, procainamide, and amiodarone); steroids (e.g., adrenocorticosteroids, tamoxifen, and progesterone); and cyclosporine and antimetabolites such as vincristine. Withdrawal from medications such as benzodiazepines or alcohol also may precipitate enhanced PT. Parkinsonian tremor can be caused by neuroleptic and dopamine-blocking drugs (e.g., haloperidol or metoclopramide), or dopamine-depleting agents (e.g., reserpine). Cerebellar tremor may occur after intoxication by lithium or alcohol. Environmental toxicants such as organophosphates and other insecticides, toxic metals, and some industrial chemicals also can cause or exacerbate tremor.

Tremor in Lower Motor Neuron Diseases and Peripheral Neuropathy

Tremor may accompany diseases of the anterior horn cell (e.g., amyotrophic lateral sclerosis) and peripheral neuropathies. Demyelinating and particularly dysglobulinemic neuropathies are particularly likely to be associated with tremor, usually postural or kinetic. It is unclear whether tremor associated with peripheral neuropathy is due to enhanced PT secondary to weakness, to an abnormality in the central nervous system, or both.

Psychogenic Tremor

Psychogenic tremors can mimic nearly any type of tremor and, at times, can be difficult to diagnose. Psychogenic origin should be suspected when features of other recognized forms of tremor are not found. Clues to psychogenic etiology include sudden onset; bizarre fluctuations in the frequency and direction; increase when attention is drawn to the movement; history of secondary gain; and response to placebo. As always, it must be remembered that psychogenic disease may coexist in patients with organic disease.

Differential Diagnosis

Tremor must be differentiated from other movement disorders. Unlike tremor, clonus is increased by passive stretch of the muscle. Myoclonus, although difficult to distinguish, may have an electroencephalographic correlate, is generally more dysrhythmic, and has visible pauses between the jerks. Epilepsy partialis continua may continue through sleep and generally has electroencephalographic correlates. Asterixis (also called *negative myoclonus*) is characterized by a sudden loss of a maintained posture, followed by recovery, rather than an active movement.

Diagnostic Approach

The history should focus on the onset of tremor, family history, alcohol sensitivity, spreading sequence, associated disease, medication or chemical exposure, and possible drug abuse. The neurologic exam should assess akinesia and bradykinesia, muscle tone, postural abnormalities, dystonia, cerebellar signs, pyramidal signs, neuropathic signs, gait, and stance. Consideration should not be limited to the nervous system because tremor may result from other causes such as endocrine disease, hepatic failure, or neoplasm.

A history of relapsing and remitting neurologic symptoms, or the findings of other neurologic abnormalities associated with action tremor, may suggest evaluation for multiple sclerosis, mass lesions, or stroke. Effective treatments for some tremor-inducing conditions (thyroid dysfunction or Wilson's disease) make it reasonable to check thyroid function in all movement disorder patients and

ceruloplasmin levels in young patients. Holmes' tremor requires an extensive workup to identify local lesions in the brainstem, cerebellum, or thalamus pathway. If the tremor is bilateral and symmetric, but not associated with other clinical abnormalities, then imaging of the head is unlikely to be revealing.

Management and Therapy

Optimum Treatment

Effective treatment of the underlying disease is generally the most appropriate initial approach. Early in the course of PD, tremor may respond to anticholinergic medications (amantadine, trihexyphenidyl), or later to levodopa and dopamine agonists. ET may be responsive to propranolol (initially 80 mg/day in long-acting form, increased incrementally to 320 mg/day if required and tolerated), although primidone may also be effective (initially 50 mg/day, increasing to 250 mg twice a day or higher if required and tolerated). Topiramate has also been shown to be effective in treating ET (initially 25 mg/day, increasing to 100 mg twice a day or higher if required and tolerated). Isolated reports also suggest relief from gabapentin, clonidine, clonazepam, acetazolamide, or methazolamide.

Primary OT is sometimes treated by clonazepam, phenobarbital, primidone, or valproate, although careful studies are not available. Neither alcohol nor propranolol is helpful. Treatment of dystonia with botulinum toxin often results in significant improvement of tremor (e.g., in cervical dystonia), but dystonic tremor may also respond to benzodiazepines (e.g., clonazepam, 0.25 to 2 mg/day). The overall treatment of cerebellar tremor remains unsatisfactory. Appending weights to the wrist may damp the amplitude of cerebellar, dystonic, and ET, but this rarely results in sustained functional improvement.

Stereotactic surgical ablation, or more commonly today, deep brain stimulation of the thalamus or basal ganglia is reserved for patients with severely disabling and medically intractable rest, essential, intention, dystonic, and rubral tremor. Trained and experienced multidisciplinary teams, appropriate patients, and clearly identified neuroanatomic targets are the critical factors for successful outcome.

Avoiding Treatment Errors

- Drugs are a common cause of tremor and can exacerbate existing milder tremor. It is important to address these drug issues before introducing new medication to treat the tremor.
- Different types of tremors can manifest in the same patients and require different approaches to treatment. For example, it is not uncommon that a patient with long-standing ET develops PD tremor at an older age. Introducing dopaminergic drugs is important to control the tremor and other associated PD symptoms.

- Tremor associated with dystonia is commonly misdiagnosed as ET. In some circumstances (e.g., head tremor with cervical dystonia), very satisfactory control can be obtained with periodic botulinum toxin injections. Looking for the dystonic component in evaluating tremor, especially in patients who fail to respond to ET treatment, is very important.
- Complete control of most tremors is not easily accomplished with current medications. The goal of treating tremor is not for the patient to be tremor free, but to maximize patient function within an acceptable range of drug side effects. Chasing the tremor-free goal may sometimes be medically futile, and even harmful to patients (especially elderly patients).

Future Directions

It is likely that deep brain stimulation will become increasingly useful as targets and methods are refined. Similarly, a wealth of new knowledge becoming available about the chemical neurocircuitry of the brain should also lead to better mechanistic understanding and to the discovery of new pharmacotherapeutic agents.

Parkinson's Disease

Introduction

Parkinson's disease (PD) is defined as a chronic, progressive neurodegenerative disorder of unknown etiology that can cause significant disability and early mortality if untreated. Parkinson's disease was first described in a classic monograph on "Shaking Palsy" in 1817 by James Parkinson. The disease affects about 1% of Americans older than 60 years, and its prevalence in the United States is expected to more than triple in the next 50 years as the U.S. population ages. The lifetime risk for PD is higher in men than in women—2.0% versus 1.3%. The estimated cost of PD in the United States is at least \$6 billion annually in direct health-related costs, indirect disability-related costs, and lost productivity.

There have been significant advances in symptomatic treatment based primarily on dopamine replacement and, more recently, deep brain stimulation (DBS), that have dramatically improved the quality of life and life expectancy of patients with the disorder. Patients with this condition, however, continue to experience progressive motor and nonmotor deficits that impair their quality of life and are significant challenges for their caregivers.

Etiology and Pathogenesis

The most prominent pathologic change in PD is degeneration of melanin-pigmented dopamine neurons in the zona compacta of the substantia nigra (SNc) in the mid-brain. Changes in the SNc are most pronounced in its ventrolateral region. Affected neurons also have intracellular inclusions known as Lewy bodies, which are now known to contain protein aggregates that, in some cases, are related to the cause of the disease. Neurodegenerative changes can also be found in the locus coeruleus, nucleus basalis of Meynert, pedunculopontine nucleus, cerebral cortex, and spinal cord.

Neurochemically, the hallmark of PD is a reduction in striatal dopamine. Less marked changes may also be seen in serotonergic, noradrenergic, and cholinergic systems. The most likely reason for the motor signs and symptoms is the dopamine deficiency or dysfunction in the basal ganglia, although there remains considerable uncertainty about the exact pathophysiologic basis of individual aspects of PD.

Genetic causes have been found only for familial PD, accounting for less than 5% of all patients. Mutations include several genes that produce proteins involved in

synaptic function and protein processing. They have provided important research ideas, but not a specific cause for the much more common sporadic form of PD. Another landmark occurred when drug users injected MPTP (a byproduct of the production of an illicit opioid) intravenously and developed a rapidly progressive syndrome that was nearly identical to sporadic PD. Although the initial excitement around MPTP-like compounds in the environment playing a role in PD was not supported by later studies, this finding provided an impetus for the current hypothesis that sporadic PD results from the interactions between genetic and environmental factors.

Parkinson's disease is paradoxical in some interesting ways. For example, both smoking and coffee use have been consistently associated with a *lower* incidence of PD. Smoking certainly has proven health risks that make its association with a lower prevalence of PD surprising. Recently, there have been reports that the apolipoprotein $\epsilon 2$ allele, but not the $\epsilon 4$, is associated with an increased risk for PD. Generally, the apolipoprotein $\epsilon 2$ allele is linked to longevity and lower risk for Alzheimer's disease, whereas the $\epsilon 4$ allele is a major risk factor. If indeed sporadic PD is a result of complex genetic and environmental interactions, finding simple causes is unlikely.

Clinical Presentation

Cardinal Features

The cardinal clinical symptoms of PD are tremor, bradykinesia, rigidity, and gait disorders (Fig. 130-1). At least two of the first three symptoms should be present to make a diagnosis.

Tremor typically occurs at rest and with a frequency of 4 to 7 Hz. Unlike essential tremor, in which postural and action components are predominant, PD tremor can be cosmetic, without affecting much function, because it disappears with use. Also, unlike essential tremor, the tremor of PD can affect the chin while not causing voice or head tremor.

Bradykinesia is a slowing of motor function. Rigidity is a finding of increased muscle tone with passive limb movement on examination. Varying degrees of bradykinesia and rigidity result in a spectrum of clinical presentations. Handwriting is affected, with difficulty initiating hand movement associated with a gradual reduction in the size of the words (micrographia). Ambulation is slowed, with decreased arm swing and reduced head turning. Poor turning ability, decreased reaction time, and a shuffling gait combine to increase the risk for falls. Facial expression is typically reduced (mask-like), and the frequency of spontaneous eye blinks is decreased. Speech is slow, and vocal volume fades. Rigidity contributes to generalized immobilization and is a feature that leads to stooped posture when standing and walking (see Fig. 130-1, stage 3). Passive movement of the extremities often brings out cogwheel rigidity, a fine ratcheting feeling detected by the examiner in the muscles, which appears to be a product of intermixed rigidity and tremor. PD generally has an asymmetrical onset. Symmetrical disease early in the course is a red flag for other causes such as exposure to phenothiazines, hypothyroidism, or other causes of parkinsonism.

Mask-like facies, decreased eye blink, tremor at rest, cogwheel rigidity, micrographia, bradykinesia, decreased arm swing with walking, stooped posture, and shuffling gait can all be demonstrated by examination. There is also a significant absence of some findings such as abnormal tendon reflexes, lateralized weakness, sensory changes, and cerebellar signs. In recent years, it has been recognized that PD is often associated with (1) cognitive deficits such as impaired attention, executive function, and working memory, all related to frontal lobe function; and (2) disturbances in mood, sleep, olfaction, and autonomic nervous system function. These nonmotor deficits become especially challenging when the disease progresses in these areas while motor symptoms are well managed with dopaminergic replacement and deep brain stimulation (DBS).

Differential Diagnosis

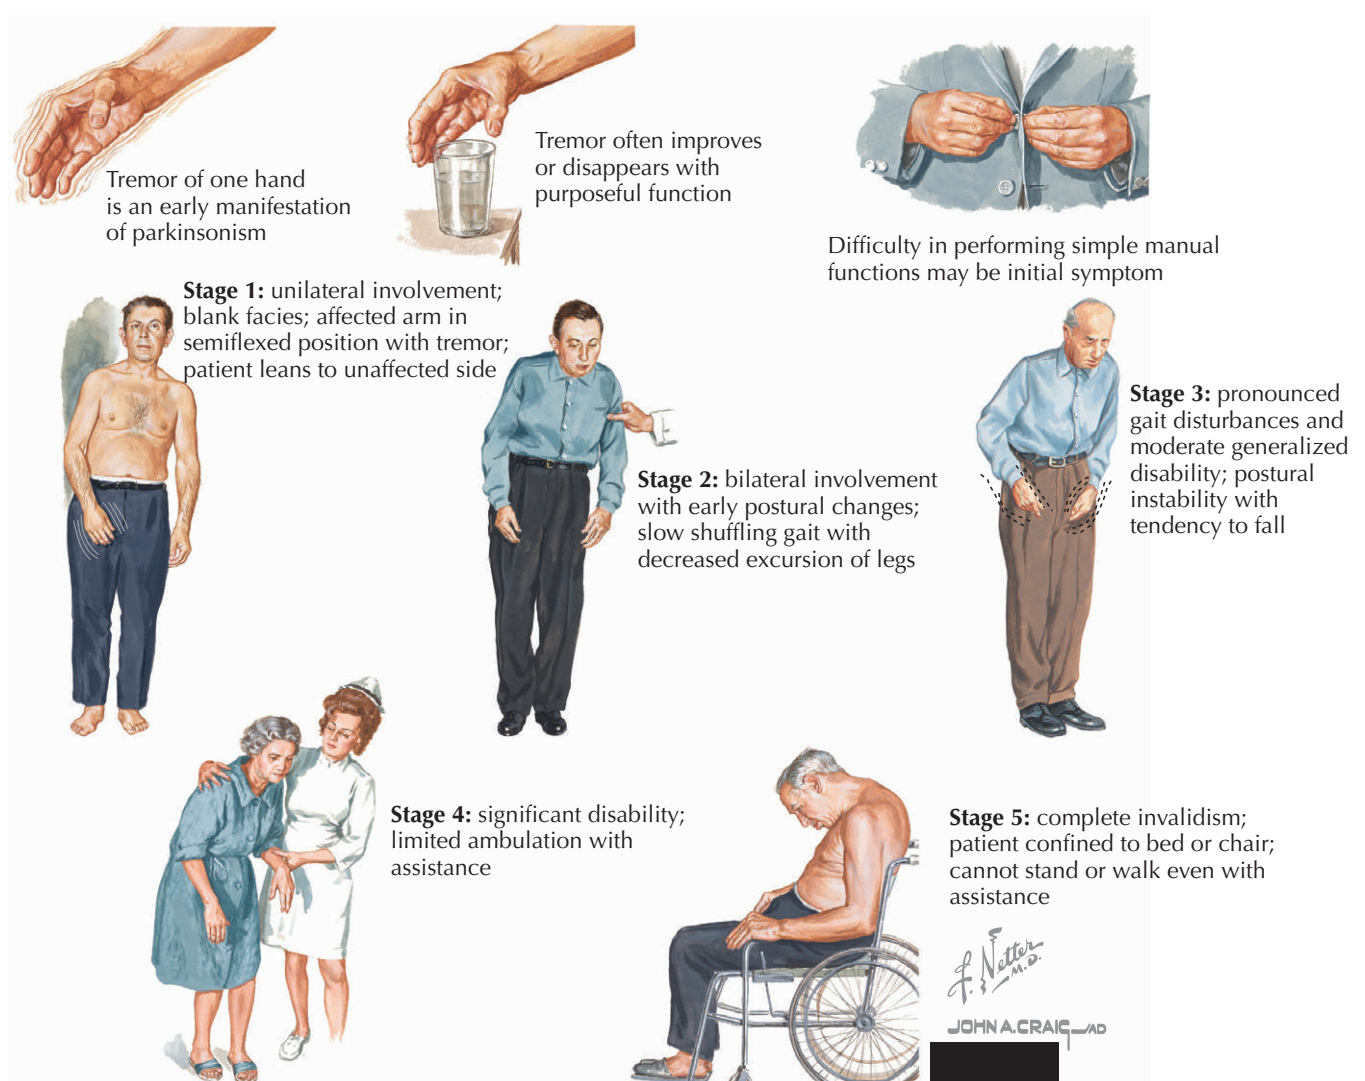

Box 130-1 provides the differential diagnosis for Parkinson's disease.

Box 130-1 Differential Diagnosis of Parkinsonism

- Drug effects: medications, especially typical antipsychotics like the phenothiazines, can produce the findings of PD.
- Depression: flat affect, psychomotor retardation, and pseudodementia may be present, but the primary findings of PD such as tremor and cogwheel rigidity are absent.
- Head trauma: lateralized deep tendon reflexes, motor weakness, and sensory findings help to distinguish traumatic injury from PD (e.g., subdural hematomas).
- Stroke: vascular injury to the brain can produce parkinsonian signs and symptoms that are generally sudden in onset and not progressive.
- Wilson's disease: family history, Kayser-Fleischer rings on slit-lamp examination, liver dysfunction, abnormal serum ceruloplasmin, and elevated copper in serum and urine lead to the diagnosis.
- Progressive supranuclear palsy (PSP): bradykinesia and rigidity may be present and the loss of voluntary eye movements, particularly upward gaze, is characteristic.
- Intracranial tumors: the neurologic examination should help in identifying features that are not consistent with PD, leading to further diagnostic studies.
- Viral and postviral factors: neurologic examination suggests more diffuse brain involvement with other physical symptoms and signs.
- Normal-pressure hydrocephalus (NPH): gait is more suggestive of apraxia ("stuck foot"), and apathetic dementia and urinary incontinence are more evident.
- Huntington's disease: a positive family history, choreiform movements, and dementia are predominant.
- Multisystem atrophy (MSA), including Shy-Drager syndrome: parkinsonian features may be present, and autonomic insufficiency, including postural hypotension, is a major component.
- Hypothyroidism: bradykinesia, skin thickening, constipation, cold intolerance, and low energy dominate the picture.

Diagnostic Approach

The diagnosis of PD is based on clinical criteria, including two of the classic triad (resting tremor, rigidity, and bradykinesia), asymmetry of symptoms and signs at initial presentation, and a significant positive response to levodopa. There are no reliable biologic markers of the disease. Although single-photon emission computed tomography and positron emission tomography are used in some research studies to determine the integrity of dopamine systems (i.e., dopamine transporters and fluoro-dopa uptake), they are not more accurate in diagnosing the disease than a trained clinician. Magnetic resonance imaging can help to eliminate other causes in the differential diagnosis such as mass lesions, stroke, cerebellar pontine atrophy in multisystem atrophy, brain stem atrophy in progressive supranuclear palsy, and large ventricles in normal-pressure hydrocephalus. Laboratory tests should include thyroid and parathyroid function evaluation and,

Figure 130-1 Clinical Signs of Parkinson's Disease.

if onset is earlier than age 50 years, a serum ceruloplasmin for Wilson's disease.

Management and Therapy

Optimum Treatment

Medication

Levodopa, a precursor of dopamine, remains the most effective medication for symptom management, including all cardinal features of the disease. Levodopa is thought to allow the remaining dopamine neurons in the SNc to produce more dopamine, thereby resulting in near-normal dopamine receptor activation (Fig. 130-2). Almost all patients with PD will show a positive response to levodopa, and lack of such a response makes the diagnosis questionable. There is no evidence of benefit in delaying sympto-

matic treatment of PD. Early short-term and later long-term side effects are noted with levodopa. Early side effects include nausea, postural hypotension, confusion, hallucinations, and cardiac arrhythmias. Long-term use is associated with *wearing off* and dyskinesias. Wearing off results in the need for more frequent dosing of the drug. *On-off phenomena* are unpredictable, sudden, and usually brief losses of levodopa effectiveness in long-term users. Motor fluctuations occur in about half of patients after 5 years of levodopa therapy, increasing to 70% after 15 years. Carbidopa (aromatic amino acid decarboxylase inhibitor) is usually combined with levodopa to reduce the peripheral metabolic breakdown of levodopa. By decreasing the peripheral conversion of levodopa into dopamine, norepinephrine, and epinephrine, systemic side effects of levodopa, such as hypotension and cardiac dysrhythmias, are dramatically reduced. Blood tests are unnecessary with levodopa therapy.

Figure 130-2 Hypothesized Role of L-Dopa in Parkinson's Disease.

Dopamine agonists directly activate dopamine receptors in the brain without the need for bioconversion. When used with levodopa, benefits include reduction in fluctuating responses to levodopa and the pulsatile activation of dopamine receptors. There is clinical evidence that including a dopamine agonist in the treatment regimen may reduce dyskinesias associated with levodopa. The older dopamine agonists (bromocriptine and pergolide) are ergot derivatives with major side effects, including delusions, hallucinations, hypotension, and pulmonary and retroperitoneal fibrosis. Although the newer dopamine agonists, such as ropinirole and pramipexole, as nonergot derivatives, have significantly decreased risk for those problems, they can cause postural hypotension, peripheral edema, nausea, dyskinesias, confusion, and excessive somnolence.

Recently, compulsive behavior such as gambling has also been associated with use of dopamine agonists. Ropinirole and pramipexole may be helpful as an initial therapy in early PD, but their role is primarily adjunctive. Apomorphine, introduced in the U.S. market in 2005, can be given subcutaneously to treat severe PD freezing episodes.

Catechol-O-methyl transferase (COMT) inhibitors improve levodopa availability by reducing the peripheral conversion of levodopa to 3-*O*-methyldopa. COMT inhibitors reduce fluctuations in response to levodopa, resulting in more "on" time. The use of COMT inhibitors requires a 20% to 30% reduction in the daily dosage of levodopa to avoid side effects of excessive medication, such as dyskinesia. Tolcapone and entacapone are the available COMT inhibitors. Entacapone is more commonly used because it causes

fewer hepatic side effects than tolcapone. The acute hepatic failure seen in a small number of patients taking tolcapone requires monitoring of liver function tests before and up to 6 months after the start of therapy. Other tolcapone side effects include diarrhea, abdominal pain, sleep disturbance, and postural hypotension. Despite these limitations, tolcapone appears to have superior effectiveness, probably because it penetrates the blood-brain barrier to a greater extent, thereby increasing the duration of action of dopamine.

Amantadine is effective in PD, but improvement may be transient. It is the only drug proven to be effective in the treatment of dyskinesias. The mode of action is likely to be through its effects on *N*-methyl-*D*-aspartate glutamate receptors. Although the drug is generally well tolerated, side effects may include peripheral edema, urinary retention, livedo reticularis, restlessness, confusion, dizziness, vivid dreams, and insomnia.

The *monoamine oxidase B inhibitors* selegiline and rasagiline have been suggested to be neuroprotective, slowing disease progression. Because both drugs have small beneficial effects on the primary symptoms, it has been difficult to get unequivocal data confirming neuroprotection. Selegiline and rasagiline may reduce both fluctuations in levodopa responsiveness and the daily dose of levodopa. Although they do not require the dietary restrictions of monoamine oxidase A inhibitors, they do adversely interact with some drugs, including meperidine, tricyclic antidepressants, and selective serotonin reuptake inhibitors. Selegiline is associated with more side effects, such as hallucinations and sleep disturbance, possibly because it is metabolized to *L*-amphetamine. The newer agent rasagiline has fewer side effects in this older population.

The *anticholinergic agents* benztropine and trihexyphenidyl, may relieve tremor and may also reduce drooling. The dosing range is limited because of the significant side effects, commonly including blurred vision, urinary retention, memory disturbance, hallucinations, and confusion.

Diet

Restricting dietary protein improves the gastrointestinal uptake of levodopa and also improves transport of levodopa across the blood-brain barrier. High protein diets increase amino acids that compete with levodopa for transport and may produce fluctuations in nervous system levodopa levels. Although vitamin E (tocopherol) acts to limit the effects of free radicals and is theoretically neuroprotective, a single large study did not confirm benefits in PD.

Physical Therapy and Exercise

There is evidence that regular exercise decreases the risk for PD and improves long-term quality of life in those with the condition. Regular exercise and physical therapy help maintain flexibility and strength. Speech therapy may help with volume and clarity.

Neurosurgical Approaches

A variety of ablative neurosurgical procedures used previously for control of tremor and rigidity have largely been replaced by DBS with implanted electrodes, resulting in better efficacy coupled with lower morbidity and mortality. DBS has become established during the past 5 years as an important part of the therapeutic armamentarium for use in selected patients who can no longer be managed medically. DBS may improve both motor fluctuations and dyskinesias, while decreasing the required doses of medication that cause many nonmotor side effects. The benefits of DBS have been reported to persist for up to 10 years in some cases. The potential side effects, in addition to perioperative stroke and infection, include disorganization of thought processes, speech impairment, visual and sensory disturbances, gait disturbance, incoordination, headaches, seizures, and depression. Medical centers performing DBS for PD are growing in number as the requisite interdisciplinary skills and experience are acquired.

Avoiding Treatment Errors

- Avoid using antipsychotic medications that can worsen PD. These drugs include typical antipsychotic drugs (e.g., haloperidol) as well as some atypical ones (e.g., olanzapine and risperidone). It is preferable to use those atypical antipsychotic drugs that are less likely to worsen PD (clozapine and quetiapine) if needed.
- Avoid antiemetic drugs that can worsen PD. These drugs include prochlorperazine, metoclopramide, and promethazine. Instead, use trimethobenzamide or ondansetron if needed.
- PD is a slowly progressive disorder. Many stressors, both medical (e.g., infection) and social (e.g., divorce, loss of spouse), can exacerbate PD symptoms acutely. These factors should be considered and managed during acute exacerbations of PD.
- Treating PD often involves polypharmacy because many patients are elderly. Carefully explaining the regimen to patients, family, and caregivers and writing down the treatment plan legibly can play a crucial role in the successful implementation of treatment.
- Starting medications at low doses and tapering upward slowly is the rule to minimize side effects for all PD medications.
- Treating nonmotor symptoms (e.g., depression, sleep disorder, cognitive and behavioral impairment) that are commonly associated with PD is critical to provide the best quality of life for the patients and their families.

Future Directions

Based on a variety of research approaches, a host of neuroreceptor targets have been suggested as playing a role in the development of PD. Several new dopamine agonists

are being tested that either are delivered in novel ways (e.g., sublingually and transdermally) or target different populations of dopamine receptors. In addition, adenosine and glutamate receptor antagonists, as well as several other classes of drugs, are in development. Currently, a moratorium has been placed on experiments using transplantation of embryonic neurons for severe PD. However, there is a major research effort to determine whether genetically engineered stem cells may have treatment utility. There is also major interest in neuroprotective strategies, including both small molecules and gene therapeutics. Although the goals of either neuroprotection or curative procedures remain unmet, the current level of research activity in these arenas offers significant promise of success.

EVIDENCE

- Davis GC, Williams AC, Markey SP, et al: Chronic parkinsonism secondary to intravenous injection of meperidine analogues. *Psychiatry Res* 1:249-254, 1979.
This article provides the first description of acute, permanent, and dramatic parkinsonism caused by injection of MPTP, a compound made accidentally by addicts seeking to synthesize a meperidine congener. The subject responded to antiparkinson medication and, at necropsy, had pathologic changes remarkably similar to PD. This led to the most useful animal model of PD.
- Dubois B, Pillon B: Cognitive deficits in Parkinson's disease. *J Neurol* 244:2-8, 1997.
Cognitive deficits are seen in some patients with PD, including impaired executive function, defective memory storage, and impaired visuospatial processing. Evidence is reviewed for possible causes and underlying neural mechanisms.
- Edwards LL, Pfeiffer RF, Quigley EM, et al: Gastrointestinal symptoms in Parkinson's disease. *Mov Disord* 6:151-156, 1991.
This controlled clinical study in 98 subjects with PD supports direct involvement of gastrointestinal function by the primary disease process that is not explained by medication side effects or other factors. Symptoms that were greater in PD subjects included abnormal salivation, dysphagia, nausea, constipation, and defecatory control.
- Elbaz A, Bower JH, Maraganore DM, et al: Risk tables for parkinsonism and Parkinson's disease. *J Clin Epidemiol* 55:25-31, 2002.
This epidemiologic study found that lifetime risk for developing parkinsonism from birth was 4% for men and 3.7% for women in Olmsted County, Minnesota. For PD, the figures were 2% for men and 1.3% for women. These figures provide useful information in discussions with patients and their families.
- Garcia-Borreguero D, Larrosa O, Bravo M: Parkinson's disease and sleep. *Sleep Med Rev* 7:115-129, 2003.
Sleep disturbance is found in almost two thirds of those with PD and includes excessive daytime sleepiness, parasomnias, and problems with initiation or maintenance of sleep. This is an important area of clinical inquiry and management because quality of life can be severely affected by poor sleep in this population.
- Hornykiewicz O, Kish SJ: Biochemical pathophysiology of Parkinson's disease. *Adv Neurol* 45:19-34, 1987.
Our basic understanding of the pathophysiology of PD is reviewed. Complex interrelationships of neuroanatomy and neurochemistry are explained and explored.
- Huang X, Chen PC, Poole C: APOE-ε2 allele associated with higher prevalence of sporadic Parkinson disease. *Neurology* 62:2198-2202, 2004.
A meta-analysis revealed that APOE-ε2 allele, but not the ε4 allele, is positively associated with sporadic PD. This contrasts to Alzheimer's disease, for which the APOE-ε4 allele increases the prevalence of the disease and the APOE-ε2 allele is protective, underscoring that neurodegenerative diseases differ.
- Katzenschlager R, Lees AJ: Olfaction and Parkinson's syndromes: Its role in differential diagnosis. *Curr Opin Neurol* 17:417-423, 2004.
Loss of olfactory function is common in PD, dementia with Lewy bodies, and some of the spinocerebellar syndromes, but not in PSP, corticobasal degeneration, or vascular parkinsonism. Testing olfaction has become more standardized and can lead to early diagnosis in some movement disorders, including PD.

This chapter is an updated review of the etiology of PD from the 1996 article.

Bell's Palsy

Introduction

The muscles of facial expression are intimately involved in our ability to communicate emotions with those around us. Acute unilateral facial palsy, also known as Bell's palsy after Sir Charles Bell who described the disorder in 1821, is the most common cause of facial weakness and the most common cranial neuropathy. Bell's palsy has traditionally been a diagnosis of exclusion and attributed to idiopathic origins; however, recent investigations have implicated herpetic viral infection with associated inflammation as the source of the paresis or paralysis. Bell's palsy is the most common cause of unilateral lower motor neuron facial palsy, accounting for 60% to 75% of all peripheral facial nerve palsies. Bell's palsy shows no gender or seasonal predilection and occurs with an incidence of about 20 to 30 per 100,000 population. As many as 71% of untreated patients recover completely, whereas 84% achieve near-normal facial function. Poor prognostic indicators for return of function include older age, hypertension, impairment of taste, pain other than in the ear, and complete facial nerve palsy.

Etiology and Pathogenesis

An understanding of the anatomy of the facial nerve is critical to the understanding of Bell's palsy. The facial nerve primarily carries fibers for motor control to the muscles of facial expression, the stapedius muscle, and the posterior belly of the digastric muscle. In addition to these motor fibers, sensory branches and parasympathetic fibers course within the facial nerve. Taste sensation from the anterior two thirds of the tongue joins the facial nerve through the chorda tympani branch. Parasympathetic fibers reach the lacrimal and submandibular glands through the greater superficial petrosal nerve and the chorda tympani, respectively. Loss of nerve conduction in the facial nerve can potentially disrupt all these fibers (Fig. 131-1).

The facial nerve travels through the temporal bone housed in a bony canal (fallopian canal), entering the temporal bone at the internal auditory canal and exiting from the stylomastoid foramen. The narrowest segment of the bony canal is located at the lateral end of the internal auditory canal. Acute unilateral facial palsy has been postulated to arise from an inflammatory process causing the facial nerve to swell within the bony canal surrounding it.

Although still a controversial topic, a large body of evidence implicates herpes simplex virus (HSV) infection as

the primary cause of acute unilateral facial palsy. Nucleic acids from HSV have been found to be present in the geniculate ganglion of the facial nerve, and HSV DNA has been detected in the endoneural fluid of the facial nerve in patients with acute paralysis undergoing surgical decompression. An animal model of facial paralysis has been developed by inoculating mouse tongues or auricles with HSV. It is hypothesized that primary HSV may result in the entrapment of the virus within the geniculate ganglion, and its reactivation causes the inflammatory process causing the seventh nerve neuropathy. Another herpes virus, varicella-zoster virus, is known to be associated with acute facial nerve palsy in the setting of Ramsey Hunt's syndrome.

Clinical Presentation

The onset of Bell's palsy is typically acute, with the progression of weakness in several hours to overnight (Fig. 131-2). Bell's palsy may present as a complete hemifacial paralysis or, more commonly, as an incomplete palsy that may or may not progress to complete paralysis over several days. Many patients describe pain behind the affected ear as a prodrome and a sensation of numbness on the affected side of the face, although this sensation appears to be

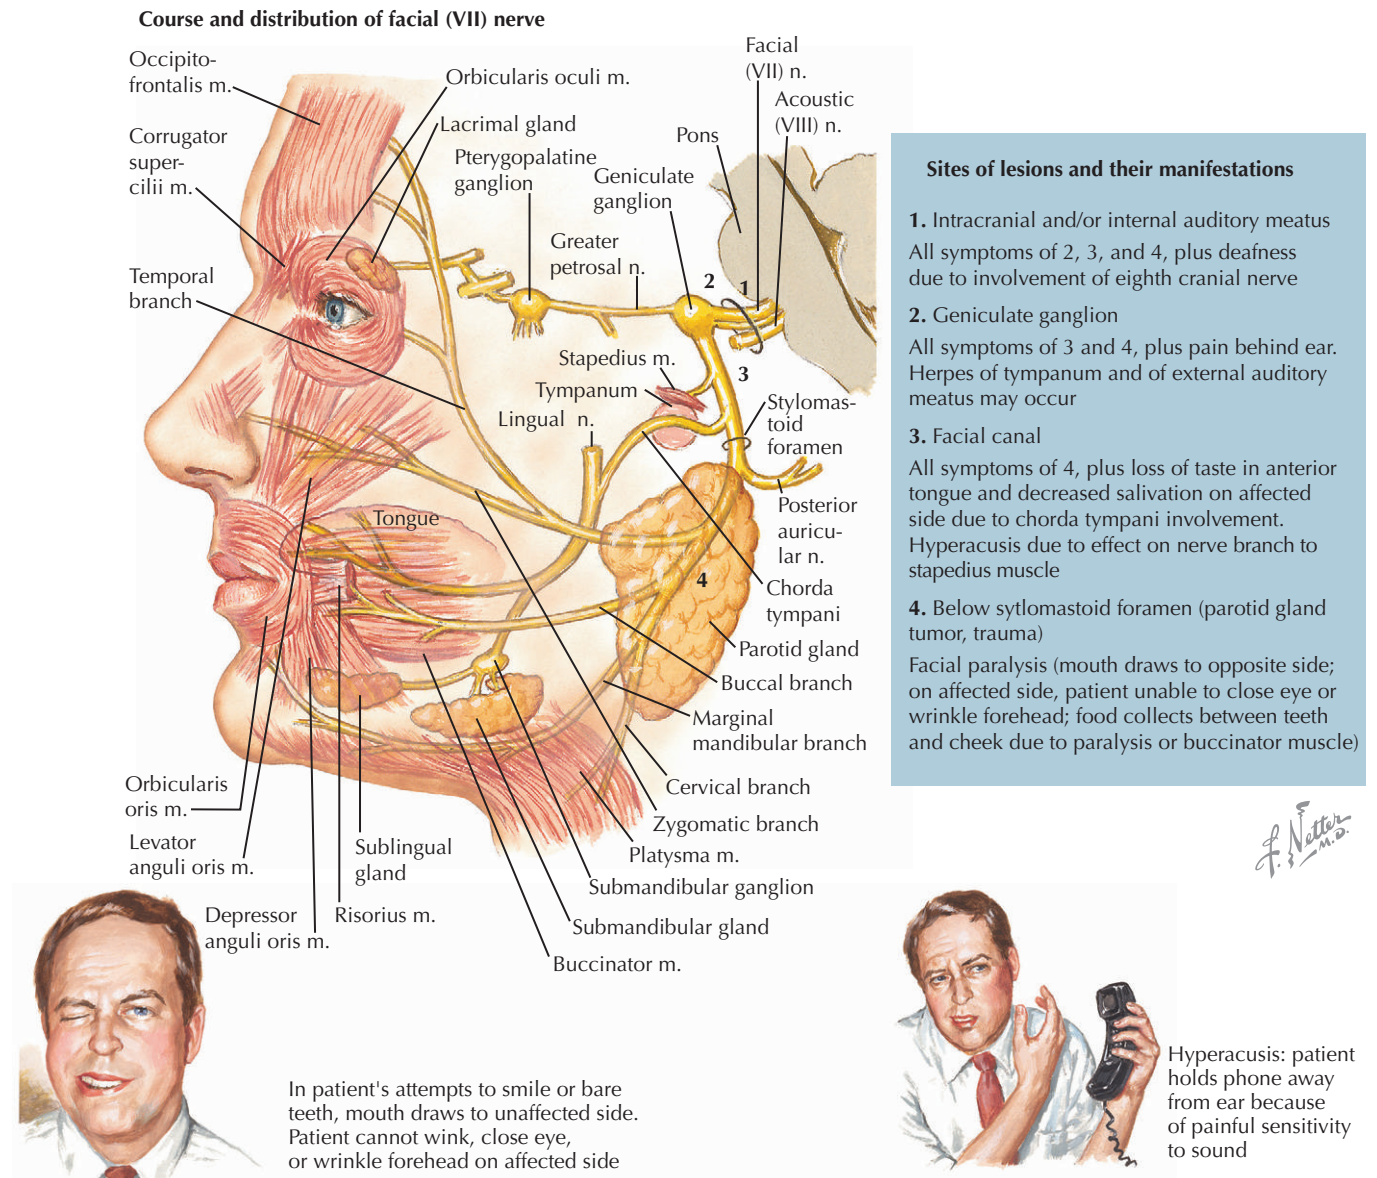

Figure 131-1 Facial (VII) Nerve.

secondary to the lack of motion. Dysgeusia (disturbed taste), hyperacusis (sounds are too loud in the affected ear), and difficulty drinking are also common complaints.

Physical examination reveals unilateral paresis or paralysis of the muscles of facial expression. An important distinction is that the unilateral paresis or paralysis involves both the upper and lower face on the affected side (lower motor neuron lesion pattern). When severe, the affected hemiface shows no voluntary movements and obvious asymmetry at rest. The degree of facial paralysis is often quantified using the House-Brackmann scale, which incor-

porates gross facial appearance, symmetry at rest, and symmetry of the forehead, eye, and mouth in motion (Table 131-1). The skin surrounding the affected side of the mouth is displaced to the opposite side with smiling, and often the affected eye cannot be completely closed with maximal effort. When attempts are made to close the affected eye, the globe is seen to roll upward into the orbit, revealing sclera (Bell's phenomenon).

Thorough history taking and a complete physical examination with cranial nerve testing is critical to establishing the diagnosis. The parotid glands must be palpated for

Figure 131-2 Bell's Palsy.

masses, and the otoscopic examination must establish clear tympanic membranes with no evidence of infection or lesions. Examination of the tongue will often reveal inflammation of the fungiform papillae on the affected side. Lacrimation may be decreased in the affected eye. Audiometric assessment will often reveal stapedial muscle dysfunction and hyperacusis on the affected side.

Other etiologies of facial nerve palsy should be explored in the following scenarios: a history of recurrent facial palsy, other cranial nerve involvement, facial twitching, no recovery after 3 to 6 weeks or only partial recovery after 3 to 6 months, and a slowly progressive palsy lasting longer than 3 weeks.

Differential Diagnosis

Bell's palsy is a diagnosis of exclusion. The reported incidence of misdiagnosing facial palsy as Bell's palsy is between 13% and 20%. The differential diagnosis for unilateral facial palsy must include infectious causes, neoplasms, trauma, inflammatory processes, and metabolic disorders; symptoms also may result from a central insult, such as cerebrovascular accident or multiple sclerosis (Table 131-2).

Infectious etiologies include Lyme disease, Ramsey Hunt's syndrome (varicella-zoster), HIV, and otitis media or mastoiditis. Varicella-zoster virus facial paralysis

Table 131-1 House-Brackmann Facial Nerve Grading System

Grade	Description	Findings
I	Normal	Normal facial function in all areas
II	Mild dysfunction	Gross: slight weakness on close inspection, very slight synkinesis At rest: normal symmetry and tone In motion: forehead—moderate to good function; eye—complete closure with minimal effort; mouth—slight asymmetry
III	Moderate dysfunction	Gross: obvious but not disfiguring difference between sides, noticeable but not severe synkinesis At rest: normal symmetry and tone In motion: forehead—slight to moderate movement; eye—complete closure with effort; mouth—slightly weak with maximal effort
IV	Moderately severe dysfunction	Gross: obvious weakness or disfiguring asymmetry At rest: normal symmetry and tone In motion: forehead—no movement; eye—incomplete closure; mouth—asymmetrical with maximal effort
V	Severe dysfunction	Gross: barely perceptible motion At rest: asymmetry In motion: forehead—no movement; eye—incomplete closure; mouth—slight movement
VI	Total paralysis	No movement

Table 131-2 Differential Diagnosis of Peripheral Facial Palsy

Category	Signs and Symptoms
Infectious	
Lyme disease	History of tick bite, other neurologic symptoms, and constitutional symptoms (asthenia, anorexia, headache)
Ramsey Hunt's syndrome (varicella zoster)	Painful vesicular lesions on external ear or within ear canal; occasional lesions on soft palate
Human immunodeficiency virus (HIV)	History of HIV
Otitis media, mastoiditis	Evidence of middle ear purulence on otoscopy; postauricular erythema, edema
Neoplastic	
Middle ear tumor	Lesion seen on otoscopy
Parotid tumor	Mass palpated on physical examination
Cerebellopontine angle tumor (acoustic neuroma)	Sensorineural hearing loss, vertigo, facial hypesthesia (impingement of cranial nerve V)
Cholesteatoma	History of chronic draining ear, otoscopic examination with squamous debris
Traumatic	
Temporal bone fracture	History of trauma, possible sensorineural hearing loss, computed tomography scan demonstrating fracture along course of facial nerve
Middle ear trauma	History of penetrating trauma to middle ear, tympanic membrane perforation
Inflammatory	
Sjögren's syndrome	Sicca complex—dryness of mucous membranes of eyes and mouth
Amyloidosis	Possible proteinuria, hepatomegaly, heart failure, arrhythmia
Sarcoidosis	History with pulmonary symptoms
Guillain-Barré syndrome	Caudal to cranial progression of weakness, tingling starting in lower extremities
Metabolic	
Diabetes mellitus	History of diabetes; visual or renal problems
Preeclampsia	Pregnant patient with hypertension and proteinuria
Central Insult	
Multiple sclerosis	Visual changes, vertigo, weakness or numbness
Cerebral vascular accident	Hemiparesis, hemisensory loss, hemineglect with sparing of the forehead on the affected side

(Ramsey Hunt's syndrome) is the second most common cause of hemifacial palsy. Typical varicella-zoster infection is associated with skin blistering or blebs involving the tympanic membrane, external auditory canal, or postauricular skin. Often these patients complain of severe pain around the affected auricle and may experience sensorineural hearing loss. The severity and prognosis for recovery of facial function is much graver in varicella-zoster infection.

Other infectious sources of unilateral facial palsy merit consideration. Acute otitis media may present as unilateral facial palsy. This is believed to be secondary to inflammation at natural dehiscences of the fallopian canal through the middle ear cavity. Suppurative or coalescent mastoiditis may alter neural conduction through the facial nerve in its vertical segment in the temporal bone. Interestingly, the most common head and neck manifestation of Lyme disease is facial nerve paralysis. HIV-associated facial nerve paralysis has also been reported.

Parotid gland neoplasms may present with hemifacial paresis or paralysis, as can paragangliomas involving the middle ear cavity. Temporal bone malignancy, primary or metastatic, may also present in a similar fashion. Cholesteatoma may also erode the fallopian canal, causing paresis of the facial nerve. A cerebellopontine angle tumor such as an acoustic neuroma may present with facial weakness as well as with hearing loss, vertigo, and facial hypesthesia.

Traumatic injury to the facial nerve, either in its intratemporal course or after exiting the stylomastoid foramen, must be excluded. This would include recent surgeries involving the parotid gland, middle ear, or internal auditory canal as well as trauma violating the tympanic membrane or resulting in a temporal bone fracture.

Inflammatory causes of facial palsy include Sjögren's syndrome, amyloidosis, sarcoidosis, and Guillain-Barré syndrome. Presentation of a patient with bilateral palsies should raise suspicion of these diagnoses.

Patients with metabolic disorders such as diabetes mellitus and preeclampsia have been noted to have a higher incidence of facial palsy of various etiologies.

Central nervous system insults such as cerebrovascular accident and multiple sclerosis may present with facial paralysis. These lesions typically present as an upper motor neuron lesion pattern without involvement of the upper face musculature on the affected side.

Diagnostic Approach

An imaging study is indicated if there is no improvement in facial paresis after one month, hearing loss, multiple cranial neuropathies, or if there signs of limb paresis or sensory loss. A CT of the temporal bones is indicated if trauma is suspected or if an intratemporal facial nerve tumor is suspected. Magnetic resonance imaging with gadolinium is the test of choice to rule out a cerebellopon-

tine angle tumor, multiple sclerosis, or other structural lesions. An audiogram with stapedial reflexes should be obtained if hearing loss is reported to help rule out an acoustic neuroma.

If a patient has evidence of systemic symptoms such as fever, weight loss, rash, or a progressive facial weakness without improvement, a complete blood count with differential helps rule out lymphoreticular malignancy. Blood glucose (or hemoglobin A1C) should be ordered if diabetes is suspected. Serum antibodies against varicella zoster and *Borrelia burgdorferi* should be obtained if these entities are high on the differential list. Serum calcium and angiotensin-converting enzyme levels should be ordered if sarcoidosis is suspected.

Management and Therapy

The management of acute unilateral facial palsy is directed toward decreasing presumed inflammation influencing the facial nerve, preventing potential complications, and establishing prognosis for recovery.

Optimum Treatment

Optimum treatment for Bell's palsy includes a regimen of corticosteroids equivalent to 1 mg/kg prednisone daily for 1 week, tapering to off over a second week of therapy. This has been demonstrated to improve return of facial function. Antiviral therapy has also been shown to improve outcome when given in conjunction with corticosteroids, and a typical dose equivalent to 1000 mg of acyclovir daily is often used for 7 to 10 days. Early treatment (within 3 days of onset) is necessary for acyclovir-prednisone therapy to have the greatest effects.

Meticulous eye protection and care is critical in patients unable to fully close the affected eye (House-Brackmann grade IV or higher). This should consist of the liberal use of artificial tears and lubricating ointment multiple times daily until the protective function of eye closing returns. In addition, the affected eye should be taped or patched in the closed position before sleeping to avoid inadvertent damage or desiccation to the exposed cornea during sleep. Rarely, a tarsorrhaphy may be required to prevent eye damage.

Electrical testing can be used as an aid to predict prognosis in acute facial paralysis. Unlike many other nerves, the facial nerve cannot easily be stimulated proximal to the presumed site of inflammation or edema. Instead, stimulation of the trunk of the facial nerve as it exits the stylomastoid foramen with measurement of compound muscle action potential amplitude at the muscles of facial expression has been shown to be helpful in establishing prognosis. This test, called electroneurography (ENOG), is only beneficial between days 3 and 21 after complete loss of voluntary movements. In patients with more than 90% degeneration on ENOG compared with the contralateral

side and no evidence of motor unit potentials on electromyography by day 14 of paralysis, a poorer prognosis for return of facial function can be given and surgical decompression considered.

The role of surgical decompression of the facial nerve in acute paralysis has generated much debate. Surgical decompression undertaken in carefully selected patients with clearly defined electrical findings has been shown to improve final outcome of facial nerve function. The approach for this surgery involves a middle cranial fossa craniotomy with selected decompression of the perigeniculate region of the facial nerve by an experienced otolaryngologist or neurosurgeon. This directed decompression is focused on the regions of the facial nerve with the most restrictive bony canal anatomy and has been shown to improve final House-Brackmann grade of facial nerve function.

Avoiding Treatment Errors

The best way to avoid treatment errors is to be thorough in the evaluation of patients with facial palsy, considering all possible etiologies before placing the patient on an acyclovir-prednisone regimen. A serious medical condition or tumor may otherwise be missed.

Recovery

Generally, recovery from paresis or paralysis of the facial nerve is satisfactory. For patients with poor recovery 3 to 6 months after onset of weakness and no other discoverable cause, several surgical procedures may help restore function. For patients with poor recovery of eye-closing function, upper eyelid gold weight implantation may be considered to enhance corneal protection. For patients with poor recovery of the muscles of facial expression, a variety of reanimation and reinnervation operations have been developed in recent years.

Future Directions

Although the current evidence linking HSV infection to Bell's palsy is strong, our understanding of when and why the latent infection causes symptoms is poorly understood. In order to demonstrate that the reactivation of HSV virus from its latent to lytic state, a study performing reverse transcriptase polymerase chain reaction aimed at detecting lytic state-specific messenger ribonucleic acids should be performed. A recent article has also reported facial palsy following the administration of the inactivated intranasal

influenza vaccine, indicating that other viruses can be pathogenic.

This meta-analysis indicates that corticosteroid treatment improves complete facial motor recovery for individuals with complete idiopathic facial nerve paralysis.

Trigeminal Neuralgia

Introduction

Trigeminal neuralgia (TGN), also known as *tic douloureux*, is a clinical entity defined by episodes of brief, lancinating facial pain in the sensory distribution of the trigeminal nerve. Painful episodes are usually triggered by specific sensory stimuli such as chewing, light touch, or shaving. No other symptoms accompany the pain episodes, and their presence should alert the examiner to question the diagnosis. The finding of a neurologic deficit on clinical exam should trigger a more exhaustive workup for other etiologies. Most cases occur in patients in their fifth decade or beyond, with an incidence ranging from 1 to 4 per 100,000 persons per year, and with females predominating over males in some reports in a 2 : 1 ratio.

Etiology and Pathogenesis

The exact cause of TGN is unclear. In 1934, Walter Dandy published a series of 215 cases of TGN. Although Dandy did not discuss presenting symptoms, he found that in most cases there was vascular compression of the sensory component of the trigeminal nerve, most commonly by the superior cerebellar artery, or no obvious abnormality. Currently, the leading etiologic theory is that the sensory root entry zone of the trigeminal nerve is particularly susceptible to mechanical compression, most commonly by the superior cerebellar artery. Microscopically, the root entry zone adjacent to the brainstem provides an area of transition from central to peripheral myelin. Pathophysiologically, mechanical disturbance as a result of vascular compression may result in ephaptic transmission and the conduction of painful stimuli.

Clinical Presentation

Patients presenting with idiopathic TGN complain of brief, recurrent episodes of lancinating pain confined to one or more divisions of the trigeminal nerve (Fig. 132-1). Most commonly, the V2 (maxillary) and V3 (mandibular) divisions are involved unilaterally. Fewer than 6% of cases involve V1 (ophthalmic). The pain is often induced by touch of the affected dermatome. Long periods of spontaneous remission are common. Episodes tend to become more frequent and more severe with time, which may lead to malnutrition and poor hygiene of the affected region. Bilateral symptoms occur in about 5% of patients and

should alert the examiner to the possibility of multiple sclerosis. The presentation of patients with TGN is often quite stereotypical and includes paroxysmal lancinating pain, triggers based on chewing or touch to a trigger area, and presence during the day and absence during sleep. Many authors also include response to a trial of carbamazepine as diagnostic, with failure of response indicative of a need to search for other etiologies.

Differential Diagnosis

The presence of any neurologic deficit should alert the physician to consider diagnoses other than idiopathic TGN. Facial pain, accompanied by neurologic deficits, may be caused by a variety of mass lesions, including tumors, infection, aneurysms, other vascular malformations or even multiple sclerosis. A small minority of patients with underlying mass lesions may present without neurologic deficit, complaining only of lancinating, paroxysmal pain episodes inseparable from those of TGN. The differential diagnosis is broad (Box 132-1). The diagnosis is made by careful history and physical examination. Any deviation from the stereotypical presentation outlined earlier or the presence of other accompanying symptoms and findings should prompt an evaluation for other diagnoses.

Diagnostic Approach

Strict attention to the clinical history and physical examination is the key to successful diagnosis of both primary

Figure 132-1 Typical Distribution Patterns of Trigeminal Neuralgia and Relevant Anatomy.

and secondary TGN. Specifically, attention to the defining characteristics of the pain is critical. The exact location, the precise quality, the duration and timing, and the triggering and alleviating factors of pain should all be noted. Pain that is atypical for TGN (constant, dull, or throbbing; a pain that awakens the patient from sleep or is in an unusual distribution) should prompt consideration of other etiologies because any of these characteristics make the diagnosis of TGN suspect. Furthermore, any neurologic deficit found on physical examination should point to diagnoses other than that of idiopathic TGN. Finally, most TGN patients respond to carbamazepine at least briefly. Given the broad range of diseases that present similarly to TGN, magnetic resonance imaging (MRI) of the brain should be performed to help eliminate other causes of

facial pain. An otherwise negative MRI helps confirm the diagnosis of TGN and may demonstrate vascular compression of the trigeminal nerve. There are no laboratory tests that help make the diagnosis, although such tests can be helpful in narrowing the differential diagnosis as suggested by the history and physical examination.

Management and Therapy

Optimum Treatment

The goal of optimum treatment is to alleviate the patient's pain with a minimum of side effects. Initial treatment is almost always pharmacologic. First-line therapy is carbamazepine, which provides initial relief in more than 80%

Box 132-1 Limited Differential Diagnosis of Facial Pain
Neuralgias Trigeminal neuralgia Geniculate neuralgia Glossopharyngeal neuralgia Occipital neuralgia Sphenopalatine neuralgia
Infectious Herpes zoster
Demyelinating Multiple sclerosis
Tumor Intracranial tumors Cerebellopontine angle masses Head and neck cancers
Tooth and Jaw Dental disease Temporomandibular disease
Eyes, Orbits, and Sinuses Glaucoma Iritis Optic neuritis Sinusitis
Vascular Temporal arteritis Aneurysms Vascular malformations
Headache syndromes Cluster headache Migraines
Psychiatric Atypical facial pain

of patients. Over time, the effectiveness of carbamazepine declines in many patients, and up to 40% of patients have some type of side effect. Furthermore, carbamazepine is an inducer of hepatic metabolism and can interact with many other pharmacologic agents. The usual initial dose is 200 mg/day and is titrated upward to the usual therapeutic range, 800 to 1200 mg/day. Side effects can include dizziness, sedation, nystagmus, hepatic and bone marrow toxicity, syndrome of inappropriate antidiuretic hormone secretion, congestive heart failure, and rashes. Periodic monitoring of complete blood count, platelet count, and liver function tests is mandatory. Gabapentin is often the second agent added to or substituted for carbamazepine. It should begin at 300 mg, then, on the second day, 300 mg twice a day, followed by 300 mg 3 times a day. The dosage may then be titrated up to 2.4 g/day. Phenytoin is also used, although it has not been demonstrated to be as effective as carbamazepine and should be considered only after other therapies fail. If there is no response to anticonvul-

sants or if breakthrough pain occurs, baclofen may be added or substituted. However, the long-term response rate of baclofen is less than 50%. Dosing should begin at 5 mg 3 times a day, increasing 5 mg per dose every 3 days to a maximum of 80 mg per day. Clonazepam has been shown to be effective but is often too sedating to use in clinical practice.

Surgical Approaches

Failure to respond to medical therapy or the presence of intolerable side effects mandates surgery. Surgical approaches fall into three categories: percutaneous ablative procedures, microvascular decompressive procedures, and stereotactic radiosurgical procedures.

Various ablative procedures have been used for the treatment of TGN. All result in some degree of facial numbness. The most common procedures include percutaneous retrogasserian glycerol injection, percutaneous balloon compression of the trigeminal ganglion, and percutaneous radiofrequency trigeminal rhizotomy (PTR). In each procedure, the foramen ovale is cannulated percutaneously through a needle introduced through the cheek ipsilateral to the patient's symptoms. Patient selection includes those who have failed medical management, are older than 70 years, are in poor health, are willing to tolerate facial numbness, and have symptoms excluding the V1 distribution. Of patients treated by ablation of the trigeminal nerve, 99% experience initial pain relief after one procedure. Forty-six percent of patients experience postoperative facial analgesia, 42% dense hypalgesia, and 17% mild hypalgesia, however. Dysesthesia develops in 36% of patients with postoperative analgesia, in 15% of patients with dense hypalgesia, and in 7% of patients with mild hypalgesia. Pain recurrence occurs in 18% of patients with postoperative analgesia, 21% of patients with dense hypalgesia, and 47% of patients with mild hypalgesia. Mortality is rare.

Microvascular decompression (MVD) of the trigeminal nerve is more invasive than the percutaneous procedures but offers the advantage of preserving facial sensation. This treatment modality should be entertained in younger patients, in patients with symptoms in the V1 distribution, and in patients expressing unwillingness to tolerate facial numbness. Based on several reports, in 75% of cases, the superior cerebellar artery compresses the trigeminal root, whereas a vein accounts for compression in an additional 12% of cases. Immediate pain relief occurs in 82% of patients. Ten years after surgery, 70% continue to have excellent pain relief. The rate of facial numbness is 1% and that of dysesthesia requiring treatment, 0.3%. Major complications in a study involving 1185 subjects included two deaths (0.2%), one brainstem infarction (0.1%), and 16 cases of ipsilateral hearing losses (1%). Factors predictive of long-term operative success include male gender, duration of preoperative symptoms less than 8 years, absence

of venous compression, and immediate postoperative relief.

Reported success rates for the treatment of TGN demonstrate that immediate relief of pain for all procedures is excellent, ranging from 91% for glycerol rhizotomy to 98% for MVD and PTR. The recurrence rate is highest for glycerol injection (54%) and lowest for MVD (15%), with PTR having a 20% to 23% recurrence rate. Major dysesthesia occurs in 2% to 10% of PTR procedures, 55% of glycerol injections, and 0.3% of MVD procedures. Perioperative mortality is 0.6% for MVD and close to 0% for percutaneous procedures.

Recently, stereotactic radiosurgery (SRS) has been used in the treatment of TGN. SRS, the least invasive of the surgical approaches, consists of focused-beam radiation therapy. Emerging evidence suggests that this is an effective technique, although recurrence rates are unknown. The most common side effect is facial numbness. Effectiveness is decreased if the patient has undergone previous surgical treatment. The major advantage of SRS is its lack of invasiveness. The major disadvantage of SRS is that, unlike the other surgical treatment options, pain relief is not immediate but may take weeks or months to appear. SRS is therefore not suitable for the patient with severe TGN who is unable to eat, but may be the treatment of choice for patients with less severe disease.

In summary, the diagnosis of TGN should be made based on careful history and physical examination and with the aid of MRI. Pharmacologic therapy should then be initiated, usually with carbamazepine if there is no contraindication. Failure to respond to carbamazepine requires additional therapy with other anticonvulsants or baclofen. When all medical therapies have been exhausted, surgical therapy can be entertained; the choice of surgical therapy depends on the distribution of the pain, patient characteristics, and patient preference.

Avoiding Treatment Errors

Treatment errors fall into two broad categories. The first is related to making the correct diagnosis and initiating treatment. Any instance in which the history and physical findings are not characteristic should trigger a search for other etiologies. Subsequent to that, patients should be followed for improvements and medication tolerance. The second broad category is failure to consider surgical treatment in selected patients. Newer procedures are promising and should be considered in symptomatic patients who have failed all potential medical therapies or who are unable to function because of debilitating symptoms, such as anorexia.

Future Directions

TGN remains a debilitating disease. Medical treatment is currently the clear mainstay of therapy. However, surgical treatment can provide effective results in patients who have failed a reasonable trial of drug therapy. MVD is relatively safe, is well tolerated, provides immediate relief, and may be definitive. Surgical therapy can provide immediate relief of symptoms, and should be considered early, particularly in patients who are unable to function because of severe symptoms such as anorexia. One other avenue of investigation is the efficacy and safety of SRS. Recent data in small studies have shown that repeat SRS is effective but also seem to indicate that some sensory loss is necessary for SRS to be effective. The primary advantage of SRS is that it can be performed noninvasively and apparently repeatedly. Furthermore, debilitated patients unable to tolerate surgical procedures may remain good candidates for radiosurgery.

Multiple Sclerosis

Introduction

Multiple sclerosis (MS) is a disease of central nervous system (CNS) white matter that afflicts young adults, with a peak incidence between ages 20 and 30 years. Prevalence of the disease in the United States is close to 300,000. The impact of MS is considerable given the age at onset, lost work and family time, and the overall reduction in quality of life.

The diagnosis of MS is based on a careful history and neurologic examination combined with a diagnostic magnetic resonance imaging (MRI) scan and, in some cases, a confirmatory lumbar puncture (LP). Recent advances in the treatment of MS have come through a better understanding of immune-mediated damage to the nervous system leading to effective immunomodulatory therapies designed to block specific steps in disease development. During the past 10 years, six immunomodulatory therapies have been approved for MS and are now routinely used in most patients with relapsing-remitting (R-R) disease. They effectively decrease new lesion formation, relapse rate, and disability accumulation.

Etiology and Pathogenesis

MS is a chronic inflammatory CNS disease. Most of the studies suggest an autoimmune etiology of the disease that results in perivascular demyelination of CNS white matter through an autoimmune inflammatory process. Mechanisms of remyelination are incompletely effective, accounting for partial recovery and accumulation of deficits with repeated attacks over time. The specific mechanisms responsible for initiation, maintenance, and cessation of attacks are under intensive investigation.

Genetic and environmental factors play a role in the disease development. Although individuals with the major histocompatibility subtypes HLA-DR2, B7, and A3 at greater risk for developing MS, it is likely that many genes are involved in the disease. Genetic factors influencing disease onset are reflected in twin studies, in which the monozygotic concordance rate is 35%. The rate of concordance in dizygotic twins is only 5%. First-degree relatives carry at least a 10% increased risk for the disease compared with an age-matched unrelated population.

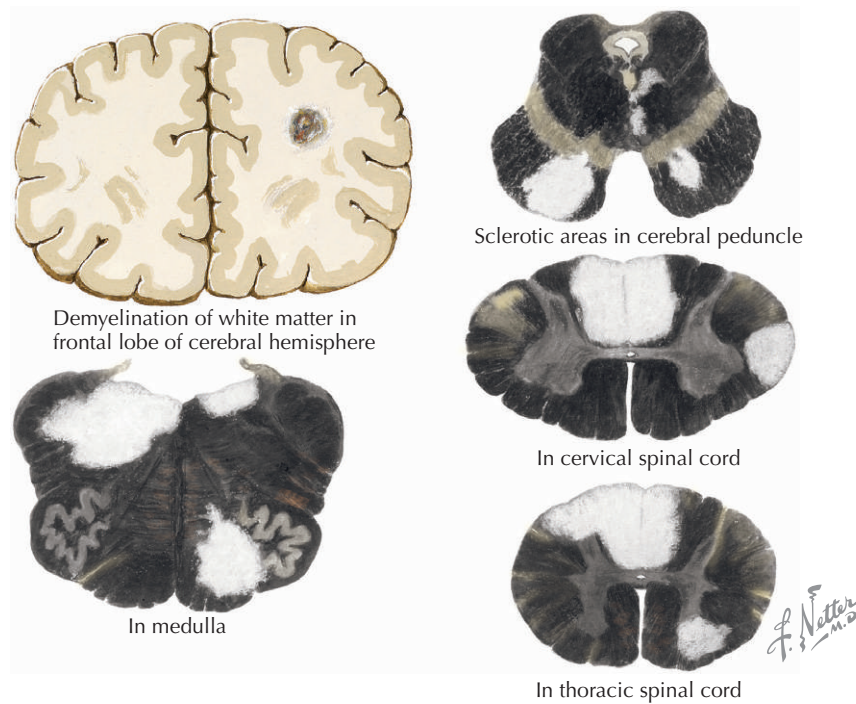

Older epidemiologic studies reported that risk for developing MS is based in part on geographic location during the first 15 years of life. The condition is progressively more common with distance from the equator in both hemispheres. Those of northern European ancestry

are at relatively high risk, whereas African Americans exhibit half the risk of whites. Asians and Hispanics in the United States carry a low overall risk. Whether the geographic risk of developing MS is more related to environment or genetics remains unknown.

Although seasonal variations in disease activity have been reported, the pace of the illness is largely independent of environmental factors. Physical trauma, emotional stress, and upper respiratory infections have been implicated and may precipitate attacks. Elevated body temperature temporarily brings out latent and reversible neurologic deficits secondary to impaired neural transmission through partially demyelinated axons.

Clinical Presentation

Typically, multiple attacks occur over a period of years, involving multiple areas of CNS white matter in a process of plaque formation (Fig. 133-1). Several patterns of attack are encountered. R-R MS occurs in about 85% of cases, is more common in younger females, and often starts with prominent sensory-visual symptoms (Fig. 133-2). The average attack frequency is less than one per year in that group. R-R MS is not only the most prevalent subtype of MS. It is also the only subtype of MS that responds

Figure 133-1 Multiple Sclerosis: Central Nervous System Plaques.

favorably to the immunomodulatory therapies. Chronic progressive MS without remitting features is seen in up to 10% of patients, typically later in onset and more frequently in males. A progressive component of the illness develops in half of those with R-R MS after 10 years, termed *secondary progressive MS*. A fulminant course without remission is encountered rarely. Cases of single attacks without further progression have been reported. Patients with clinically isolated syndrome, or first clinical attack suggestive of MS, who have, in addition, an MRI scan consistent with MS, have an 80% risk for developing clinically definite MS within 2 years. Recently, efforts have focused on starting immunomodulatory therapy as early as possible to reduce long-term disability. This approach requires early diagnosis of the disease, and this has been possible with advances in MRI.

Symptoms in the R-R form develop over hours to days and are followed by variable recovery over days to weeks. Sensory symptoms, muscle weakness, monocular blindness, double vision, vertigo (see Fig. 133-2), incoordination, and bladder dysfunction are among the most common presentations of MS. Multiple symptoms, reflecting involvement of multiple areas of white matter, can appear during a single attack. First attacks, especially if not associated with visual or motor deficits, tend to be unnoticed except in retrospect, being attributed to viral causes, stress, or minor trauma. Some patients will experience recurrent episodes involving the same brain region. Diffuse symptoms, including fatigue, cognitive deficits, diffuse pain, and depression, usually follow the initial attacks. The timing

of attacks and degree of recovery are highly variable and are best predicted by the clinical course during the first 2 years, by the accumulation of lesions noted on MRI and by the presence of contrast-enhancing lesions on MRI, suggestive of acute inflammatory changes.

Pain at presentation is uncommon, although two thirds of patients with MS will have significant pain at some time during their illness. Pain syndromes include central neuropathic pain with burning dysesthesias and radicular pain similar to trigeminal neuralgia. Lhermitte's sign is a painful shock-like sensation, usually experienced in the neck, upper back, or limbs, occurring spontaneously or with neck movement. Spasticity can lead to painful muscle contractions. Autonomic nervous system impairment can lead to painful distention of the bladder. Headache is more common (27%) in individuals with MS than in an age-matched population (12%). Optic neuritis can be painful before and during the episode. There is an increase in seizures in individuals with MS—with a frequency twice that of a matched population—but overall seizures are uncommon. Constipation and bladder dysfunction often require careful management. Emotional lability and cognitive deficits are associated with accelerated cortical atrophy noted in some patients with MS.

Prognosis

The average duration of R-R MS is 5 to 10 years from diagnosis. Limited resolution in the wake of repeated exacerbations leads to the accumulation of disability that char-

acterizes the secondary progressive phase. Overall life expectancy is reduced only by 5 to 7 years. Death from complications of MS is more common in males with progressive forms of the illness. Pneumonia and loss of respiratory drive are associated causes in those patients. Depression is common. The suicide rate is increased sevenfold, especially when the diagnosis is first established, and later when there is advanced disability.

MS is benign 40% of the time, with few limiting deficits after 15 years. Favorable prognostic factors include younger age at onset, dominance of sensory and visual symptoms, female gender, an R-R pattern of attacks, and sparing of spine and bladder. Poor prognosis is associated with age at onset older than 35 years, early motor impairment, male gender, a chronic progressive pattern, and cerebellar and spinal involvement.

MRI is the best predictor of risk for clinical exacerbations in the ensuing 6 to 12 months. It reveals disease about 10 times more often than the clinical exam. Predictors of clinical flares include significant accumulation of visualized lesions over time and the presence of gadolinium-enhancing lesions on MRI.

Differential Diagnosis

Recurrent exacerbations of CNS vasculitis can mimic MS. Atypical features for MS, such as psychosis, seizures, and gray matter lesions on MRI, assist in making the correct diagnosis. CNS systemic lupus erythematosus (SLE) is characterized by disseminated lesions in subcortical perivascular areas. However, SLE with CNS involvement generally does not have a relapsing-remitting clinical course,

and there is often an elevated serum antinuclear antibody titer along with evidence of systemic involvement not seen in MS. Behçet's disease and Sjögren's syndrome can manifest as multifocal CNS disease. Behçet's disease is suspected when there are multiple cranial nerve deficits in combination with oral or genital ulcers, uveitis, and meningoencephalitis. A diagnosis of Sjögren's syndrome can be made with a lip or parotid gland biopsy. Vitamin B₁₂ deficiency can present with progressive spinal cord symptoms that correlate with white matter lesions in the posterior columns seen with MRI. Adrenoleukodystrophy and tropical spastic paraparesis can also resemble MS, but these entities are rare. Vascular disease with multiple transient ischemic attacks or infarctions generally occurs in an older population, or in those with significant risk factors for vascular disease, and is not often mistaken for MS. Sarcoid, lues, and tumors must also be considered in the differential diagnosis. They can be distinguished by a combination of MRI and cerebrospinal fluid (CSF) studies when suspected. The diagnosis of MS can be quite difficult in the case of a first attack that has atypical features.

Diagnostic Approach

The diagnosis of MS rests on a history of multiple episodes of CNS dysfunction, occurring over a period of months to years with variable recovery, combined with a neurologic examination revealing abnormal signs referable to multiple CNS locations. MRI is invariably used to confirm diagnosis of MS and demonstrates multiple disseminated hyperintense T2 and fluid-attenuated inversion recovery (FLAIR) intensity changes in periventricular distributions. Lesions are typically larger than 0.5 cm, round or oval in shape, and oriented perpendicularly to the corpus callosum and lateral ventricles. LP and evoked potential studies are useful in confirming the clinical impression and ruling out other conditions (Figs. 133-3 and 133-4).

Definitive MS is characterized by the history of two distinct attacks with two or more lesions confirmed by clinical examination or supportive laboratory studies. MRI of brain and spinal cord, with and without gadolinium, is used to define active lesions (contrast positive) and to assess total lesion load visualized on T2-weighted and FLAIR MRI images. An absence of MRI-visualized lesions is incompatible with diagnosis of MS. The CSF is usually positive for oligoclonal bands or elevated immunoglobulin G/albumin CSF/serum ratios in 95% of confirmed cases when the disease has been present for more than 1 year. The CSF may be normal with the first attack, and repeated LPs may be needed to identify the presence of antibodies synthesized within the CNS (see Fig. 133-3).

Evoked potential electroencephalograms are useful in uncovering clinically silent white matter lesions that may confirm the diagnosis by establishing multiple sites of CNS involvement (see Figs. 133-3 and 133-4).

Management and Therapy

It is helpful for patients to know the variable and progressive nature of the disease. They should be informed about the high degree of variability of attack and recovery patterns in MS that make outcome predictions regarding disability for a given individual very difficult.

Immunomodulatory therapy is recommended for all patients with a clinically isolated syndrome suggestive of MS and for definitive R-R MS. Although immunomodulatory agents have not been shown to have efficacy in primary and secondary progressive MS, many symptomatic therapies that contribute to improved quality of life can be offered.

Optimum Treatment

Optimum treatment includes involvement of caregivers familiar with the all the different manifestations of the disease, the primary medications for acute exacerbations as well as those that directly influence the long term prognosis, dietary and stress management recommendations, and the various treatment strategies for the many symptoms that can develop. There are many choices in therapy (see later), and those therapies that are most highly recommended are listed first.

Acute Exacerbations

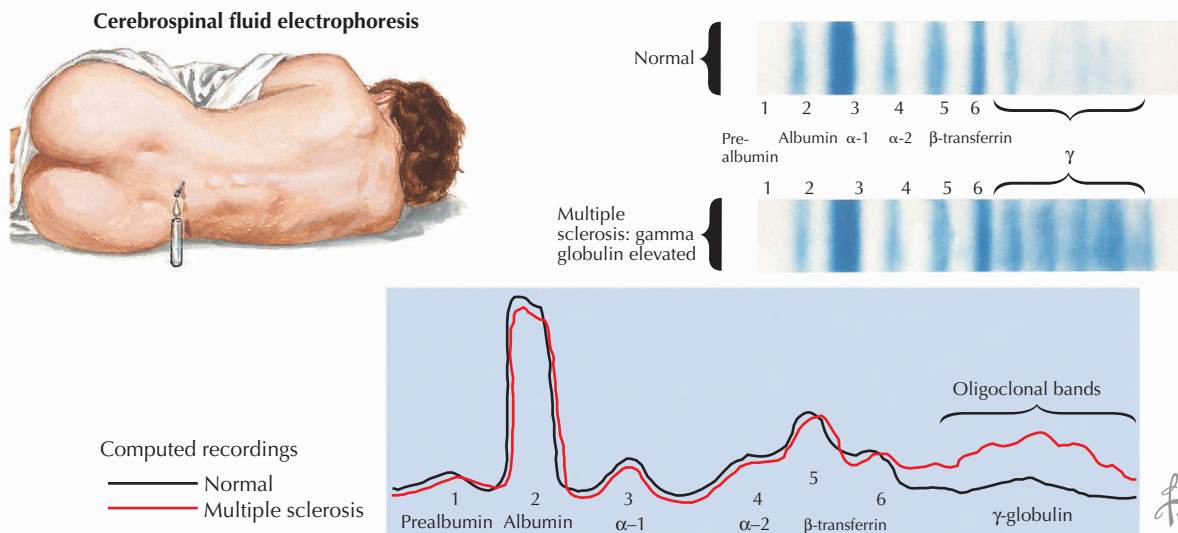

High-dose, pulsed corticosteroids have immediate anti-inflammatory effects and can significantly shorten clinical attacks. Side effects of short-term intravenous steroids are limited. Chronic oral steroids have no beneficial effects on the long-term progression of the disease and must be avoided.

Optimum therapy for acute attacks is methylprednisolone, given daily, 1 g intravenously for 5 consecutive days. Steroids are most effective if administered within 2 weeks of the onset of new symptoms. Although positive effects of steroids may be immediate, in some individuals the beneficial responses are delayed by a month or more.

Long-Term Therapy

Several medications have been shown to have efficacy in suppression of disease activity over years. The choice of agent is often determined by the fewest side effects and the preference of the patient in terms of route and time of administration.

Interferon (IFN)-β1a and IFN-β1b reduce the number of attacks in R-R forms of MS by an average of 35%. They also reduce the number of MRI-documented new lesions by up to 85%. The mechanism of action of interferons is complex. In MS, IFN-β1a and 1b likely inhibit inflammatory cell activity and T-cell migration across the blood-brain barrier. Dosing is either by weekly intramuscular injection (IFN-β1a) or every-other-day subcutaneous injection (IFN-β1a and 1b). Side effects include flu-like

Figure 133-3 Multiple Sclerosis: Diagnostic Tests I.

symptoms, headache, injection-site reactions, and possibly worsening of depression. Neutralizing antibodies occur in 5% to 45% of patients and are associated with reduction in treatment efficacy. Liver enzyme abnormalities and blood count changes occur in 5% to 20% of treated patients and require close follow-up for the duration of therapy.

Glatiramer acetate (copolymer 1, COP-1) is a mixture of four amino acids that are over-represented in the immunodominant epitope of the presumed autoantigen, myelin basic protein. It has been proposed that glatiramer acetate induces tolerance against myelin antigens that trigger autoimmune responses. Given daily by subcutaneous injection, it reduces exacerbations by one third in R-R MS. It is well tolerated with minimal side effects.

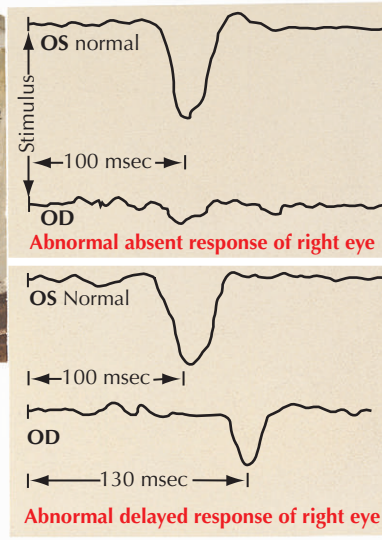

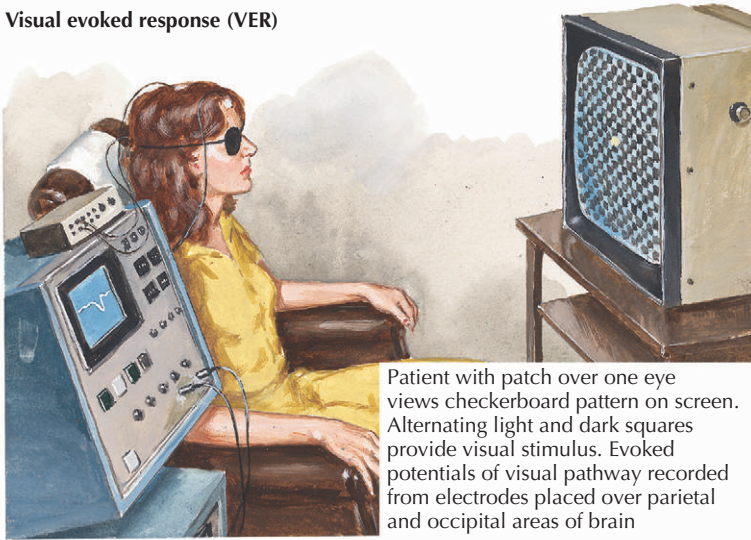

Mitoxantrone (Novantrone) is an immunosuppressive agent approved for patients with aggressive MS with

clinical disease progression despite the first-line therapy with IFN or glatiramer acetate. Intravenous infusions are administered every 3 months. Mitoxantrone is cardiotoxic and requires monitoring of cardiac ejection fraction. It also induces neutropenia with increased risk for infection. Patients receiving mitoxantrone need to be carefully monitored and also treated before each treatment with antiemetic medications.

Natalizumab (Tysabri) is a recently approved immunomodulatory therapy. It is a humanized monoclonal antibody against adhesion molecules expressed on activated mononuclear cells. Natalizumab blocks the migration of activated mononuclear cells from the peripheral circulation into the CNS. The efficacy of natalizumab is somewhat higher than IFN treatment. However, upon initial approval of the drug, three fatal cases of progressive

Figure 133-4 Multiple Sclerosis: Diagnostic Tests II.

Visual evoked response (VER)

Brainstem auditory evoked response (BAER)

multifocal leukoencephalopathy were associated with its use. Therefore, it is restricted to a subset of patients with very aggressive disease who are willing to accept the risk.

Intravenous immunoglobulin and plasmapheresis are used in patients with neuromyelitis optica, a subset of MS mediated by antibodies.

Azathioprine, methotrexate, cladribine, cyclophosphamide, and cyclosporine have limited benefit in patients with rapidly progressive MS, and these agents are only rarely considered because of the significant side-effect profile that limits their use.

Dietary Therapies

Dietary recommendations currently include the supplemental use of vitamin D and adopting a diet low in saturated fats. Epidemiologic studies suggest that regular intake of vitamin D from supplements, but not from food,

may protect against developing MS. Older studies show that lowering saturated fats in the diet can reduce the number of exacerbations.

Additional studies around fats in the diet have yielded mixed results. One randomized, controlled clinical trial that compared supplements of a vegetable oil mixture containing either linoleate or oleate for 2 years found a greater severity of clinical relapses in patients taking oleate than those receiving the linoleate. Another randomized clinical trial compared four groups using lower and higher dosages of linoleic and oleic acid and reported marginally shorter, and less severe, exacerbations in those taking a higher dose of linoleic acid.

Stress Management

Stress management is an important element in successful management of MS. One study showed that MS relapse

F. Netter M.D.

rate is predicted by the frequency of acute stressors as well as coping responses that utilize social support. These studies suggest that avoidance of multiple stressors, amelioration of perceived stress, and enhancing coping through social support may be beneficial in reducing relapse risk. Mindfulness meditation and other relaxation therapies that have been shown to reduce self-perceived stress and anxiety in mixed patient populations may be helpful.

Symptomatic Therapies

Optimum treatment of MS includes attention to the many symptoms that can accompany the disease and reduce function and quality of life.

Effects of fatigue can be reduced with regular exercise, yoga, the addition of complex carbohydrates to the diet, and multivitamin supplements. Amantadine, 100 mg up to 3 times a day, and modafinil (Provigil), 100 mg up to 2 times a day, are the only proven therapies for this problem.

Painful muscle spasms may be reduced with baclofen, starting at 5 mg 3 times per day up to 80 mg/day, or tizanidine (Zanaflex), from 4 mg 3 to 4 times a day up to 36 mg/day. Drowsiness and fatigue are side effects at higher doses. Patients with severe spasticity may benefit from intrathecal baclofen, administered by an implantable pump delivery system, which provides higher CSF concentrations with fewer systemic side effects. Physical therapy, massage, osteopathy, yoga, acupuncture, meditation, and biofeedback can all be helpful.

Therapy for significant urinary incontinence or retention should be guided by urodynamic studies when possible. Urgency, frequency, or a “no-warning” bladder can be treated with anticholinergic agents such as oxybutynin chloride (Ditropan), 5 mg twice a day up to 20 mg/day, or an extended release form once a day. When urodynamics reveal problems with bladder emptying, urinary bladder catheterization every 4 to 6 hours is recommended. Biofeedback can also be helpful in controlling bladder dysfunction.

Burning dysesthesias and lancinating, tic-like pain may respond to gabapentin, up to 800 mg 4 times a day; carbamazepine, up to 400 mg three times a day; or other anti-epileptic agents. Muscular pain responds to slow stretch exercise, massage, and cooling. Transcutaneous nerve stimulation and trigger point injections are also useful for muscle pain. Use of tricyclic antidepressants for pain is limited by side effects. Training in self-hypnosis can also be useful.

Depression is encountered in more than half of patients at some time in their disease, particularly in younger patients early in the illness. Counseling combined with selective serotonin reuptake inhibition can ameliorate these symptoms that are often part of the response to this chronic disabling disease. Guided imagery, self-hypnosis, massage, and meditation practices are helpful alternative treatments for anxiety.

Avoiding Treatment Errors

In the treatment of acute exacerbations, it is important to avoid leaving the patient on steroids for longer than a few weeks. Steroids tend to worsen pulmonary, urologic, and dermatologic infections that are often a part of moderate and advanced levels of disease.

The recent important advances in treatment through more direct modification of the immune system provide many choices for the patient and clinician. From the standpoint of compliance, it is important that the patient is comfortable with the choice of route of administration of those drugs (particularly for injectable medications). Depression or cognitive decline in an individual patient may at times be mistakenly attributed to the primary disease process when in fact they may be reversible side effects of medications. It is important to recognize major depression in MS because it can be effectively treated pharmacologically. Occult infections, particularly urinary tract, can result in marked clinical worsening and should be looked for at each visit and with each exacerbation. Levels of social support, the extent of physical disabilities, and nutritional status assessment are all critical in overall management and should be assessed regularly.

Future Directions

Major areas of investigation include further definition of key steps in the immune process leading to plaque formation: suppression of T-cell activation, limitation of T-cell penetration into the CNS, and inhibition of proinflammatory cytokine production. Because the disease is associated with early and irreversible axonal loss, neuroprotective agents are actively being sought. Use of combination therapies is likely to be an important approach in the future, with different immunomodulatory therapies targeting different steps in disease development. In addition, neuroprotective agents will provide better protection in terms of new lesion development and the accumulation of neurologic deficits leading to disability. Tailoring therapies toward disease subsets, as well as toward the individual patient, will be guided by gene expression profiling. The roles of lifestyle adjustments, such as diet, supplements, and alternative therapies, is promising and will be further evaluated in controlled clinical trials.

Additional Resources

Bowling AC: *Alternative Medicine and Multiple Sclerosis*, 1st ed. New York, Demos Press, 2005.

This is an excellent compendium of evidence and recommendations relating to the use of complementary and alternative therapies in multiple sclerosis. The potential for the effects of diet on the disease is covered, as are such topics as use of herbals and supplements, movement therapy, acupuncture, and many other modalities.

Ernst E, Pittler MH, Wider B: *The Desktop Guide to Complementary and Alternative Medicine: An Evidence-Based Approach*, 2nd ed. London, Mosby, 2006.

This is an excellent source for assessment of the nature of evidence for and against use of complementary and alternative therapies in multiple sclerosis.
Noseworthy JH, Lucchinetti C, Rodriguez M, Weinshenker BG: Multiple sclerosis. *N Engl J Med* 343(13):938-952, 2000.

The authors provide a good review of the major clinical features of multiple sclerosis.

EVIDENCE

1. Brown RF, Tennant CC, Sharrock M, et al: Relationship between stress and relapse in multiple sclerosis: Part I. Important features. *Mult Scler* 12(4):453-464, 2006.

In this important prospective study of 101 subjects with MS followed for 2 years, a bidirectional effect of stress and increased relapse rates was discovered. Chronic stress, including the stress of having MS, did not have an effect, whereas acute stress was correlated with increased relapse rates, and vice versa. Multiple lesser acute stress events had a greater effect on relapse than fewer major stress events.

2. Brown RF, Tennant CC, Sharrock M, et al: Relationship between stress and relapse in multiple sclerosis: Part II. Direct and indirect relationships. *Mult Scler* 12(4):465-475, 2006.

This is an extension of the above study showing again that the frequency of acute stressors was the most important factor correlating with an increase in relapse. Rates of relapse were not correlated with extent of disease, demographics, psychosocial factors, or lifestyle. Management of even minor acutely stressful situations may be important in slowing disease activity.

3. Calabresi PA: Considerations in the treatment of relapsing-remitting multiple sclerosis. *Neurology* 58(8 Suppl 4):S10-S22, 2002.

Thorough review of immunomodulatory medications available for relapsing-remitting MS, which is largely still current. The evidence for effectiveness through use of MRI is discussed along with the role of corticosteroids in management of acute exacerbation.

4. Hafler DA: Multiple sclerosis. *J Clin Invest* 113(6):788-794, 2004.

After a brief review of what is known about the immunology of MS from the standpoint of autoreactive T cells and the chain of events leading to CNS damage, the author discusses new methods to define the molecular pathology through cutting-edge genetic methodology.

5. McDonald WI, Compston A, Edan G, et al: Recommended diagnostic criteria for multiple sclerosis: Guidelines from the International Panel on the diagnosis of multiple sclerosis. *Ann Neurol* 50(1):121-127, 2001.

A panel of experts presents recommendations that allow integration of MRI data with clinical presentations to facilitate diagnosis, determination of prognosis, and decision making in the management of the disease.

6. Sospedra M, Martin R: Immunology of multiple sclerosis. *Annu Rev Immunol* 23:683-747, 2005.

This highly informative review of the role of the immune system in multiple sclerosis is written from the standpoint of possible inciting events, the resulting immunologic cascade with particular attention to key reactions, and the contributing role of the nervous system in determining clinical presentations.

Myasthenia Gravis

Introduction

Myasthenia gravis (MG) is the most common primary disorder of neuromuscular transmission. The usual cause is an acquired immunologic abnormality, but some cases result from genetic abnormalities related to proteins, receptors, and hormones critical for normal function of neuromuscular junctions. The estimated incidence of MG is 9 per million per year with a prevalence of 200 per million population; however, MG is probably underdiagnosed. Previous studies showed that women are more often affected than men. The most common age at onset is the second and third decades in women and the seventh and eighth decades in men. With aging of the population, the average age of onset of MG has also increased. Today males are more often affected than females, and the onset of symptoms is usually after age 50 years.

Etiology and Pathogenesis

The normal neuromuscular junction releases acetylcholine (ACh) from the motor nerve terminal in discrete packages (quanta). These ACh quanta diffuse across the synaptic cleft and bind to specific receptors on the folded muscle end-plate membrane. Stimulation of the motor nerve releases many ACh quanta that depolarize the muscle end-plate region and the muscle membrane, causing muscle contraction. In acquired MG, the postsynaptic muscle membrane is distorted and simplified, having lost its normal folded shape. ACh receptor (AChR)-specific antibodies attach to the membrane, and as a result, the concentration of AChRs is reduced on the muscle end-plate membrane. ACh is released normally, but its effect on the postsynaptic membrane is reduced as a result of these abnormalities, lessening the probability that any nerve impulse will cause a muscle action potential.

Thymic abnormalities are associated with MG, but the nature of the association is uncertain. Ten to 15% of patients with MG have a thymic tumor, and 70% have hyperplastic changes (germinal centers) that indicate an active immune response. These hyperplastic changes occur in areas within lymphoid tissue where B cells interact with helper T cells to produce antibodies. Because the thymus is the central organ for immunologic self-tolerance, it is reasonable to suspect that thymic abnormalities cause the breakdown in tolerance that produces an immune-mediated attack on AChR in MG. The thymus contains

all the necessary elements for the pathogenesis of MG: myoid cells that express the AChR antigen, antigen-presenting cells, and immunocompetent T cells. Thymus tissue from patients with MG produces AChR antibodies when implanted into immunodeficient mice. It remains to be elucidated whether the role of the thymus in the pathogenesis of MG is primary or secondary.

Most thymic tumors in patients with MG are benign, well differentiated, and encapsulated and can be removed completely at surgery. It is unlikely that thymomas result from chronic thymic hyperactivity because MG can develop years after thymoma removal, and the human leukocyte antigen haplotypes that predominate in patients with thymic hyperplasia are different from those in patients with thymomas. Patients with thymoma usually have more severe disease, higher levels of AChR antibodies, and more severe electromyographic (EMG) abnormalities than patients without thymoma. Almost 20% of patients with MG whose symptoms began between the ages of 30 and 60 years have thymoma; the frequency is much lower when symptom onset is after age 60 years.

Clinical Presentation

Patients with MG complain of specific muscle weakness rather than generalized fatigue. Ocular motor disturbances, ptosis or diplopia, are the initial symptom of MG in two thirds of patients; almost all have both symptoms within

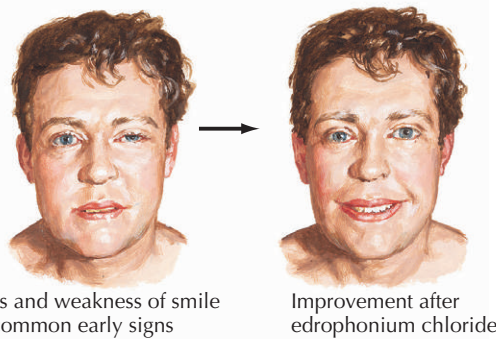

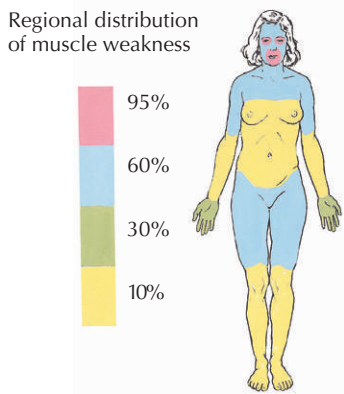

Figure 134-1 Myasthenia Gravis.

Normal neuromuscular junction: Synaptic vesicles containing acetylcholine (ACh) form in nerve terminal. In response to nerve impulse, vesicles discharge ACh into synaptic cleft. ACh binds to receptor sites on muscle sarcolemma to initiate muscle contraction. Acetylcholinesterase (AChE) hydrolyzes ACh, thus limiting effect and duration of its action

Myasthenia gravis: Marked reduction in number and length of subneural sarcolemmal folds indicates that underlying defect lies in neuromuscular junction. Anticholinesterase drugs increase effectiveness and duration of ACh action by slowing its destruction by AChE

Clinical manifestations

2 years (Fig. 134-1). Oropharyngeal muscle weakness (difficulty chewing, swallowing, or talking) is the initial symptom in one sixth of patients. Limb weakness occurs in only 10%. Initial weakness is rarely limited to single muscle groups such as neck or finger extensors or hip flexors. The severity of weakness fluctuates during the day, usually being least severe in the morning and worse as the day progresses, especially after prolonged use of affected muscles.

The course of disease is variable but usually progressive. Weakness is restricted to the ocular muscles in about 10%

of cases. The rest have progressive weakness during the first 2 years involving oropharyngeal and limb muscles. Maximum weakness occurs during the first year in two thirds of patients. Before corticosteroids were used for treatment, about one third of patients improved spontaneously, one third became worse, and one third died of the disease. Without treatment, spontaneous improvement can occur early in the course of the disease, but typically symptoms fluctuate over a relatively short time and then became progressively severe for several years. Treatment (see later) has improved the course and prognosis of MG.

Myasthenic symptoms are made worse by emotional upset, systemic illness (especially viral respiratory infections), hypothyroidism or hyperthyroidism, pregnancy, the menstrual cycle, drugs affecting neuromuscular transmission, and increases in body temperature.

Differential Diagnosis

The differential diagnosis of muscle weakness is broad; however, in typical cases, the diagnosis is apparent to the clinician. Variable eyelid ptosis and fluctuating ophthalmoparesis are unique to MG. In less typical cases, one must consider diseases of the motor neuron and the muscle membrane (mitochondrial myopathies). Rarely, neurotoxins, central nervous system disorders involving the brainstem, and cavernous sinus thrombosis must be considered. Careful neurologic examination and appropriate diagnostic testing should clarify each diagnosis.

Diagnostic Approach

Weakness caused by abnormal neuromuscular transmission characteristically improves after intravenous administration of edrophonium chloride. Often, it is diagnostic in patients with ptosis or ophthalmoparesis, but it is less useful when other muscles are weak. Some patients, particularly infants and children, who do not respond to intravenous edrophonium chloride, may respond to intramuscular neostigmine because of the longer duration of action. In some patients, a therapeutic trial of daily oral pyridostigmine produces improvement that cannot be appreciated after a single dose of edrophonium chloride or neostigmine.

Serum antibodies that bind human AChR are found in 70% to 90% of patients with acquired generalized myasthenia and 50% to 75% with ocular myasthenia. The serum concentration of these anti-AChR antibodies varies widely among patients with similar degrees of weakness and cannot predict the severity of disease. About 10% of patients, who do not have binding antibodies, have other antibodies that modulate the turnover of AChR in tissue culture. The concentration of anti-AChR antibodies may be low or absent at symptom onset and become elevated later. Anti-AChR antibodies are rarely increased in patients with systemic lupus erythematosus, inflammatory neuropathy, amyotrophic lateral sclerosis, rheumatoid arthritis and taking D-penicillamine, and thymoma without MG, and in normal relatives of patients with MG. False-positive test results are reported when blood is drawn within 48 hours of a surgical procedure using general anesthesia and muscle relaxants. An elevated concentration of AChR-binding antibodies in a patient with compatible clinical features confirms the diagnosis of MG, but normal antibody concentrations do not exclude the diagnosis. Antibodies to muscle-specific receptor tyrosine kinase (MuSK), a surface membrane component essential in the development of the neuromuscular junction, are found in up to

50% of MG patients who are seronegative for AChR antibodies.

The amplitude of the compound muscle action potential elicited by repetitive nerve stimulation (RNS) is normal or only slightly reduced in patients without MG. The amplitude of the fourth or fifth response to a train of low-frequency nerve stimuli falls at least 10% from the initial value in myasthenic patients (Fig. 134-2). This decremental response to RNS is seen more often in proximal muscles, such as the facial muscles, biceps, deltoid, and trapezius, than in hand muscles, and becomes more marked as the disease progresses. A significant decrement to RNS is found in about 60% of patients with MG.

Single-fiber EMG (see Fig. 134-2), the most sensitive clinical test of neuromuscular transmission, shows increased jitter in some muscles in almost all patients with MG. Jitter is greatest in weak muscles but may be abnormal even in muscles with normal strength. In mild or purely ocular muscle weakness, increased jitter may be in facial muscles only. Increased jitter is a nonspecific sign of abnormal neuromuscular transmission and is seen in other motor unit diseases. Normal jitter in a weak muscle excludes abnormal neuromuscular transmission as the cause of weakness.

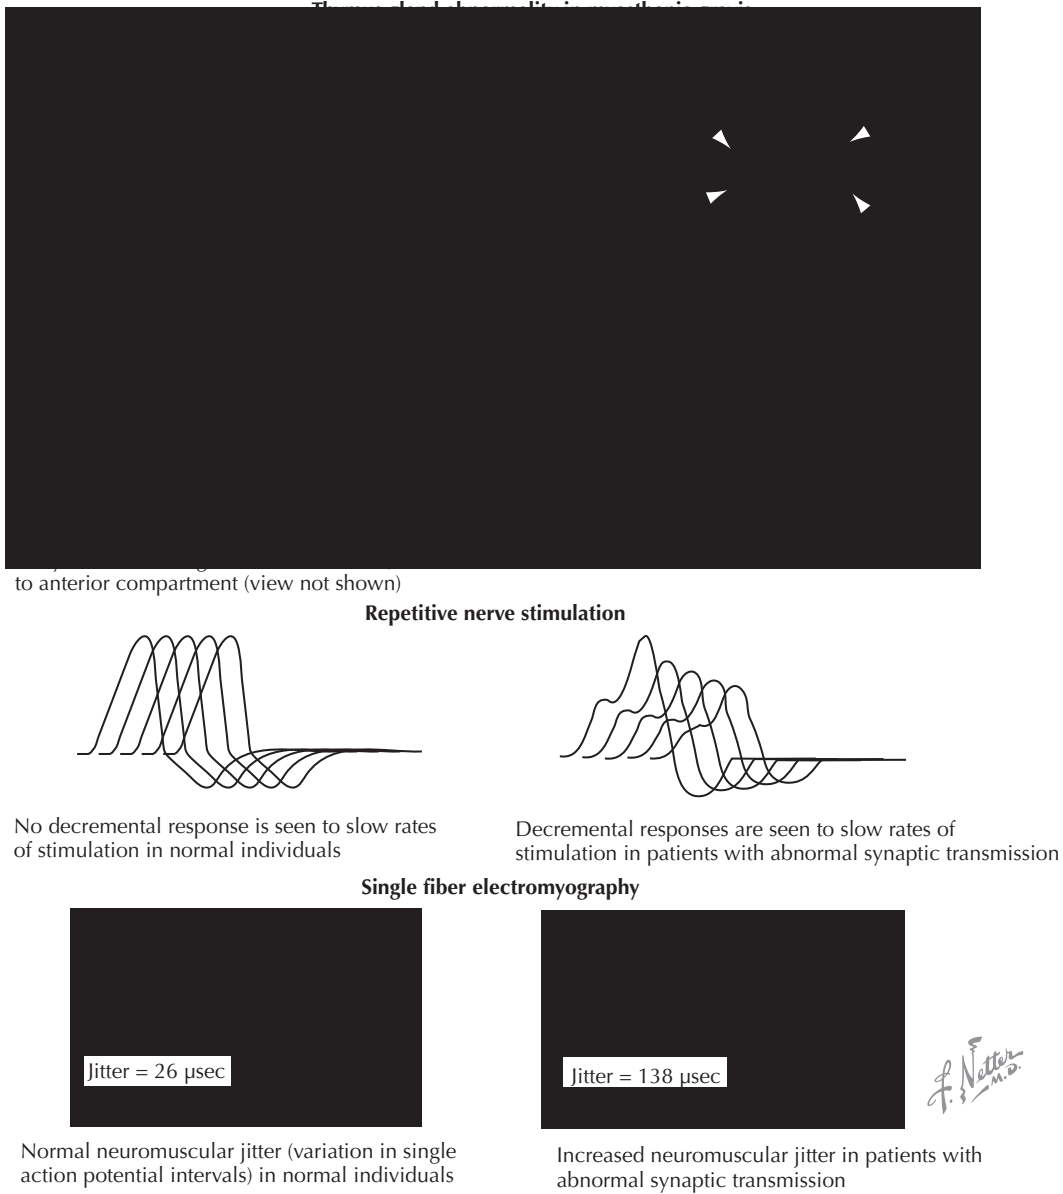

Management and Therapy

There are numerous treatment options for MG. All recommended regimens are empirical, and there is no consensus opinion among experts on a specific treatment of choice. Treatment decisions should be based on knowledge of the natural history of disease in each patient and the predicted response to a specific form of therapy. Treatment goals must be individualized according to the severity of disease, the patient's age and gender, and the degree of functional impairment. The response to any treatment is difficult to assess because the severity of symptoms fluctuates. Spontaneous improvements, even remissions, occur without specific therapy, especially during the early stages of the disease.

Cholinesterase (ChE) inhibitors retard the enzymatic hydrolysis of ACh at cholinergic synapses so that ACh accumulates at the neuromuscular junction and its effect is prolonged. ChE inhibitors cause considerable improvement in some patients and little to none in others. Strength rarely returns to normal. Pyridostigmine bromide and neostigmine bromide are the most commonly used ChE inhibitors. No fixed dosage schedule suits all patients. The need for ACh inhibitors varies from day to day and during the same day in response to infection, menstruation, emotional stress, and hot weather. Different muscles respond differently; with any dose, certain muscles get stronger, others do not change, and still others become weaker.

Gastrointestinal complaints (queasiness, loose stools, nausea, vomiting, abdominal cramps, and diarrhea) are common. Increased bronchial and oral secretions are a

Figure 134-2 Complementary Exams.

serious problem in patients with impaired swallowing or respiratory insufficiency. These adverse effects of ChE inhibitors likely result from ACh accumulation at muscarinic receptors on smooth muscle and autonomic glands and at nicotinic receptors of skeletal muscle. Central nervous system side effects are rarely seen at the ChE inhibitor doses typically used to treat MG. Symptoms of muscarinic overdosage may indicate that nicotinic overdosage (weakness) is also occurring. Excessive nicotinic receptor overdosage results in myasthenic crisis characterized by severe generalized weakness and respiratory failure.

Thymectomy is recommended for most patients with MG. Unfortunately, there are few studies that have directly correlated the severity of weakness before surgery with the

timing or degree of improvement after thymectomy. In general, however, the maximal favorable response to thymectomy occurs 2 to 5 years after surgery. However, this time frame is relatively unpredictable, and significant impairment may continue for months or years after surgery. The best responses to thymectomy are in young people early in the course of their disease, but improvement can occur even after 30 years (or more) of symptoms. Patients with disease onset after the age of 60 rarely show substantial improvement from thymectomy. Patients with thymomas do not respond as well to thymectomy as do patients without thymoma.

Marked improvement or complete relief of symptoms occurs in more than 75% of patients treated with prednisone, and even the remaining 25% of treated individuals

experience some improvement. Much of the improvement in symptoms occurs in the first 6 to 8 weeks, but strength may increase to total remission in the months that follow. The best responses occur in patients with recent onset of symptoms, but patients with chronic disease may also respond. The severity of disease does not predict the ultimate improvement. Patients with thymoma have an excellent response to prednisone before or after removal of the tumor. The most predictable response to prednisone occurs when treatment begins with a daily dose of 1.5 to 2 mg/kg/day. About one third of patients become weaker temporarily after starting prednisone, usually within the first 7 to 10 days, and lasting for up to 6 days. Treatment can be started at low dose to minimize exacerbations; the dose is then slowly increased until improvement occurs. Exacerbations may also occur with this approach, and the response is less predictable. The major disadvantages of chronic corticosteroids are their side effects.

Several other immunosuppressive medications are used in treatment of MG. Mycophenolate mofetil and azathioprine reverse symptoms in most patients. The effect is delayed by 4 to 8 months with azathioprine. Once improvement begins, it is maintained for as long as the drug is given, but symptoms recur 2 to 3 months after the drug is discontinued or the dose is reduced below therapeutic levels. Patients who do not respond favorably to corticosteroids may respond to other immunosuppressive drugs, and the reverse is also true. Some patients respond better to combination treatment with corticosteroids and another immunosuppressive drug than to either alone. Because the response to azathioprine is delayed, both drugs may be started simultaneously with the intent of rapidly tapering prednisone when azathioprine becomes effective. About one third of patients have mild dose-dependent side effects that may require dose reductions but do not require stopping treatment.

Cyclosporine inhibits predominantly T-lymphocyte-dependent immune responses and is sometimes beneficial in treating MG. Most patients improve 1 to 2 months after starting cyclosporine, and improvement is maintained as long as therapeutic doses are given. Maximum improvement is typically achieved 6 months or longer after starting treatment. After achieving the maximal response, the dose should be gradually reduced to a minimum dose that maintains improvement. Renal toxicity and hypertension are the most concerning adverse reactions. Many drugs interfere with cyclosporine metabolism and should be avoided or used with caution.

Cyclophosphamide can also be used intravenously and orally for the treatment of MG. More than half of patients become asymptomatic after 1 year. Side effects are common. Life-threatening infections are an important risk in immunosuppressed patients and patients with invasive thymoma. The long-term risk for malignancy is not established.

Therapeutic apheresis (plasma exchange) is used as a short-term intervention for patients with sudden worsening of myasthenic symptoms for any reason, to rapidly improve strength before surgery, and as a chronic intermittent treatment for patients who are refractory to all other treatments. The need for plasma exchange and its frequency of use is determined by the clinical response. Almost all patients with acquired MG improve temporarily following plasma exchange. Maximum improvement may be reached as early as after the first exchange or as late as after 14 exchanges. Improvement lasts for weeks or months, and then the effect is lost unless the exchange is followed by thymectomy or immunosuppressive therapy. Most patients who respond to the first plasma exchange will respond again to subsequent courses. Repeated exchanges do not have a cumulative benefit.

Favorable response to high-dose (2 g/kg infused over 2 to 5 days) infusions of intravenous immunoglobulin (IVIG) has been reported. Improvement occurs in 50% to 100% of patients, usually within 1 week, and clinical improvement often lasts for several weeks or months. The common adverse effects of IVIG are related to the rate of infusion. The precise mechanism of action is not known but most likely involves a nonspecific down-regulation of antibody production.

Avoiding Treatment Errors

Treatment errors can be avoided when the treating clinician has a thorough understanding of the predicted course of disease in each patient, the predicted response to a specific treatment, and the potential side effects of treatment decisions. Treatment goals must be individualized according to the severity of disease, the patient's age and gender, and the degree of functional impairment. Successful treatment of MG requires close medical supervision and long-term follow-up. Return of weakness after a period of improvement should be considered a herald of further progression that requires reassessment of current treatment and evaluation for underlying systemic disease or thymoma.

Future Directions

The future of MG treatment lies in the elucidation of the molecular immunology of the anti-AChR response with the goal of developing a rational treatment for the illness that will cure the abnormality in the immune system that results in the AChR immune response. To this end, six broad categories of theoretical treatment strategies need to be explored: first, treatments that target the antigen-specific B cells; second, treatments that target the antigen specific CD4+ T cells; third, treatments that interfere with co-stimulatory response for antigen presentation; fourth, treatments aimed at inducing tolerance or anergy of the CD4+ T cell to the autoantigen or the CD4+ epitopes;

fifth, treatments designed to stimulate those immunologic circuits that activate CD8+ cells specific for the activation antigens expressed by CD4+ cells; and sixth, treatments that intervene with cytokine function and discourage auto-immune-mediated inflammatory responses.

Urinary Tract Infection

Introduction

Urinary tract infection (UTI) is a broad term describing microbial colonization of the urine and infection of any of the components of the urinary tract, including the urethra, bladder, ureters, renal pelvis, and kidneys. UTI is among the most common reasons for office visits in general medical practice; it is also among the most common predisposing causes of bacteremia and sepsis in hospitalized patients. UTI is divided into four categories: asymptomatic bacteriuria (AB), uncomplicated UTI, complicated UTI, and acute pyelonephritis. Uncomplicated UTIs are those that occur in otherwise healthy adult women who are not pregnant and who do not have underlying abnormalities of the urinary tract. Complicated infections are all others.

Etiology, Pathogenesis, Clinical Presentation, Differential Diagnosis, and Diagnostic Approach

Asymptomatic Bacteriuria

In adult, nonpregnant, healthy women of childbearing age, the prevalence of AB is about 6%, using a urine culture cutoff of more than 10^5 colony forming units/mL. The most common infecting organism is *Escherichia coli*. Epidemiologic studies have shown that AB may resolve spontaneously, but it is sometimes associated with an increased incidence of symptomatic UTI with the onset of sexual activity. Treatment is not indicated unless there is a history of recurrent UTI.

Screening and treatment for AB are an essential part of prenatal care because, untreated, it is associated with a 40% risk for UTI and a 20% to 60% risk for acute pyelonephritis in late pregnancy. AB is also associated with prematurity and low birth weight.

In diabetic women, the incidence of AB may be as high as 18%. Treatment is still not generally recommended because recurrence is extremely high, and no long-term benefit can be documented. Treatment is also not recommended in elderly people who live independently because no adverse effects have been documented. In those with long-term indwelling catheters who are colonized, treatment tends to select out resistant strains and will not eradicate bacteriuria while the catheter remains in place.

Uncomplicated Urinary Tract Infection

Acute cystitis is extremely common. About one half of adult women report having had at least one UTI. Young, sexually active women have about 0.5 episodes per person year. *E. coli* is responsible for infection in about 80% of episodes in healthy adult women, whereas *Staphylococcus saprophyticus* accounts for most of the rest. Cystitis develops when fecal flora from the rectum colonize the vaginal introitus and periurethral zone, colonize the urethra, ascend into and invade the bladder mucosa, proliferate in the urine, and incite an inflammatory response (Fig. 135-1). The shorter urethra in women may help explain why women are more susceptible than men, but not why some women are more susceptible than others. Studies have indicated that uropathogens, such as *E. coli*, have special characteristics that facilitate this process of colonization and invasion, whereas other studies indicate that host factors also play a role. Of particular interest are the studies examining the role of behavioral or mechanical factors. In women otherwise predisposed to UTI, the frequency of sexual intercourse and the use of spermicide-containing contraceptives, particularly the diaphragm-spermicide combination, are clearly associated, as is a history of UTI. Perineal hygiene and the direction of wiping have not been shown to be associated.

The usual symptoms of cystitis are dysuria, along with frequency, urgency, suprapubic discomfort (and tenderness), and hematuria. The diagnosis is made by the history,

Figure 135-1 Factors in Etiology of Cystitis.

physical examination (temperature, abdominal exam, and evaluation for costovertebral angle tenderness), and examination of the urine. Although the gold standard for pyuria is the finding of 10 to 20 leukocytes/mm³ in an unspun, midstream urine using a counting chamber, examination of the urine sediment for white blood cells and bacteria is more routinely done. In practice, urine dipsticks that detect leukocyte esterase, indicating significant pyuria, provide a reliable method for excluding and a rapid method for confirming the likelihood of infection. Dipsticks also allow testing for nitrite, which, when positive, indicates the presence of Enterobacteriaceae, which convert nitrate to nitrite. Urine cultures are not routinely done with uncomplicated UTI, unless it fails to resolve with treatment,

relapses quickly after treatment, or frequently recurs. Imaging studies of the urinary tract are also unnecessary.

Patients presenting with dysuria as their predominant symptom have the broadest differential diagnosis. Hematuria makes cystitis more likely. Urethritis due to *Neisseria gonorrhoea* or *Chlamydia trachomatis* is suggested by a history of sexually transmitted disease (STD), a new partner or one with urethral symptoms, a more gradual or uneven onset of symptoms, and the presence of pyuria with negative urine culture results. Pelvic examination is indicated to look for discharge from the urethral or cervical os. Although Gram stain and culture of discharge are still valuable in the diagnosis of gonococcal infection, DNA amplification tests on urine have emerged as highly sensi-

tive and specific for detection of both *Chlamydia* and *N. gonorrhoea*. In patients with dysuria, particularly when it is perceived as an external burning and is accompanied by symptoms of vaginitis (vaginal discharge or odor, pruritus, and dyspareunia), infection with *Candida albicans*, *Trichomonas vaginalis*, and *Gardnerella vaginalis*, especially in young, sexually active women, is more likely. Patients with vaginitis usually have a negative urine culture, and pyuria is less common. Pelvic examination to detect and characterize the vaginal discharge is indicated, as well as microscopic examination of the discharge to distinguish among the three common infecting organisms and to guide treatment.

Recurrent Urinary Tract Infection

Most recurrent UTIs in otherwise healthy women represent reinfection, not relapse or recurrence with the same strain. The epidemiology, organisms, clinical presentation, and treatment regimens are the same as those for initial episodes. Most recurrences occur within 3 months, and single recurrences are quite common. In those predisposed, the frequency of sexual intercourse and the use of the diaphragm-spermicide combination are strongly associated, as is recent antibiotic use and a history of UTI.

Complicated Urinary Tract Infection

Complicated UTIs are those that occur during pregnancy, in the presence of structural or functional abnormalities of the urinary tract (obstruction, stones, or indwelling urinary catheters), in patients with underlying diseases such as diabetes who are immunosuppressed, in institutionalized elderly patients, in men, and in children (see Fig. 135-1).

In pregnancy, the focus is on detecting asymptomatic bacteriuria by urine culture and preventing the significant morbidity of UTI and acute pyelonephritis later in pregnancy. The same uropathogens are involved as in uncomplicated UTI. Predisposing factors include dilation of the ureters and forward displacement of the bladder as the uterus enlarges, along with incomplete emptying.

In men, UTI may be asymptomatic or present with symptoms of cystitis, prostatitis, epididymitis, or pyelonephritis. Bacteriuria and symptomatic infections are uncommon in males younger than 50 years in the absence of urinary tract instrumentation or prostatitis. Organisms that persist in the prostate gland and intermittently colonize the bladder urine usually cause recurrent UTI in younger men. Prostatic infections are difficult to eradicate, especially when prostatic stones are present. In older men, the organisms are those associated with complicated infection, usually in association with obstructive symptoms or the use of indwelling catheters.

Patients with diabetes usually have uncomplicated UTI. However, some diabetic patients, mostly women with a history of recurrent UTI due to multidrug-resistant organ-

isms, have an increased risk for severe acute cystitis and acute pyelonephritis, complicated by papillary necrosis, perinephric abscess, and bacteremia. Predisposing factors in these patients include impaired bladder emptying, impaired leukocyte function, and focal damage to the kidney as a consequence of diabetic microangiopathy.

Patients with spinal cord injuries and demyelinating diseases such as multiple sclerosis suffer high morbidity and mortality because of urosepsis associated with neurogenic bladders. Chronic indwelling catheters should be avoided in these patients in favor of intermittent (4 times/day) in-and-out catheterization.

UTI in the more debilitated elderly patient is usually complicated, often by concomitant disease, by bladder malfunction, incontinence, or indwelling catheters. UTI accounts for more than 50% of episodes of bacteremia in institutionalized elderly patients, often in those with long-term indwelling catheters.

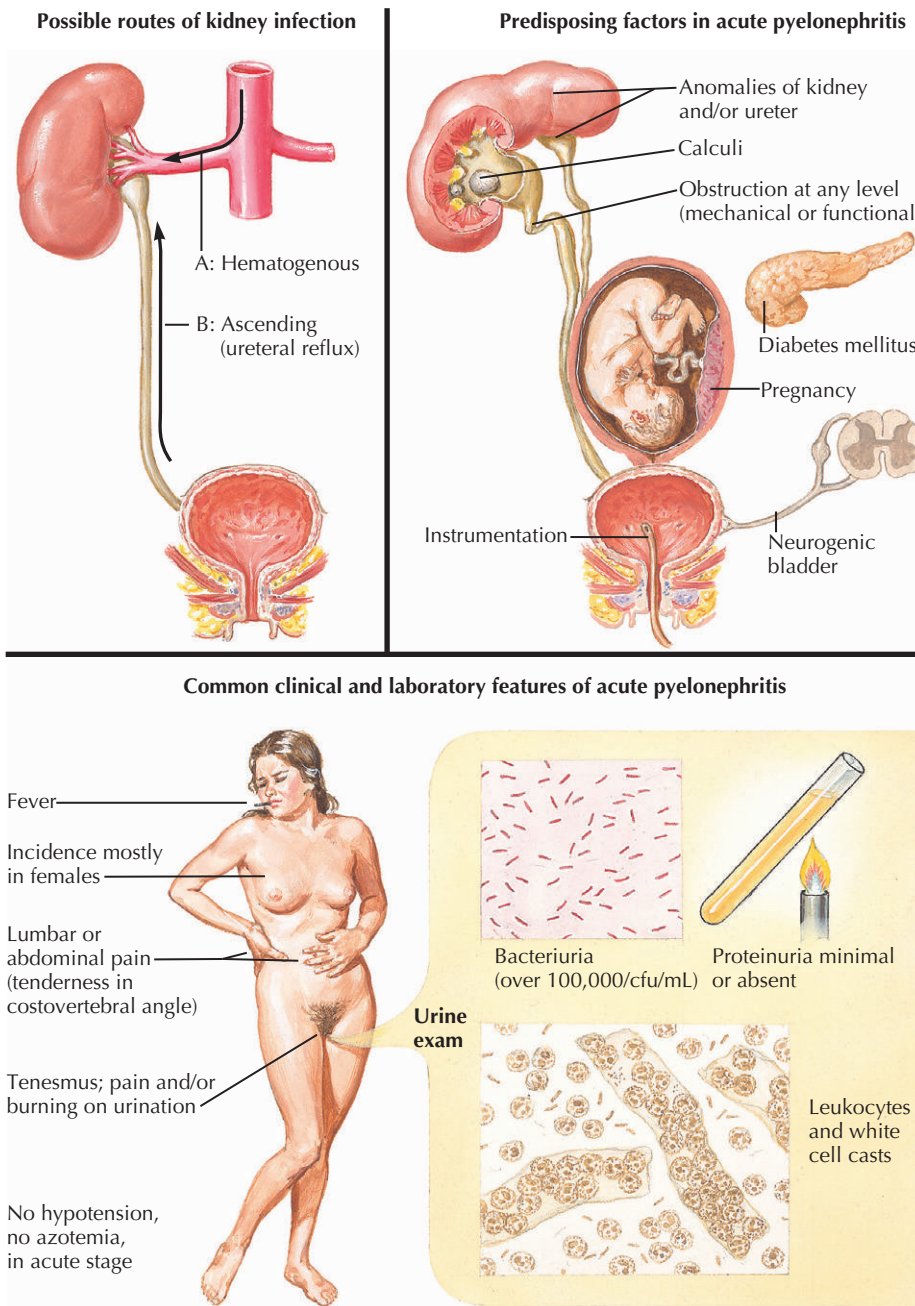

Acute Pyelonephritis

Acute pyelonephritis presents with fever, flank pain, costovertebral angle tenderness, leukocytosis, pyuria with white cell casts in the urine sediment, positive urine culture results, and frequently, bacteremia (Figs. 135-2 and 135-3). The risk factors for pyelonephritis are similar to those for acute and recurrent cystitis, which supports the concept that pyelonephritis is caused by the ascent of organisms from the bladder. Specific variables associated with pyelonephritis include frequency of intercourse, new sexual partners, spermicidal use, diabetes, history of previous UTI, and stress incontinence. With regard to specific sexual practices, anal sex was marginally associated with acute pyelonephritis, but oral sex was not. The most common (85%) organism causing acute pyelonephritis is *E. coli*. Most uncomplicated episodes occur in young women and respond to treatment with no residual damage. In all others, renal and bladder ultrasound studies are standard. These studies are rapid, noninvasive, and less expensive than other radiologic screening procedures, show the extent of renal involvement, eliminate obstruction and stones, and indicate the ability to empty the bladder. The differential diagnosis includes renal or ureteral stones, acute cholecystitis, appendicitis, diverticulitis, tubo-ovarian abscess, and acute pancreatitis (Box 135-1).

Management and Therapy

Optimum Treatment

Uncomplicated Urinary Tract Infection

For cystitis, 3-day, short course antibiotic regimens for uncomplicated UTI using trimethoprim-sulfamethoxazole, trimethoprim, or the fluoroquinolones (ofloxacin, ciprofloxacin, norfloxacin) are more effective than 1-day

regimens, and equally as effective as 7-day regimens with lower cost and better compliance. Nitrofurantoin, for 7 days, remains an established alternative. Many do not recommend the fluoroquinolones as initial drugs because of concerns about cost and the emergence of resistance. The increasing resistance of *E. coli* to trimethoprim-sulfamethoxazole needs to be kept in mind. No adverse effects on renal function or long-term morbidity have been documented as a consequence of uncomplicated UTI.

Figure 135-3 Acute Pyelonephritis: Pathology.

Surface aspect of kidney: Multiple minute abscesses (surface may appear relatively normal in some cases)

Cut section: Radiating yellowish gray streaks in pyramids and abscesses in cortex; moderate hydronephrosis with infection; blunting of calyces (ascending infection)

Acute pyelonephritis with exudate chiefly of polymorphonuclear leukocytes in interstitium and collecting tubules

J. Netter M.D.

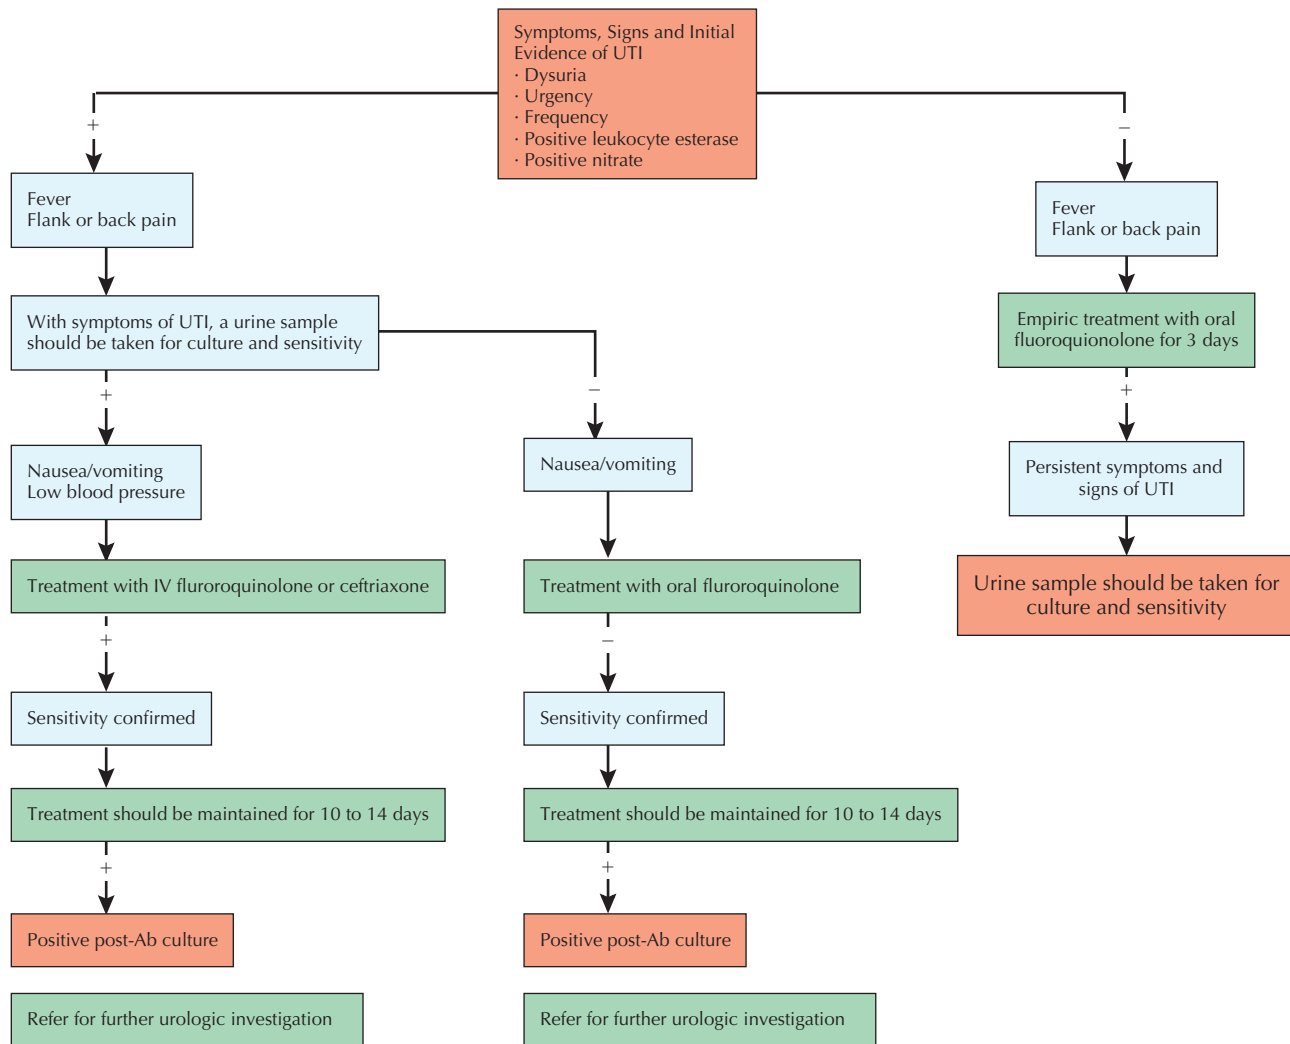

Recurrent Urinary Tract Infection

Highly recurrent infections, more than two within a year, indicate the need to consider preventive and prophylactic measures. Successful approaches, using trimethoprim-sulfamethoxazole, trimethoprim, or the fluoroquinolones (ofloxacin, ciprofloxacin, norfloxacin) have been reported using three regimens: continuous daily treatment for at least 6 months, and sometimes for an additional 2 years in the event of relapse; postcoital single-dose treatment if the episodes are temporally related to intercourse; and intermittent self-treatment at the first onset of symptoms in reliable, highly motivated patients. Decisions on which to use are based on physician and patient preference. Imaging

studies are almost always unrevealing, and no long-term adverse consequences have been noted.

Complicated Urinary Tract Infection

The presence of underlying structural abnormalities determines the nature of invading organisms and choice of therapy. Treatment of complicated infections remains difficult; it is more important to relieve obstruction, remove foreign bodies, such as stones and catheters, and restore complete emptying than to eradicate organisms. The usual pathogens include the more resistant strains of *E. coli*, enteric gram-negative organisms, *Pseudomonas*, *Staphylococcus aureus*, enterococci, yeast, and fungi.

Figure 135-4 Algorithm for Treatment of Uncomplicated UTI.

Treatment during pregnancy is complicated by the fact that trimethoprim and the quinolones are not approved for use, and tetracycline is contraindicated because it concentrates in bone and teeth. The β -lactam antibiotics and nitrofurantoin are highly effective. A single course of therapy is not always effective, and follow-up cultures are mandatory, including in the postpartum period when risk remains high. Abdominal and renal ultrasound studies are indicated in those in whom treatment repeatedly fails.

Antibiotic selection in men should be guided by urine culture. Nitrofurantoin and β lactams may not achieve predictable tissue concentrations. The fluoroquinolones provide the best initial coverage and adequate tissue levels. The site of infection, severity of symptoms, and frequency of recurrence determine the duration of therapy. Imaging studies are indicated, except in younger males with uncomplicated presentations.

Diabetes mellitus is an indication for initial therapy with a fluoroquinolone. Subsequent therapy is guided by cultures and imaging studies of the urinary tract and kidneys. Recurrences are difficult to prevent while impaired emptying persists.

In elderly patients who live independently and void normally, UTI is usually uncomplicated and responds to treatment without increased morbidity or mortality. However, it is complicated in the more debilitated elderly patients by septic shock in one third of cases, and the fatality rate in patients with bacteremia approaches 20%. These infections may be resistant to multiple antibiotics and are difficult to treat if the underlying abnormalities are not corrected. Incontinence occurs in 5% to 10% of elderly people living independently and in 50% of those in long-term facilities. It should be managed without a catheter whenever possible, using prompted voiding in the more

responsive or diapers in women and condom catheters in men. The indwelling catheter is an independent risk factor for premature death.

Acute Pyelonephritis

Hospitalization and intravenous drugs (guided by urine culture along with ultrasound studies) are indicated for hypotensive septic patients as well as those with nausea who cannot be treated at home; oral treatment is indicated otherwise. The usual duration of treatment is 10 to 14 days, and the fluoroquinolones are recommended for empiric therapy until cultures are available to guide treatment. If enterococcus is not documented on culture, ceftriaxone (1 g intravenously daily) is an effective and inexpensive agent.

Avoiding Treatment Errors

It is important to differentiate between lower (cystitis) and upper (pyelonephritis) UTI because pyelonephritis frequently requires more aggressive antibiotic therapy. The presence of costovertebral angle tenderness, fever, tachycardia, and hypotension is consistent with a diagnosis of pyelonephritis, which requires treatment with parenteral antibiotics (Fig. 135-4). Failure to recognize and treat urodynamic abnormalities (e.g., neurogenic bladder, vesicoureteral reflux, prostatic obstruction) will frequently result in failure to eradicate UTI on a long-term basis. The removal of infected struvite stones is indicated before antibiotic therapy and is effective in preventing recurrent infection. Finally, in patients with chronic indwelling Foley catheters, long-term suppression therapy is ill advised because it frequently selects out antibiotic-resistant organisms.

Future Directions

The need for a better understanding of the factors that predispose to urethral colonization and bladder infection, particularly in otherwise healthy women, is obvious. There is also a clear need, particularly in institutionalized elderly patients, to develop methods to restore function of the urinary tract that do not predispose to complicated infection. As resistance emerges to today's standard antibiotic regimens, the importance of developing new antibiotics will continue. Lactobacillus probiotics represent a new innovation in the treatment of institutionalized females. These lower the pH of the periurethral area and thereby decrease the risk for colonization by coliforms.

Bladder Function Disorders

Introduction

Bladder symptoms are a common presenting complaint in the primary care setting. Many of these symptoms are the result of infectious or inflammatory processes of the lower urinary tract. Others represent abnormalities in bladder storage and emptying. Urinary incontinence is a common and distressing symptom within this group, affecting between 25% and 38% of the female population. Many women do not seek treatment because of embarrassment and lack of knowledge of treatment options.

Adequate bladder storage and emptying depend on the anatomic relationships of the lower genitourinary system and the neurologic control of micturition. These bladder functions are also influenced by other systemic medical conditions and medications.

Etiology and Pathogenesis

Continence requires that the urethral closure pressure exceeds the intravesical pressure (Fig. 136-1). Urethral closure pressure is maintained by smooth and striated muscle, urethral vasculature, and the elasticity of the urethral tissue. It is also influenced by abdominal pressure due to the intra-abdominal location of the proximal urethra. Intravesical pressure increases with increases in intra-abdominal pressure and with detrusor contractions. With normal pelvic anatomy, intra-abdominal pressure is transmitted equally to the bladder and proximal urethra.

Neurologic control of urethral closure depends on stimulation of α receptors within the smooth muscle of the urethral sphincter by the sympathetic nervous system. In addition, the sympathetic system aids in storage of urine by relaxing the detrusor through stimulation of β receptors by norepinephrine. The parasympathetic system aids in voiding by contracting the detrusor muscle through stimulation of receptors by acetylcholine.

Control of micturition depends on a system of complex neurologic loops that interconnect the cerebral cortex, brainstem, sacral micturition center, detrusor muscle, and urethral sphincter. The integrity of these loops is necessary for proper storage and emptying of the bladder. Consequently, varied neurologic disorders, systemic diseases, and medications can affect the neurologic pathways involved.

Clinical Presentation

When evaluating a patient who complains of urinary incontinence, a thorough guided history and physical examination are essential. Important information includes duration, frequency, estimated volume, nocturia, enuresis, sensation of incomplete emptying, postvoid dribbling, impact on quality of life, history of urinary tract infections or urolithiasis, dysuria, hematuria, and associations with the loss of urine (e.g., coughing, laughing, running water). Pertinent parts of the history include medications; general medical history; previous surgeries, particularly gynecologic or urologic procedures; and an obstetric history including methods of delivery, birth weights, and delivery complications. A functional status evaluation is important to determine whether a patient is able to get to the toilet and to comply with treatment options. Smoking, caffeine, and alcohol intake are important variables to consider. A review of systems should include the gastrointestinal system, with particular emphasis on history of constipation. A review of systems should also probe for underlying neurologic or medical diseases that can affect proper bladder function. The patient should document a 3- to 7-day diary that tracks the amount and kind of fluid intake as well as the timing and volume of urinary voids and leaking episodes.

A complete pelvic examination should include testing pelvic floor muscle strength, reflexes, and sensation. The

Figure 136-1 Bladder Function.

Tonic relaxation of detrusor muscle and contraction of sphincters and levator muscles allow bladder filling. Accomplished via parasympathetic inhibition and stimulation of sympathetic and pudendal nerves

Voiding initiated by afferent input to cortical centers from stretch receptors in bladder wall. Parasympathetic inhibition released by pontine center. Sphincter and levator relaxation with detrusor contraction culminate in voiding

presence and degree of pelvic organ prolapse are important to assess. The bimanual examination should evaluate for gynecologic disorders and should include palpating the urethra for masses or tenderness. A Q-tip test is performed by placing the cotton end of a cotton swab through the urethra to the level of the vesical neck. The angle between the cotton swab and the horizontal when the patient is lying flat is measured at rest and with Valsalva maneuvers; 30 degrees or greater with strain indicates hypermobility of the urethrovesical angle. A rectal examination should

exclude a fecal impaction. A lower extremity neurologic examination is also essential.

Differential Diagnosis of Storage and Emptying Disorders

Urodynamic stress incontinence (USI) is defined by the observation of involuntary urine loss through the urethra with an increase in abdominal pressure in the absence of a detrusor contraction. Patients complain of loss of urine

Figure 136-2 Urinary Incontinence: Stress Incontinence.

Patient with defective fascial support of urethrovesical (U-V) junction. Increased intra-abdominal pressure results in urine loss

with maneuvers such as coughing, sneezing, or running. Inadequate support of the proximal urethra, usually as a result of childbirth, repeated Valsalva maneuvers, or atrophy due to advancing age, is the usual underlying cause. The proximal urethra is displaced inferiorly out of its normal intra-abdominal location. Consequently, an increase in intra-abdominal pressure causes a greater increase in the intravesical pressure than the intraurethral pressure, thus favoring incontinence. Physical examination often reveals a cystourethrocele (Fig. 136-2). The Q-tip test reveals hypermobility of the urethrovesical angle.

Intrinsic sphincter deficiency (ISD) is urinary incontinence associated with a urethra that does not coapt properly to prevent leakage of urine. Urethral closure pressure

is diminished. Patients complain of frequent loss of urine even with small increases in intra-abdominal pressure. ISD can be caused by denervation injury, radiation, neurologic disorders, or scarring. The Q-tip test can show a normal or hypermobile urethrovesical junction with strain. Diagnosis requires more sophisticated testing than office cystometrics.

Detrusor overactivity (DO) is due to uninhibited detrusor contractions during the filling phase. Patients often complain of large volumes of urine loss, nocturia, urinary frequency (more than 7 times a day with normal fluid intake), enuresis, and a sense of urgency with fear of urinary leakage. DO can be idiopathic or neurogenic. Possible etiologies include decreased central nervous system inhibi-

Figure 136-3 Other Causes of Incontinence.

tion due to disease or tumor, spinal lesions, or dietary irritative substances. Secondary causes include infection, foreign body, stone or tumor in the bladder, or surgical compression of the urethra after bladder neck suspension procedures (Fig. 136-3). Detrusor overactivity with impaired contractility is a condition found in elderly patients in which detrusor overactivity coexists with incomplete bladder emptying on volitional voids due to detrusor weakness.

Overflow incontinence (OI) occurs when incomplete emptying and decreased sensation of fullness are present and result in the bladder being filled to maximum capacity

from which the patient constantly leaks. A high postvoid residual (usually greater than 300 mL) supports this diagnosis. Patients may complain of a sense of incomplete emptying, a slow urine stream, or the need to use abdominal strain to void. OI can be due to obstruction such as with an enlarged prostate gland or due to an inadequate detrusor contraction. The latter can be due to neurologic diseases, diabetes mellitus, medications, or aging.

Functional incontinence occurs in individuals who have normal emptying capabilities but are incontinent because of decreased mobility or decreased cognitive function. Congenital ectopic ureters may present in children who

are not able to toilet train. Urinary tract fistulas can result from pelvic surgery and inflammatory conditions such as inflammatory bowel disease and can present as incontinence. Patients complain of constant loss of urine from the vagina. Orange coloring on a tampon in the vagina after a patient has taken oral Pyridium can document the vaginal fluid as urine. Urethral diverticula are outpocketings of the urethral mucosa that can fill with urine during micturition and then drain when the patient stands up, thus presenting with postvoid dribbling. On physical examination, urethral diverticula can occasionally be palpated, or purulence can be milked from the urethra. Often a double-balloon radiologic study is necessary to confirm the diagnosis.

Systemic illnesses or medications can disrupt the neurologic loops that control micturition and storage (Boxes 136-1 and 136-2).

Diagnostic Approach

Initial evaluation should include a urinalysis and urine culture. A pad test to quantify the amount of leaking involves placing a pad on the patient's perineum for 1 hour while maneuvers are performed. An increase in the weight of the pad by 2 g indicates incontinence. Pyridium can be used to confirm that the fluid is urine. Office cystometrics are performed as follows: The patient voids, and a postvoid residual (PVR) is obtained by transurethral catheterization. A PVR of less than 50 mL is normal, whereas a PVR of greater than 200 mL represents inadequate bladder emptying. The bladder is filled with water by gravity through this catheter using a 50-mL syringe without the

plunger. During filling, sensation and capacity are documented. In the absence of an increase in abdominal pressure, a rise in the column of water in the open syringe during filling, usually associated with urgency, indicates a detrusor contraction. The catheter is then removed, the patient coughs while standing, and any leaking is noted.

Multichannel urodynamic studies are commonly performed at academic institutions and provide more detailed information. Patients who warrant referral for these studies include those who describe mixed symptoms or have a history of failed anti-incontinence surgery. Other indications include the desire to rule out detrusor overactivity when the history is suggestive of its presence but simple cystometry is negative, to identify risk factors for surgical failure (e.g., ISD), and to determine the voiding mechanism to attempt to predict those who will have postoperative urinary retention. Cystourethroscopy may identify bladder lesions, foreign bodies, urethral diverticula, fistulas, strictures, and ISD.

Management and Therapy

Optimum Treatment

Conservative measures for genuine stress urinary incontinence (GSI) include pelvic floor muscle exercises (Kegel exercises), biofeedback with or without electrical stimulation, weighted vaginal cones, and placement of a vaginal pessary. Surgical procedures to correct GSI stabilize the urethrovesical angle. Urethropexy and pubovaginal slings are the preferred surgical procedures for GSI.

Intrinsic sphincter deficiency with hypermobility of the urethrovesical junction requires surgical management with creation of a pubovaginal sling to help support and coapt the urethra. ISD without urethrovesical hypermobility is an indication for injection of periurethral bulking agents such as collagen.

The management of detrusor overactivity and urge incontinence includes pelvic floor muscle exercises, bladder retraining programs, and behavioral techniques based on patterns identified from the voiding diary. Bladder infections are treated with antibiotics. The avoidance of bladder irritants such as alcohol, caffeine, carbonated drinks, and acidic foods or drinks is often helpful. Anticholinergic medications can decrease frequency and incontinence episodes and are available in extended-release oral and transdermal forms. Common side effects include dry mouth and constipation. Nocturia, often associated with DO, can also be due to mobilization of lower extremity edema in the supine position. Elevation of the legs during the day or compression stockings can decrease this problem.

Overflow incontinence due to obstruction requires correction of the obstruction. OI due to an acontractile bladder usually is an indication for self-catheterization, Credé's maneuver, or an abdominal strain technique (see Fig. 136-3). The approach to functional incontinence

Box 136-3 Treatments for Incontinence**Urodynamic Stress Incontinence**

- Pelvic floor muscle exercises
- Incontinence ring (pessary)
- Urethropexy or sling

Intrinsic Sphincter Deficiency

- Without urethral hypermobility—periurethral bulking agents
- With urethral hypermobility—sling

Detrusor Overactivity

- Behavioral therapy
- Pelvic floor muscle exercises
- Dietary restrictions
- Anticholinergic medications

Overflow Incontinence

- Remove obstruction
- Void/catheter regimen

Functional Incontinence

- Bedside commode
- Assistance with ambulation
- Verbal prompts

Nocturia

- Decrease evening fluids
- Support stockings
- Improve sleep pattern
- Evening dosing of anticholinergics or tricyclic antidepressants

includes providing assistance in the form of a bedside commode, assistance with mobility, or verbal prompts to void. Fistulas and bladder diverticula are indications for surgical excision and repair. Underlying neurologic and medical diseases require an optimal treatment regimen, including the dosage or timing of medications. For all forms of urinary incontinence, the initial approach is to try conservative methods, followed by surgical procedures (Box 136-3) if medical therapy fails.

Avoiding Treatment Errors

The anterior colporrhaphy and needle suspension procedures, once commonly performed for USI, are no longer preferred because of a high rate of failure. Conservative treatments such as pelvic floor muscle exercises for ISD are often not as successful as when used for USI and DO. DO is best managed with a combination of behavioral and dietary changes along with medication as needed. Failures are commonly due to lack of compliance to these measures, inadequate dosing or duration of medication use, or discontinuation of medications because of side effects. Treatment of DO with anticholinergics requires assessment of the PVR before and during treatment to prevent retention and OI.

Future Directions

Surgical outcomes research is ongoing, including comparisons of Burch urethropexy with sling for treatment of USI and the effectiveness of different mesh slings and laparoscopic and robotic suspension procedures. Sacral nerve stimulators to modulate reflexes may improve emptying or storage of urine in patients who have incomplete emptying or detrusor overactivity. Other periurethral bulking agents are available that may last longer than the originally used collagen for ISD. Botulinum toxin (Botox) injections have shown promise in controlling detrusor overactivity in initial studies.

Hematuria

Introduction

Hematuria is a clinical sign requiring careful evaluation because it may be the earliest manifestation of serious underlying processes such as renal or bladder carcinoma or glomerulonephritis. Classified as gross versus microscopic, depending on appearance of the urine, and upper tract versus lower tract, based on the site of bleeding, hematuria can also reflect benign processes such as menstrual bleeding or recent strenuous exercise. Prevalence estimates of microscopic hematuria vary widely from less than 1% to more than 16%, depending on the population studied and screening methodology. With a diversity of causes, each patient requires an individualized evaluation plan that considers the anatomic source of bleeding as well as the individual's risk factors for disease.

Etiology and Pathogenesis

Blood may enter the urine at any point along the urinary tract from the kidneys to the urethra. Considering the urinary tract in two parts, the upper tract (kidneys, renal collecting system) and the lower tract (ureters, bladder, prostate, urethra), helps the clinician organize a differential diagnosis and focus the evaluation. Gross bleeding is often from the lower tract, whereas microscopic hematuria can be more difficult to localize (Fig. 137-1).

Upper Tract

Urine is produced by filtering blood through the layers of the glomerulus: the capillary endothelium, basement membrane, and epithelium (Fig. 137-2). An intact glomerulus allows passage of plasma ultrafiltrate, such as urea, while preventing essential proteins and cells from passing through, such as albumin and red blood cells (RBCs). Damage to the glomerular endothelium from inflammation, as in vasculitis and crescentic glomerulonephritides, can permit passage of RBCs into the urine. Similarly, a change in the structure of the basement membrane may allow RBC passage into the urine. Such is the case in the hereditary conditions of Alport's disease and thin basement membrane disease, in which the basement membrane is altered by mutations in its collagen components. Isolated damage to glomerular epithelium rarely produces hematuria. Minimal change disease, a condition characterized by

changes limited to the epithelium, is notable for profound proteinuria in the absence of hematuria.

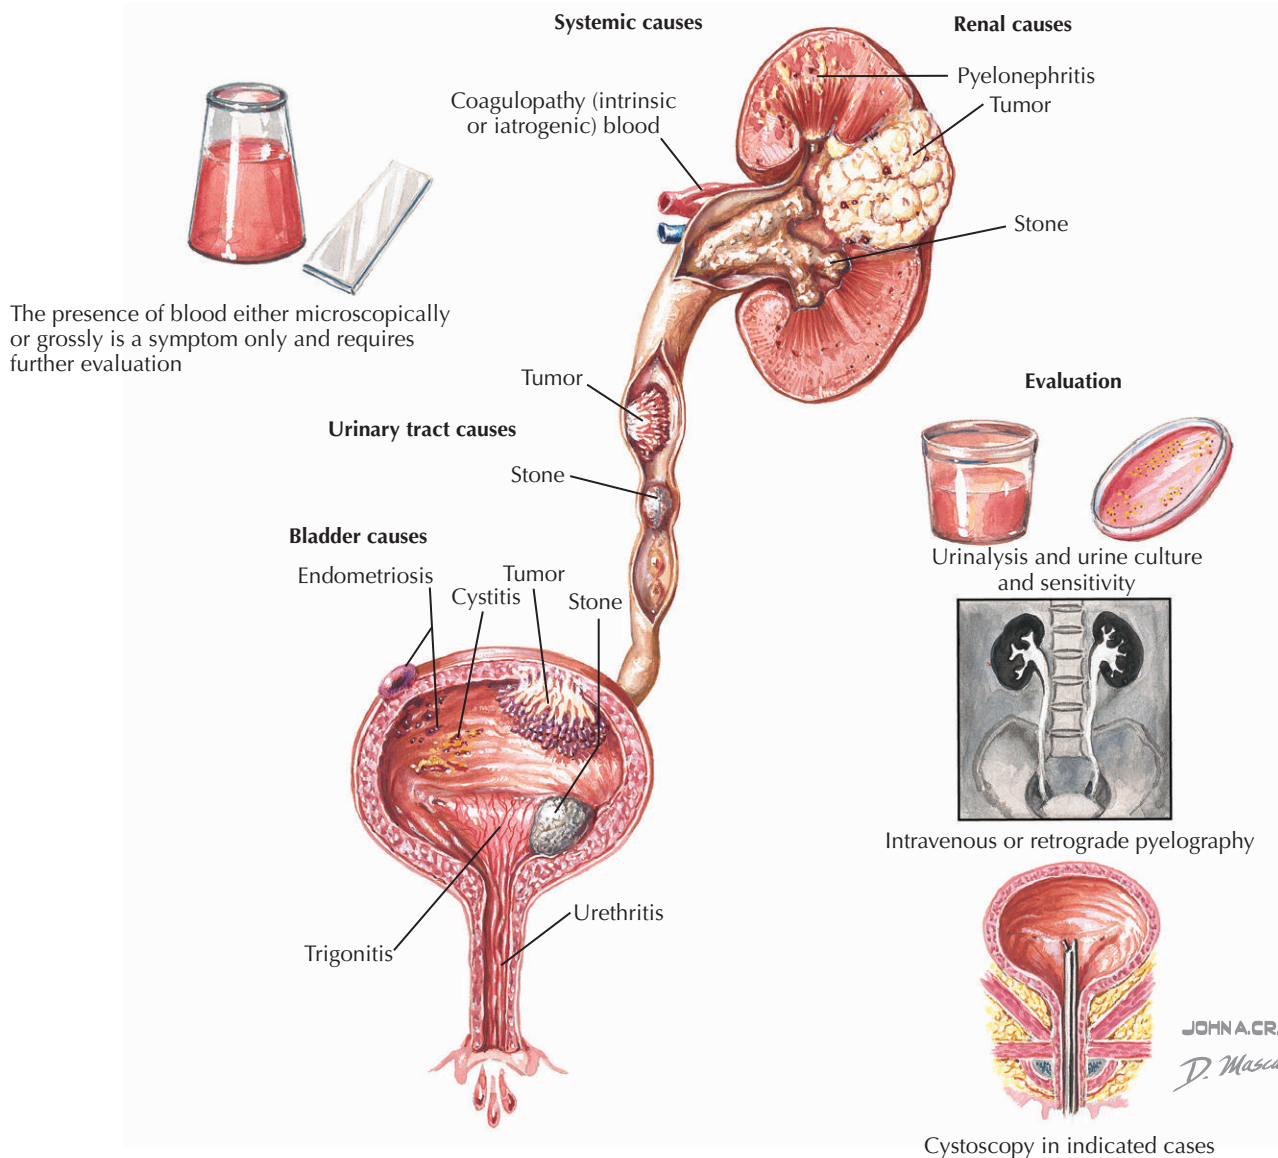

Urine is further modified as it courses through the tubular system of the kidney into the more proximal collecting ducts. Injury to the tubules from ischemia (e.g., arterial thrombosis or hypotension in sepsis) or toxin injury (e.g., aminoglycoside toxicity) may cause acute tubular necrosis (ATN) with subsequent RBC passage into the urine. Additionally, damage to the collecting ducts, calices, or renal pelvis from nephrolithiasis, renal cell carcinoma, or pyelonephritis can cause hematuria.

Lower Tract

Urine flows out of the kidney into the ureters, where it is transported to the bladder. Nephrolithiasis, urothelial tumors, and ascending infection can damage the lining of this transport system with resultant bleeding. Damage to the bladder wall by tumors, infection, or foreign bodies can also cause hematuria. In men, hematuria may result from inflammation of a highly vascular prostate gland secondary to prostate cancer or infection. Finally, blood may enter the urine more distally, as in the case of urethritis or contamination from menses.

Clinical Presentation

Gross hematuria describes a visible change in the color of the urine to red, pink, or brown. It is often brought to the

Figure 137-1 Sources of Microscopic and Macroscopic Hematuria.

attention of a physician by a concerned patient. Red or pink urine that is opaque is consistent with a urinary tract source, whereas brown (tea-colored) translucent urine is suggestive of glomerular bleeding. Microscopic hematuria, undetectable by the unaided eye, is commonly discovered by urine dipstick or automated urinalysis. Hematuria may present amid a complex of localizing symptoms, such as unilateral colicky flank pain associated with nephrolithiasis. It may be discovered unexpectedly (asymptomatic hematuria) such as during screening of a diabetic patient for proteinuria, an early sign of diabetic nephropathy. Because dipstick assays lack specificity, it is important to confirm the diagnosis of microscopic hematuria by repeat testing and microscopic examination of the urine (see "Diagnostic Approach"). As always, a focused history and

physical exam are mandatory to guide the workup and limit the differential diagnosis.

History

A focused history should begin with a complete description of the chief complaint, paying particular attention to associated symptoms and risk factors for underlying disease. It is helpful to structure the interview around an age-appropriate, anatomically organized differential diagnosis that considers the epidemiology of hematuria.

When gross hematuria is first identified by the patient, it is important for the clinician to understand the timing of the first episode as well as the frequency of subsequent episodes. Cyclical hematuria coinciding with menstruation

Figure 137-2 Structure of the Glomerulus.

may reflect endometriosis in the urinary tract or contamination of the sample. Although clinically significant blood loss is rare (unless clots obstruct the urinary tract), one should attempt to quantify hematuria by assessing the quality of the urine (e.g., was the urine bright red with clots, light pink, brown?).

For both gross and microscopic hematuria, it is important to identify preceding events or illnesses that may suggest a source (e.g., recent trauma, exercise, sexual activity, menstruation, or upper respiratory tract infection—a common predecessor to glomerulonephropathy). One should pay particular attention to the location and quality of associated pain (e.g., dysuria associated with a urinary tract infection [UTI]; lower abdominal pressure associated with UTI or tumor; or colicky flank pain associated with nephrolithiasis or pyelonephritis), evidence of infection

(e.g., fever, chills, sweats), symptoms of obstruction (e.g., urinary hesitancy, urgency, incontinence), symptoms of renal insufficiency (e.g., oliguria, nausea, loss of appetite), and symptoms that may point to systemic illness (e.g., fatigue; respiratory tract, gastrointestinal, or musculoskeletal symptoms; or rashes). The presence of flank pain along with fever or dysuria should prompt an emergent evaluation to rule out obstruction-related infection, which can lead to life-threatening sepsis syndrome.

A detailed medication history is important, with special attention given to nonsteroidal anti-inflammatory drugs (e.g., analgesic nephropathy, papillary necrosis), antibiotics (e.g., interstitial nephritis), drugs known to change urine color (e.g., rifampin), and anticoagulants. Importantly, hematuria in the setting of anticoagulation still requires a complete evaluation. A comprehensive past medical history

should identify previously diagnosed renal disease (e.g., glomerulonephritis, medullary sponge kidney), past UTI or pyelonephritis, nephrolithiasis, cancer (with particular attention to chemotherapy exposure and radiation), sickle cell disease (e.g., papillary necrosis), and bleeding disorders. Family history should identify others with hematuria or known renal disease (e.g., thin basement membrane disease, Alport's syndrome, or polycystic kidney disease). Additionally, one should elicit a complete travel history, assessing risk factors for regional infections (e.g., schistosomiasis, tuberculosis), and consider exposure to mutagens such as tobacco, phenacetin, cyclophosphamide, and industrial chemicals as risk factors for genitourinary cancers.

Physical Examination

The purpose of the physical exam is to search for clues that localize the source of hematuria or suggest a causative process. Hypertension and edema are common in glomerular diseases of many kinds. Nephrotic range proteinuria (>3 g/day), common in many glomerular diseases, is associated with edema and is an independent risk factor for renal vein thrombosis. Oral sores, scleral injection, swollen joints, and rash can be found in various vasculitic and autoimmune processes. Cachexia, swollen lymph nodes, and flank or abdominal tenderness may reflect a cancer or chronic infection. Atrial fibrillation and valvular vegetations (often first identified by cardiac murmur) increase risk for renal artery embolism. A tender or asymmetric prostate or testicle may also reflect an underlying cancer or infection.

Differential Diagnosis

A comprehensive anatomically based differential grounded in basic epidemiology and prioritized by the most threatening conditions should guide the diagnostic evaluation (Box 137-1). Examples illustrating the importance of this balance are glomerulonephritides and urinary tract cancers.

Glomerular diseases are a common cause of hematuria in children but account for only 5% of hematuria in adults. However, one must immediately consider a glomerular process in any patient with hematuria and renal insufficiency because an untreated, rapidly progressive glomerulonephropathy often advances quickly to end-stage renal disease and the need for dialysis. Meanwhile, isolated glomerular hematuria (hematuria in the absence of proteinuria or renal insufficiency) in an adult is most commonly caused by immunoglobulin A nephropathy, Alport's syndrome (i.e., hereditary nephritis), or thin basement membrane disease (i.e., benign familial hematuria). It is critical to check the renal function of anyone with a new diagnosis of hematuria early in their evaluation.

A second example is that of urinary tract malignancies. These are an important cause of hematuria in adults, accounting for up to 15% of cases, two thirds of which are

due to bladder cancer. However, they are rare in patients younger than 35 years of age (about 1 in 100,000).

Diagnostic Approach

Because microscopic hematuria is often transient and may be secondary to a benign process (e.g., vigorous exercise, recent sexual activity, or menstruation), it is often helpful to evaluate a second urine sample collected several days after the first, avoiding confounding activities around the time of collection. It is important to note, however, that transient hematuria in those with an appreciable risk for malignancy may warrant a complete evaluation in the absence of positive follow-up testing. Ideally, urine samples are collected midstream in the absence of external bleeding, such as menses, and examined within 1 hour. Those with gross hematuria require a thorough evaluation of the upper and lower urinary tract.

One should start by considering all information provided by the urinalysis. Concurrent positive tests for leukocyte esterase or nitrites in the right clinical setting should prompt a urine culture. Evidence of proteinuria should be followed with a urine protein-to-creatinine ratio for estimation of the 24-hour protein excretion (a ratio >0.2 reflects abnormal proteinuria and likely glomerular disease). Alternatively, a 24-hour urine collection may be sent for protein quantification. It is also important to assess the renal function of all patients with newly diagnosed hematuria with a measure of the serum urea nitrogen and creatinine. Any elevation of these tests should prompt an urgent evaluation for obstruction and intrinsic renal disease.

Substances such as myoglobin (e.g., from rhabdomyolysis) and hemoglobin (e.g., from hemolysis) can produce gross color change of the urine and false-positive results on dipstick assays. Therefore, it can be helpful to centrifuge urine for gross examination and repeat dipstick testing of the supernatant. It is important to perform microscopic evaluation of the sediment.

Samples should be prepared by centrifugation of 10 mL of urine at 2000 rpm for 5 minutes. Hematuria from intact RBCs in the absence of lysis will produce a clear supernatant and sediment with a reddish hue, depending on the volume of cells. Most dipstick assays can detect as few as 1 or 2 RBCs per high-power field, although hematuria is often defined as more than 2 RBCs per high-power field. If the supernatant remains red, it should be retested with a dipstick. A positive test may reflect myoglobinuria or hemoglobinuria. A red supernatant negative for blood on dipstick testing may reflect phenazopyridine or porphyria.

The supernatant is then discarded, and the sediment is resuspended for examination under low- and high-power light microscopy. Identification of intact RBCs in the absence of contamination (often indicated by the presence of multiple squamous cells) confirms the diagnosis of hematuria.

Box 137-1 Causes of Hematuria Organized Anatomically***Renal****Glomerular**

Immunoglobulin A nephropathy (the most common primary glomerulonephritis, often occurs within 1-3 days of an upper respiratory infection)

Poststreptococcal glomerulonephritis (most commonly occurs >10 days after streptococcal pharyngitis)

Foreign bodies

Perineal irritation

Sexual intercourse

Schistosomiasis (consider if travel to endemic area, e.g., Africa)

Loin pain hematuria syndrome

*In some cases (e.g., nephrolithiasis), the anatomic distinction is somewhat artificial because the process may occur in multiple sites along the urinary tract.

Dysmorphic erythrocytes (acanthocytes) and RBC casts on light microscopy are virtually diagnostic of glomerular disease, an important finding that can often make a lower tract evaluation unnecessary. Evidence of proteinuria would support this diagnosis. Demonstration of other formed elements, such as white blood cell casts, granular casts, and pigmented casts, suggests a tubular or interstitial process such as pyelonephritis, interstitial nephritis, or ATN. An elevated serum creatinine would support a renal source of blood as well.

When glomerular bleeding is thought to be unlikely, it is important to image the upper tract for evidence of neoplasm, stones, obstruction, or polycystic kidney disease. Selecting the appropriate imaging modalities requires an understanding of their various performance characteris-

tics. Ultrasound, a noninvasive procedure, is often less expensive than other tests, but is limited in the detection of small tumors. Computed tomography (CT) scans without contrast are ideal for the evaluation of stones. Excretory urography, which introduces the risks associated with intravenous contrast administration (e.g., nephrotoxicity and allergic reaction), can be helpful to diagnose medullary sponge kidney or to assess for stones when CT is unavailable. CT and magnetic resonance imaging with contrast provide the most detailed images of the renal parenchyma but should be used cautiously in those with renal insufficiency.

Urine cytology is indicated on a first morning void for those at risk for a urinary tract neoplasm. Test performance is determined by the quality of the sample,

experience of the pathologist, and differentiation of the tumor cells. Cytology is more sensitive for cancers of the bladder than those of the upper urinary tract, such as transitional cell carcinoma. In general, cytology is relatively insensitive, although specific.

Cystoscopy, visualization of the lower urinary tract through a fiberoptic camera inserted into the bladder, warrants consideration for those at risk for bladder cancer. This includes men older than 40 years (although there is disagreement about the appropriate age cutoff) and patients with a history of phenacetin use or analgesic abuse, significant smoking history, exposure to mutagenic dyes, exposure to cyclophosphamide, or persistent or recurrent episodes of gross hematuria. Specific cases may require specialty consultation or review of available guidelines.

In many cases, a complete workup will yield no definitive source of bleeding. The most common cause in these instances is an indolent glomerular disease. However, because malignancy may eventually become evident, particularly for those at higher risk, it is important to have an appropriate follow-up plan.

Management and Therapy

Optimum Treatment

Appropriate management of hematuria and the need for subsequent therapy is dictated by the underlying cause and need for subspecialty evaluation. For those with evidence of glomerular disease or polycystic kidney disease, referral to a nephrologist is appropriate. Evidence of progressive renal insufficiency in the setting of glomerular disease warrants urgent referral for consideration of a renal biopsy. Referral to a urologist should be made for those with gross hematuria, an identified mass, or persistent hematuria, and those at high risk for malignancy.

Avoiding Treatment Errors

It is important to consider the etiology of hematuria carefully in all patients in whom it is detected. Early assessment of renal function in each case will help ensure timely diagnosis of progressive glomerulonephropathy, a condition that requires immediate evaluation by a nephrologist. A thorough evaluation of the urinary tract for those at greatest risk for malignancy, and a timely referral to the

appropriate subspecialist when indicated, will ensure the best possible outcome. Contacting a subspecialist with questions about the necessity or timing of a referral will help avoid unnecessary errors.

Future Directions

With continued development and improvement of non-invasive imaging technologies and urinary markers for disease, the elimination of invasive evaluations and the use of contrast with its associated comorbidities may ultimately be possible. The availability of more sensitive and specific low-risk testing will undoubtedly change the clinical approach to the evaluation of hematuria.

Urinary Stone Disease (Nephrolithiasis)

Introduction

Nephrolithiasis is a common disorder with an annual incidence of 0.1% to 0.5%. The peak age at onset is 20 to 30 years, and males are affected more than females through most of adult life until about the sixth decade, when the incidence increases in women and tends to decrease in men. Rates of stone formation may be affected by genetic, nutritional, and environmental factors. The relative risk for nephrolithiasis for patients with a positive family history may be as great as 2.5. In the United States, the prevalence of stones has risen over the past 20 years from 3.2% to 5.2%. Wide geographic variations exist, and in the United States, prevalence is greatest among those who live in the southern latitudes. This may be due to differences in diet and water composition, as well as ambient and sunlight exposure. An estimated 28% to 50% of patients experience a recurrence at 5 years.

Etiology and Pathogenesis

Calcium Stones

About 75% to 80% of all kidney stones contain calcium. Most are composed of calcium oxalate alone or in combination with calcium phosphate. Calcium oxalate stones are brown or gray, small, and well circumscribed on radiographs. Calcium oxalate crystals may appear as dumbbells or pyramids (Fig. 138-1). Calcium phosphate stones are beige or white and form apatite and brushite crystals. Calcium oxalate stones are thought to arise and grow from Randall's plaques. These are plaque-like aggregates that originate in the basement membrane of the thin loop of Henle and spread; they can protrude into the uroepithelium in the renal papillae and serve as a nidus for crystal aggregation and growth. Calcium crystals may form in urine that is supersaturated from excess excretion of calcium, oxalate, or uric acid. Diminished citrate in the urine may also lead to calcium stone formation. Hypercalciuria, the most common metabolic disorder in people in whom stones form, affects 50% of patients. Hypercalciuria may be broadly classified as absorptive, renal leak, or hormonal.

Absorptive Hypercalciuria

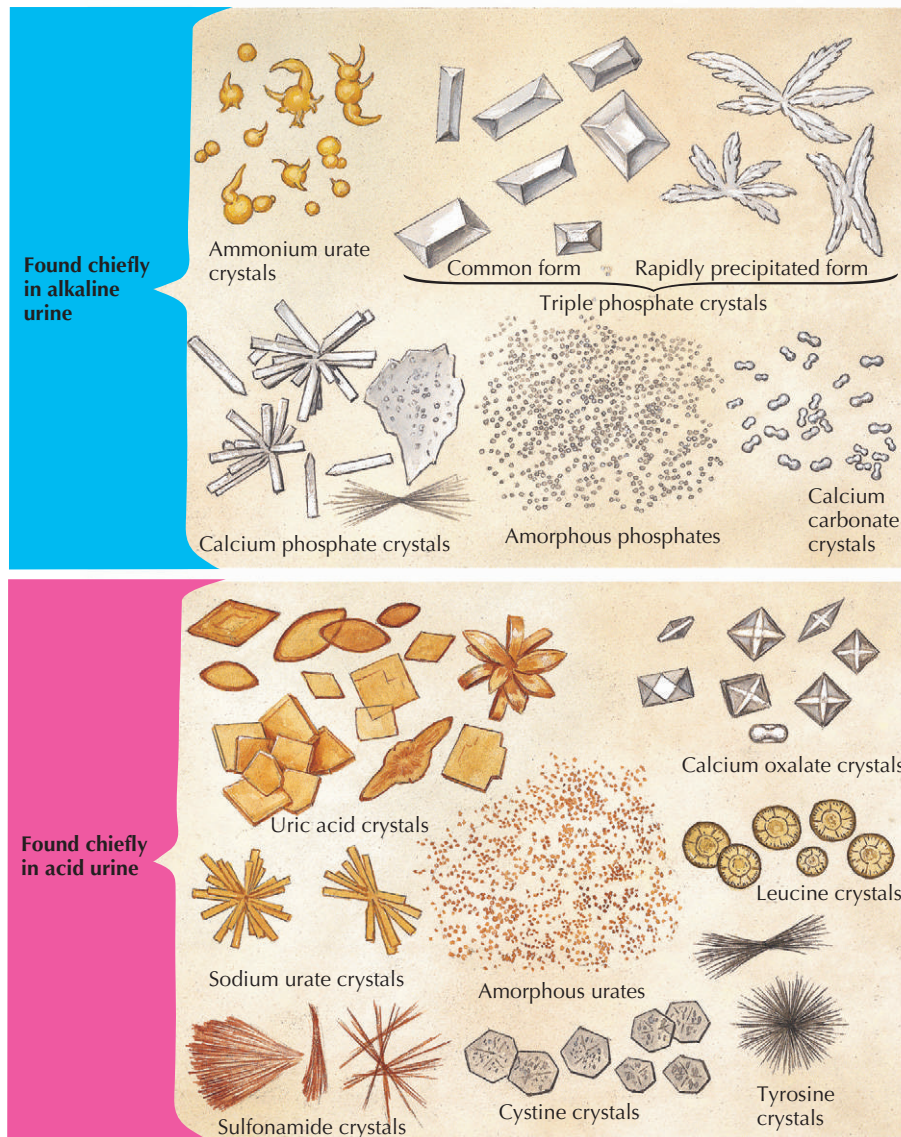

Absorptive hypercalciuria is the most common cause of abnormal calcium excretion. These patients have a tendency to absorb and excrete a higher proportion of dietary calcium than normal people. The disorder is familial and affects both sexes equally.

Renal Leak

Renal leak or renal hypercalciuria is a syndrome of inappropriate renal wasting of calcium. This wasting leads to the stimulation of parathyroid hormone and subsequently 1,25-OH vitamin D in efforts to normalize the serum calcium.

Hormonal Hypercalciuria

Hormonal hypercalciuria develops in the setting of hyperparathyroidism of both primary and paraneoplastic origin. Granulomatous disorders such as sarcoidosis may also lead to hypercalciuria due to increased levels of 1,25-OH vitamin D.

Figure 138-1 Unorganized Elements That May Be Found in Urinary Sediment.

Hypocitraturia

Citrate is an inhibitor of calcium stone formation that complexes with calcium, reducing its free urinary concentration, and subsequently decreases the saturation of calcium oxalate and calcium phosphate. Hypocitraturia may be idiopathic or secondary to metabolic acidosis, a metabolic state that reduces urinary citrate excretion by increasing its proximal reabsorption. Type I renal tubular acidosis is a defect in hydrogen ion secretion that leads to metabolic acidosis and inability to acidify the urine. More than half of these patients have nephrolithiasis, nephrocalcinosis, or both. Increased bone turnover due to the metabolic acidosis leads to increased filtration of calcium and phosphorus. The metabolic acidosis decreases calcium

reabsorption and increases citrate reabsorption. Finally, the alkaline urine pH leads to supersaturation of calcium phosphate.

Hyperoxaluria

Primary hyperoxaluria types I and II are rare genetic disorders caused by enzyme deficiencies that lead to massive oxaluria. Patients may excrete up to 300 mg per day and deposit calcium oxalate in multiple tissues, including kidneys, heart, and blood vessels. Enteric hyperoxaluria occurs when small bowel absorption is altered from any mechanism. This results in increased intraluminal bile salts and fatty acids, which increase the permeability of the colonic mucosa to oxalate and bind to calcium. The

end result is an increase in the free oxalate available for absorption. This is accompanied by a markedly reduced urinary citrate due to additional bicarbonate loss through the bowel and systemic acidosis. Hyperoxaluria may also occur from ingestion of a diet high in oxalate-containing foods such as spinach, beets, chocolate, rhubarb, and nuts.

Hyperuricosuria

There is an increased incidence of hyperuricosuria in calcium stone formers. Uric acid crystals may serve as a nidus for heterogeneous nucleation; 5% to 10% of calcium stones contain a uric acid core.

Uric Acid Stones

Uric acid stones account for 5% to 10% of stones, although in Mediterranean countries, they may cause up to 30%. They are yellow or orange and transparent on plain radiography. Urate crystals take various shapes, including rhomboids, rosettes, needles, or amorphous material (see Fig. 138-1). Hyperuricosuria, low urinary volume, and low urine pH predispose to uric acid nephrolithiasis. Excessive urinary excretion of uric acid may be secondary to increased dietary intake of purines or hyperuricemic disorders such as tumor lysis syndrome, or they may be related to certain medications. Urine pH is the major determinant of uric acid supersaturation; an increase to 6.5 can increase the solubility markedly and possibly dissolve existing stones. Decreased urinary volume also increases uric acid supersaturation.

Struvite Stones (Magnesium Ammonium Phosphate)

Infection stones (10% to 15% of all stones), the most common cause of staghorn calculi, are more prevalent in women (Fig. 138-2). They are light brown and appear laminated on radiograph. Struvite crystals have the classic coffin-lid appearance (see Fig. 138-1). They are associated with infections of the urinary tract by urease-producing bacteria. Hydrolysis of urea sets up a cascade of events that leads to supersaturation of magnesium ammonium phosphate.

Cystine Stones

Less than 2% of all stones are composed of cystine. They are yellow-green and homogeneous on radiograph. Cystine crystals take a hexagonal form, and the stones are often bilateral and may cause staghorn calculi (see Fig. 138-2). Cystinuria is an autosomal recessive disease in which there is a tubular defect in dibasic amino acid transport. Affected patients excrete excessive amounts of cystine, ornithine, arginine, and lysine. Cystine has a low solubility

(300 mg/L), and affected patients may excrete 480 to 3600 mg/day.

Clinical Presentation

The typical presentation of nephrolithiasis is renal colic caused by an acute obstruction of the urinary tract. Severe pain begins suddenly in the flank and radiates laterally around the abdomen to the groin, testicles, or labia (Fig. 138-3). Urinary frequency and dysuria may occur when the stone reaches the ureterovesicular junction. Nausea and vomiting are common. Microscopic hematuria occurs in 75% of patients, and gross hematuria in 20% or less.

Differential Diagnosis

Various diseases causing abdominal pain may be confused with renal colic. An abdominal aortic aneurysm or acute intestinal obstruction may cause severe abdominal pain, but neither of these conditions is usually associated with hematuria. In females of childbearing age, ectopic pregnancy is in the differential, and testing with serum β -human chorionic gonadotropin is indicated. Disorders that cause significant hematuria may produce clots that obstruct the ureter, mimicking renal colic. Occasionally, renal cell carcinoma may present in this manner, but hematuria associated with glomerular diseases does not produce enough hematuria to cause ureteral obstruction.

Drug-seeking patients presenting for medical attention may self-inflict injury to cause hematuria. Unfortunately, patients with history of nephrolithiasis may also present complaining of renal colic in an attempt to obtain narcotics. Imaging to identify stones within the ureter and not the kidney can aid management.

Diagnostic Approach

The usual diagnostic approach is to obtain an imaging study. Radiography of the kidneys, ureters, and bladder reveals most stones, with the exception of uric acid stones. Ultrasound of the urinary tract is noninvasive, identifies all stone types including uric acid stones, and can assess the presence of obstruction. Unfortunately, ureteral stones are not well visualized. Intravenous pyelography provides information on the structure and function of the urinary tract and determines the cause, site, and severity of obstruction. Unenhanced helical computed tomography (CT) has become the standard radiologic test for evaluating patients with acute renal colic. CT requires less time to perform, has an excellent sensitivity and specificity (96% and 99%, respectively), obviates the risks of intravenous contrast material, and detects extraurinary diseases that may present with symptoms similar to renal colic. Given the higher exposure to radiation with CT, however, ultrasonography may still be the preferred imaging choice in children. Once

Figure 138-2 Renal Calculi.

a diagnosis of nephrolithiasis has been made, an evaluation should be performed as outlined in Box 138-1.

Although some recommend further metabolic screening for all patients with nephrolithiasis, it is generally accepted that patients with recurrent stone disease, those with nephrocalcinosis, first stone formers with a moderate to high risk for recurrent disease, and all children should undergo a 24-hour urine collection to establish risk factors for nephrolithiasis. Obtaining at least two 24-hour urine samples on a normal diet is optimal. The normal values of all the constituents that should be tested are listed in Table 138-1.

Management and Therapy

Optimum Treatment

In the acute phase of renal colic, the goal of management is to relieve pain, treat infection, establish the size and location of the stone and the presence of obstruction, and facilitate stone passage. Most ureteral stones 4 mm in diameter or smaller pass spontaneously. There is a gradual decrease in the spontaneous passage rate for stones larger than 4 mm. For patients with urosepsis, acute renal failure, intractable pain, and nausea or vomiting, immediate urologic consultation is indicated. Outpatient urology referral

Figure 138-3 Calculous Urinary Obstruction.

should be made for patients who fail to pass the stone with conservative therapy and for those in whom the stone is larger than 10 mm. Further urologic management may include extracorporeal shock wave lithotripsy, ureteroscopic removal, or percutaneous nephrolithotomy.

To decrease the incidence of stone recurrence, all patients should be treated with nonspecific therapy. Urinary volume should exceed 2 L/day. Increased urinary volume alone has been shown to reduce the incidence of recurrent nephrolithiasis. Certain dietary restrictions have been shown to change urine constituents favorably. A

low-protein diet (0.8 g/kg/day) is recommended for stone formers because a high-protein diet (2.0 g/kg/day) increases uric acid and calcium excretion and reduces citrate excretion. Multiple studies have shown that high dietary sodium intake increases sodium and calcium excretion, and low-sodium diets have the opposite effect; therefore, a modest sodium dietary restriction (2 to 3 g/day) is recommended. Generalized dietary restriction of calcium is no longer recommended to prevent calcium stones. Studies have shown a decreased risk for nephrolithiasis in patients with normal calcium intake. This is related to the decreased

availability of oxalate to be absorbed in the gut due to binding with calcium. Dietary oxalate should be restricted. In addition to conservative measures, specific therapy should be tailored to patients with recurrent stone disease.

Calcium Stones

In hypercalciuria, thiazide diuretics decrease urinary calcium excretion by reducing intestinal calcium absorption and increasing renal tubular reabsorption. Thiazides are the first line of treatment for patients with renal leak syndrome and have been shown to be effective in reducing stone recurrence in patients with idiopathic hypercalciuria. Adding potassium citrate may be helpful to avoid associated hypokalemia, as well as offering the benefit of increasing citraturia. Parathyroid surgery is the treatment of choice for patients with primary hyperparathyroidism and nephrolithiasis. In hypocitraturia, potassium alkali salts significantly reduce the rates of stone recurrence. Potassium citrate at doses from 15 to 30 mEq 2 to 3 times daily up to 100 mEq daily may be required. The goal of treatment of calcium phosphate stones due to type I renal

tubular acidosis is to reduce systemic metabolic acidosis, which in turn decreases bone resorption and urinary calcium excretion and increases citraturia. Potassium citrate or potassium bicarbonate may be used, but large doses are often required. A thiazide diuretic may be added if hypercalciuria persists. Primary oxaluria is treated with dietary oxalate restriction and increased urinary volume. Some patients may benefit from pyridoxine therapy. For enteric hyperoxaluria, calcium supplementation with meals will bind dietary oxalate. A low-fat diet and cholestyramine to bind bile acids may decrease oxalate absorption. For patients with metabolic acidosis due to diarrhea, potassium citrate may be a helpful adjuvant therapy. Dietary purine restriction and increasing urinary volume are first-line treatments for hyperuricosuria. If it persists, allopurinol should be added.

Uric Acid Stones

Conservative therapy, including increased urinary volume and dietary restriction of protein and purine products, may decrease uric acid supersaturation. Urinary alkalization with potassium citrate or potassium bicarbonate to a pH of 6.0 to 7.0 may help dissolve existing stones and prevent recurrence. Add allopurinol if urinary pH remains low or if hyperuricosuria persists despite dietary modification.

Struvite Stones

Therapy is aimed at removing existing calculi, which harbor the urease-producing bacteria, and eradicating infection. Acetohydroxamic acid, an inhibitor of urease production, has been shown to reduce the rate of stone growth but is poorly tolerated because of its multiple side effects.

Cystine Stones

The goal of therapy is to increase the solubility of cystine in the urine with hydration and alkalization (pH 6.5 to 7.0). For patients with severe disease, more specific therapy with chelating agents may be necessary to reduce cystine excretion.

Avoiding Treatment Errors

Caution must be used when treating calcium stone-forming patients with potassium citrate. Although this therapy has been shown to reduce the incidence of stone recurrence and is standard therapy for patients with hypocitraturia, follow-up 24-hour urine collections to assess efficacy are recommended. Calcium stone-forming patients may suffer from more than one urinary risk factor. Citrate therapy may result in a significant elevation of the urine pH. Although urinary citrate may improve, this may predispose to calcium phosphate stone formation, especially in patients who also have hypercalciuria.

Generalized treatment recommendations were made in the text, but it is important to reiterate several points.

Although drug therapies are effective at reducing the incidence of stone recurrence, excessive reliance on these agents should be avoided, and emphasis should be placed on dietary alteration, which also reduces recurrent nephrolithiasis, such as increased fluid intake and avoiding calcium restriction in the diet. High doses of thiazide diuretics are often necessary to reduce hypercalcemia; therefore, it is prudent that patients undergo serial monitoring to assess for potential side effects, including hyponatremia, hypokalemia, and hyperuricemia. Finally, sodium bicarbonate should be avoided in patients with renal tubular acidosis given the increased hypercalciuria associated with sodium-containing therapy. Potassium citrate or potassium bicarbonate should be used to treat associated metabolic acidosis and hypocitraturia.

Future Directions

There have been many advances in the surgical management of nephrolithiasis, including improved ability to access the different areas of the kidney by creation of smaller-caliber endoscopes and improved ureteral access sheaths, leading to less trauma of the ureter. Although surgical therapy continues to play a major role in management of nephrolithiasis, further research in the pathologic mechanisms determining stone formation may provide insights into additional treatment options. Measurement of crystal surface adhesion forces in stone formers may aid the design of agents that can block crystal aggregation. Other areas that require further research include the role of crystal-binding molecules such as hyaluronan in crystal retention and growth.

Chronic Kidney Disease

Introduction

Chronic kidney disease (CKD) is a common diagnosis, affecting about 12% of the U.S. population. CKD is broadly defined as the presence of renal dysfunction for longer than 3 months and is classified according to the degree of functional impairment in the glomerular filtration rate (GFR) (Table 139-1). Patients with a normal GFR who have persistent urinary sediment abnormalities, abnormal kidney structure as documented radiographically, or abnormal renal biopsies are categorized as having stage 1 CKD. The serum creatinine concentration alone is frequently a misleading indicator of GFR, a fact that has led to the routine use of equations such as the Modification of Diet in Renal Disease (MDRD) and the Cockcroft-Gault equations. These should be routinely used when estimating renal function from the serum creatinine concentration (Table 139-2).

The number of patients with stage 5 CKD (end-stage renal disease [ESRD]) continues to grow in the United States, with a total prevalent population of 452,957 patients as of 2003. About 45% of incident ESRD patients have diabetes mellitus. About 70% of the ESRD patients are maintained on dialysis, whereas only about 30% have a functioning transplant. The annual incidence rates of stage 5 CKD appear to be stabilizing following 15 years of a steady increase, possibly as a result of efforts to delay progression of CKD with measures such as the treatment of hypertension. Spending for the ESRD program continues to grow, accounting for about 7% of all Medicare expenditures. The aging of the population and the growing burden of diabetes mellitus have had a significant impact on the increasing prevalence of ESRD, which has a projected prevalence of 2.24 million in the United States by 2030. Cardiovascular disease is the most important cause of mortality and morbidity in patients with CKD. Life expectancy for ESRD patients is only 16% to 37% of that of age-, gender- and race-matched controls. It is hoped that this can be improved with earlier detection of CKD, permitting aggressive risk factor modification and timely treatment of complications.

Etiology and Pathogenesis

Prevalent causes of ESRD in 2003 according to the U.S. Renal Data System were as follows:

- Diabetes mellitus (36.2%)
- Hypertension (24.5%)
- Glomerulonephritis (19.9%)
- Cystic, hereditary, or congenital (6.7%)
- Interstitial nephritis (4.7%)
- Neoplasms or tumors (0.9%)
- Miscellaneous or uncertain causes (7.1%)

Renal function inexorably declines once the GFR has fallen below about 50 mL/min/1.73 m² of body surface area. In the Modification of Diet in Renal Disease (MDRD) study, 85% of patients with nondiabetic renal disease demonstrated a persistent decline in GFR averaging

4 mL/minute/year. The decline in GFR in patients with untreated diabetic nephropathy approaches 12 mL/minute/year. Several common pathologic and physiologic factors have been identified in all patients with CKD regardless of the cause of the initial insult. Intraglomerular hypertension, afferent arteriolar vasodilation, and decreased extracellular matrix turnover driven in part by increased angiotensin II interact to promote glomerular and vascular sclerosis, tubulointerstitial fibrosis, and progressive nephron loss. Studies have demonstrated that angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) not only reduce blood pressure but also decrease intraglomerular hypertension and tubulointerstitial fibrosis. These drugs have been shown to attenuate and in some cases halt progression of renal failure and to reduce mortality.

Table 139-1 Stages of Chronic Kidney Disease

Stage	Description	GFR, mL/min per 1.73 m ²	Action
1	Kidney damage with normal or increased GFR	≥90	Treatment of comorbid conditions; slowing progression; cardiovascular disease risk reduction
2	Kidney damage with mild decreased GFR	60-89	Estimating progression
3	Kidney damage with moderate decreased GFR	30-59	Evaluating and treating complications
4	Severely decreased GFR	15-29	Preparation for renal replacement therapy
5	Kidney failure	<15	Renal replacement therapy

Cardiovascular Disease in Chronic Kidney Disease

Excess cardiovascular risk has been well documented in patients with ESRD and is believed to be mediated in part by a proinflammatory state. The prevalence of elevated C-reactive protein levels in hemodialysis patients is about 50%. Factors that may contribute to this proinflammatory state include decreased renal clearance of inflammatory cytokines, metabolic acidosis, increased oxidant stress, and volume overload. Other factors, including effects of the hemodialysis membrane and dialysate contamination with bacterial products such as lipopolysaccharide, may also account for accelerated atherosclerosis in ESRD patients on hemodialysis. Recently, the role of altered calcium-phosphorus metabolism has gained considerable attention as a significant risk factor in cardiovascular disease and mortality. Elevated serum concentrations of both calcium and phosphorus contribute to increased vascular calcification and have been associated with higher mortality rates in the ESRD population.

Excess cardiovascular disease burden has been demonstrated in patients with CKD before the onset of ESRD. Traditional risk factors such as hypertension and dyslipidemia, as well as nontraditional risk factors such as vascular calcification and chronic inflammation, have been implicated to explain the observed excess mortality. ACE inhibitors, ARBs, and statins have been found to partially ameliorate the microinflammatory state of CKD. The effects of aspirin and antioxidants such as vitamin E have been less convincing.

Clinical Presentation

Clinical features of CKD vary depending on the underlying cause and stage of the kidney disease. Patients with incipient diabetic nephropathy may present with asymptomatic microalbuminuria, whereas those with advanced nephropathy associated with nephrotic-range proteinuria are often edematous with evidence of retinopathy and neuropathy. Patients with ischemic renal disease frequently

have bruits over the renal arteries, as well as in other vascular beds. CKD is often diagnosed in the clinical evaluation of hypertension, and it is worth noting that renal parenchymal disease remains the leading cause of secondary hypertension. Patients with adult polycystic kidney disease can present with abdominal masses and hypertension. The family history will indicate an autosomal dominant pattern of inheritance. Many patients present with nonspecific symptoms of fatigue due to progressive anemia and azotemia. Unfortunately, the symptoms and clinical findings of CKD are often subtle and go unnoticed until the GFR decreases to 5 to 10 mL/minute, at which point the uremic syndrome (Box 139-1) becomes apparent, and renal replacement therapy (RRT) is necessary to maintain life.

Differential Diagnosis and Diagnostic Approach

The etiology of CKD is often apparent after obtaining a careful history and performing a detailed physical examination (Box 139-2; Fig. 139-1). Patients with long-standing diabetes mellitus and hypertension with clinical evidence of end-organ damage in other vascular beds such as retinopathy have a high likelihood of diabetic nephropathy. The evaluation of patients with CKD should begin with a detailed examination of the urinary sediment as well as renal ultrasonography (Fig. 139-2). Serologic studies such as antinuclear antibodies, serum complement levels, and protein electrophoresis are particularly helpful in patients presenting with systemic vasculitis, proteinuria, or hematuria. Nephrologic consultation and renal biopsy are often required in these cases to arrive at a specific diagnosis.

Management and Therapy

Optimal Treatment

Treatment of CKD patients starts disease-specific therapy. Immunosuppressive therapy should be started when indicated in patients with lupus nephritis. Attention should be paid to glycemic control in patients with diabetes mellitus. Intensified glycemic control delays or prevents progression from normal urinary albumin excretion to microalbuminuria, clinical proteinuria, and overt nephropathy. The hemoglobin A1C should ideally be maintained close to 6%.

Aggressive control of cardiovascular risk factors such as dyslipidemia should be initiated from the outset in all CKD patients. The low-density lipoprotein cholesterol should be maintained at less than 100 mg/dL (2.6 mmol/L), or less than 80 mg/dL (2 mmol/L) if atherosclerosis is present or suspected. Other recommendations include discontinuation of tobacco products, avoidance of nephrotoxic agents such as nonsteroidal anti-inflammatory

Treatment of Hypertension

Control of blood pressure is the single most important therapeutic intervention currently available to retard the progression of CKD. The blood pressure should ideally be maintained at less than 130/80 mm Hg, with a goal of less than 120/80 mm Hg for patients with greater than 1 g of daily urinary protein excretion. ACE inhibitors or ARBs are preferred, especially in patients with proteinuria. Diabetic patients with microalbuminuria should be treated with ACE inhibitors or ARBs even when the blood pressure is in the normal range. Up to a 30% increase in the serum creatinine is acceptable after initiation of ACE inhibitors or ARBs. One study demonstrated sustained renoprotective benefit of continued ACE inhibitor therapy in patients with stage 3 and 4 CKD, and thus ACE inhibitors should be continued in patients with CKD whenever possible. Once-daily dosing of a low-dose ACE inhibitor or ARB should initially be employed to limit the risk for hyperkalemia. The serum potassium and serum creatinine concentration should be measured every 7 to 10 days during the initial dose titration and then every 2 to 3 months.

Most patients with advanced CKD generally require at least two to three agents to achieve blood pressure goals. Preferred agents (Fig. 139-3) should be added initially in a stepwise fashion. Therapy may also need to be tailored to individual patient needs, such as β blockade in the

patient with angina. Patients with persistent proteinuria greater than 500 mg/day despite control of hypertension may benefit from combination ACE inhibitor and ARB therapy.

Correction of Anemia

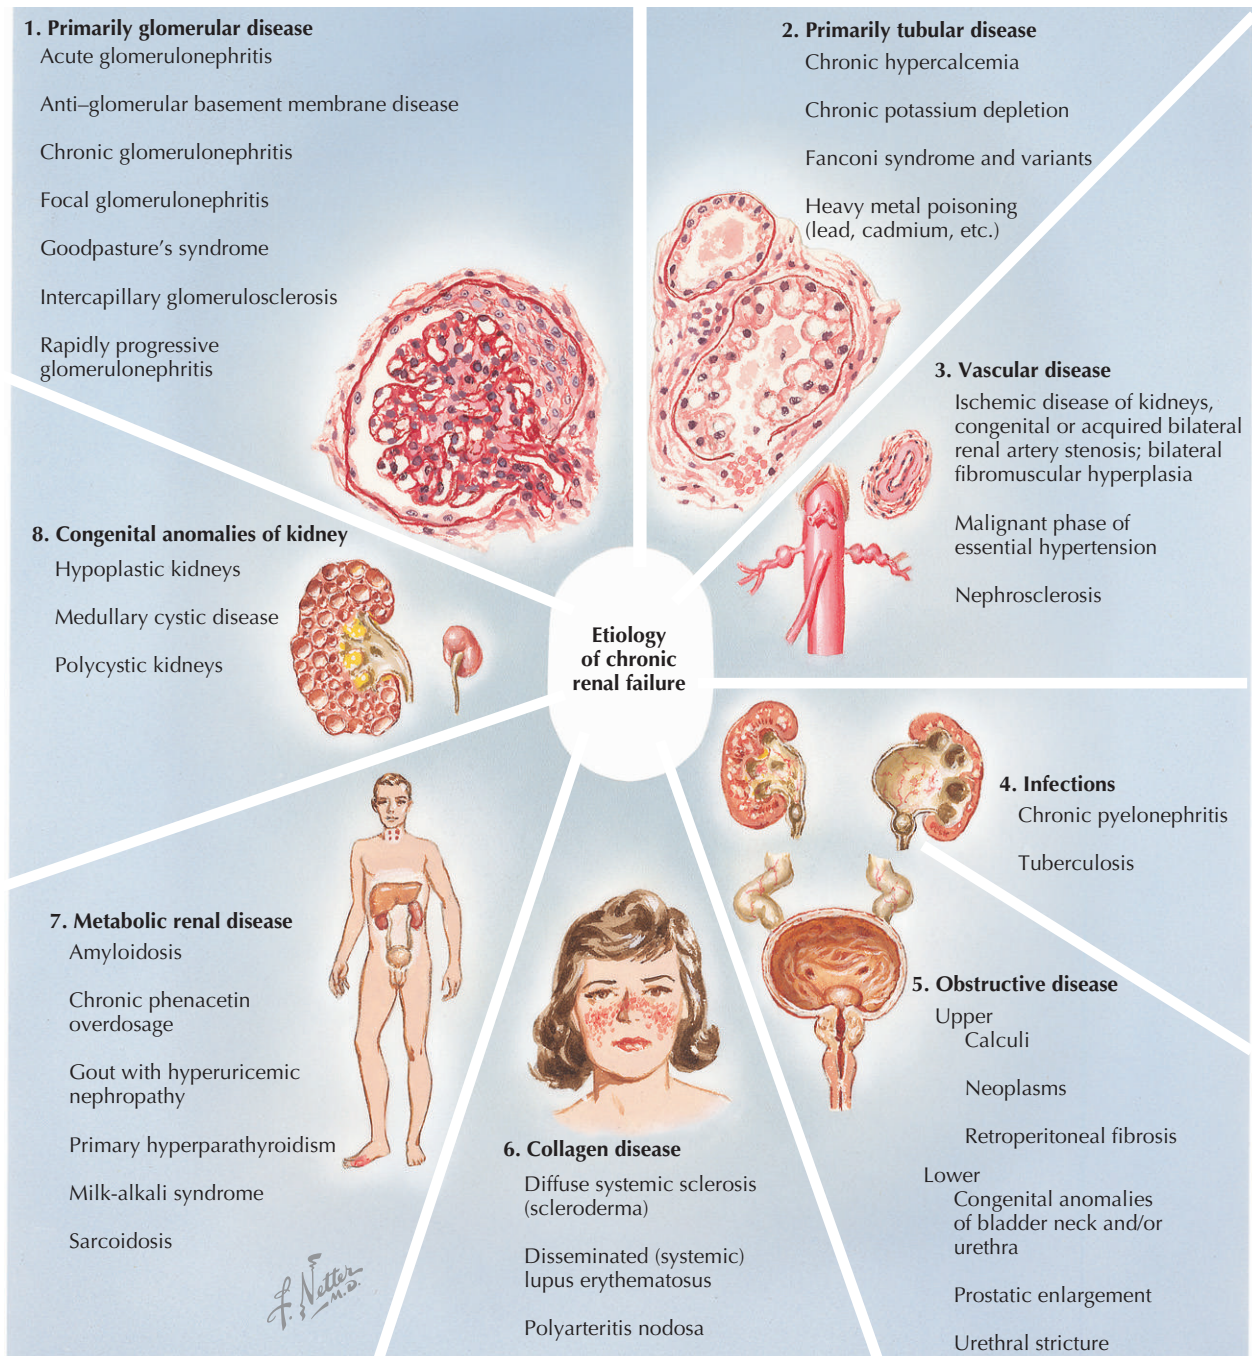

Most patients with stage 3 to 4 CKD develop normocytic and normochromic anemia due to reduced erythropoietin production. Anemia is a risk factor for the development of left ventricular hypertrophy, hospitalization, and worsened cardiovascular outcomes in patients with CKD. Correction of anemia in patients with CKD has been demonstrated to improve quality of life. Recombinant erythropoietin or darbepoetin should be considered for patients with hemoglobin levels less than 11 g/dL (110 g/L), with a goal of maintaining the hemoglobin in the 11 to 12 g/dL (110 to 120 g/L) range. Care should be taken to avoid hemoglobin levels above 13 g/dL (130 g/L) owing to an associated increased risk of cardiovascular events. Patients should also receive concurrent iron supplementation.

Calcium, Phosphorus, and Bone Metabolism

As the GFR decreases to less than 60 to 80 mL/min, the excretion of phosphorus decreases, leading to hyperphosphatemia. This results in a transient decrease in the serum calcium that is exacerbated by decreased calcium absorption as a result of low levels of 1,25-dihydroxyvitamin D. Hypocalcemia, hyperphosphatemia, and decreased 1,25-dihydroxyvitamin D all lead to secondary hyperparathyroidism. Although increased parathyroid hormone (PTH) restores the serum calcium concentration to the normal range, it does so at the expense of increased bone turnover. Persistent untreated hyperparathyroidism leads to a distinct form of bone disease characterized by increased bone turnover and fibrosis termed *osteitis fibrosa cystica* (Fig. 139-4). Once established, this bone disorder is essentially irreversible. Prevention, therefore, remains the best therapeutic strategy.

Treatment of secondary hyperparathyroidism previously relied on the use of calcium-based phosphate binders and vitamin D analogues. There has been a growing concern about the risk for arterial calcification in patients with CKD treated with calcium-based phosphate binders and vitamin D analogues. Vitamin D analogues also have the untoward effect of increasing phosphate absorption and worsening hyperphosphatemia. Studies have demonstrated an association, albeit not a causal one, between serum phosphorus levels greater than 3.5 mg/dL (1.13 mmol/L) and increased cardiovascular mortality.

Dietary phosphorus restriction is generally not effective in preventing hyperphosphatemia, and therefore oral phosphate binders such as calcium carbonate or acetate,

Figure 139-1 Etiology of Chronic Renal Failure.

sevelamer, and lanthanum carbonate are usually necessary. When calcium-based binders are used, the total dose of elemental calcium should not exceed 2000 mg/day in order to avoid positive calcium balance. Oral vitamin D analogues such as calcitriol, doxercalciferol, and paracalcitol can be administered to suppress PTH secretion and retard the development of renal bone disease. The goal of therapy is to maintain intact parathyroid hormone levels at 35 to 70 ng/L for patients with stage 3 disease, 70 to 110 ng/L in stage 4 disease, and 150 to 300 ng/L in stage 5 disease.

Careful monitoring, initially every 4 to 8 weeks, then quarterly, is important to prevent development of hypercalcemia or oversuppression of PTH. The serum calcium and phosphorus should be maintained at less than 9.5 mg/dL (2.37 mmol/L) and 4.7 mg/dL (1.52 mmol/L), respectively. Cinacalcet suppresses PTH secretion by acting primarily on the calcium-sensing receptor in the parathyroid glands and is effective in lowering the serum PTH and decreasing serum phosphorus concentrations in ESRD patients with secondary hyperparathyroidism. The role of

this agent in pre-ESRD CKD patients in optimizing bone and mineral metabolism remains to be determined pending further clinical trials.

Preparation for Renal Replacement Therapy

Discussions regarding the need for RRT and choice of modality should begin at least 1 year before the anticipated start of dialysis. The appropriate mode of dialysis should be determined as well as suitability for transplantation. Patients electing peritoneal dialysis (PD) should have a PD catheter inserted 3 to 4 weeks before the anticipated need for dialysis. Patients who choose hemodialysis should have a functioning, permanent vascular access at the time RRT is initiated. Native arteriovenous fistulas have excellent long-term patency rates and, compared with other forms

of vascular access, are consistently associated with the lowest mortality risk. Fistula maturation occurs over several months, and patients should therefore be referred for fistula creation once the serum creatinine concentration is 4 mg/dL (305 μ mol/L) or greater, or once GFR falls to less than 30 mL/min/1.73 m². Use of cephalic veins for phlebotomy or intravenous cannulation can prevent successful fistula placement. Thus, physicians caring for patients with chronic kidney failure must educate patients and medical personnel to strictly avoid venipuncture and intravenous cannulation above the level of the hands, particularly in the nondominant extremity. Peripherally inserted central catheters and subclavian catheters can also impair the creation or function of arteriovenous fistulas and are contraindicated in patients with CKD. When central venous access is required, the internal jugular site is preferred.

Table 139-3 Factors Influencing Decision of Timing of Initiation of Dialysis

Renal clearance	Creatinine clearance <15 mL/min/1.73 m ² Urea clearance <8 mL/min/1.73 m ²
Nutritional status	Spontaneous dietary protein intake <0.8 gm/kg/day (can be estimated based on 24-hr urine urea nitrogen excretion)* Weight loss Hypoalbuminemia
Congestive heart failure	Not amenable to usual medical interventions
Uremic symptoms	Nausea, dysgeusia, cognitive impairment, pruritus
Uremic complications	Pericarditis, peripheral neuropathy, acidosis, hyperkalemia
Quality of life considerations	Particularly in the elderly

*Estimated dietary protein intake = 6.25 (daily urinary urea nitrogen [g] + {30 mg/kg × weight [kg]}/1000 mg/g).

Kidney transplantation remains the treatment of choice for most patients with ESRD. Outcomes with transplantation are more favorable in all groups when compared with dialysis, with diabetic patients gaining the greatest survival advantage through transplantation. Patient and allograft survival advantages have been demonstrated for preemptive transplantation and for transplantations performed after shorter periods of dialysis. This highlights the importance of early referral of patients with progressive CKD to facilitate timely identification of potential living donors.

Timing of Initiation of Dialysis

The National Kidney Foundation Kidney Disease Outcomes Quality Initiative work group has recommended that RRT be considered when the renal clearance of creatinine falls to less than 15 mL/min/1.73 m². This level of renal function generally precedes the onset of uremic complications. RRT can be delayed, however, in patients with stable edema-free body weight and nutritional status, and complete absence of clinical signs or symptoms attributable to uremia. The early-start approach was initially advocated to improve mortality, but subsequent studies have shown no evidence to support this hypothesis. Other factors such as nutritional status and quality of life clearly need to be weighed in decisions regarding the timing of dialysis initiation (Table 139-3). Generally, younger patients and those with diabetes mellitus have the greatest benefit from earlier initiation of dialysis.

Avoiding Treatment Errors

Every effort should be made to initiate and continue ACE inhibitor or ARB therapy throughout the course of progressive CKD. Hyperkalemia can often be minimized by using these agents once daily in conjunction with dietary potassium restriction and loop diuretics. Hemoglobin levels should be monitored at least monthly in patients receiving erythropoietin or darbepoetin to permit appropriate titration of these agents to the target range. Every time a serum creatinine concentration is measured, GFR should be estimated to facilitate appropriate and timely

initiation of interventions such as placement of vascular access.

Future Directions

Although considerable advances have been made in understanding mechanisms leading to CKD, future research is required to further elucidate the pathogenesis of progressive nephron loss. It is hoped that this will lead to new approaches that will further retard loss of renal function. The pathogenesis of accelerated cardiovascular disease needs to be further characterized in CKD populations to help identify new therapeutic strategies. The management of mineral and bone metabolism is in evolution, and the optimal therapeutic approach remains to be determined. Competing concerns of abnormal bone metabolism must be balanced with adverse cardiovascular outcomes. Finally, the impact of cardiovascular screening and interventions needs to be studied in CKD populations with the hope of ultimately decreasing excess cardiovascular mortality.

Acute Kidney Injury

Introduction

The term *acute renal failure* has been applied to a variety of situations in which the function of the kidneys declines over a period of hours to days. In the most severe cases, this leads to a prolonged increase in plasma concentrations of urea and creatinine, disruption of fluid and electrolyte balance, abnormalities in acid-base metabolism, and impairment of renal endocrine function.

There are many instances, however, in which there is a less severe impairment of renal function without overt failure. It is now known that even a minor elevation in the serum creatinine concentration (S_{Cr}) has a negative impact on both short-term and long-term mortality. Consequently, the term *acute kidney injury* (AKI) is now considered more appropriate, with further separation into stages depending on its severity (Table 140-1).

The actual incidence of AKI is difficult to determine because of the ambiguity in the definition of AKI itself. One definition considers renal function to be compromised with a more than 25% increase in S_{Cr} or an increase of 0.5 mg/dL. An increase in S_{Cr} of 50% or more above baseline or 1.0 mg/dL indicates serious renal impairment.

AKI that is hospital acquired may affect 5% of all inpatients; ischemic injury and exposure to nephrotoxic agents are the leading causes. AKI occurs in a much higher percentage of patients in intensive care units. When dialysis is necessary in these patients, the mortality rate exceeds 50%. AKI also may be community acquired, with alterations in systemic hemodynamics and urinary tract obstruction leading the list of causes. In all cases, the most susceptible patients are those with chronic kidney disease (CKD), with the risk increasing as the CKD worsens.

Etiology and Pathogenesis

AKI is often classified as prerenal, postrenal, or intrinsic, which is in turn further categorized on the basis of the proximate cause of the renal injury. Each of these conditions has different mechanisms of injury.

Prerenal Acute Kidney Injury

Prerenal AKI is marked by a reduction in the glomerular filtration rate (GFR) due to a disturbance in systemic or renal hemodynamics. Absolute volume depletion in severe dehydration, blood loss, or septic shock is a frequent cause of prerenal AKI. In other circumstances, there is a functional rather than an absolute decrease in the effective blood volume that leads to acute changes in renal function. In situations such as decompensated liver disease or congestive heart failure, the picture is complicated by an

increase in renal vascular resistance (RVR) that results in a decrease in renal blood flow (RBF) and GFR.

In advanced liver disease, the fall in GFR may decline to such an extent that renal replacement therapy (RRT) with dialysis is necessary. This often is an indication of the development of the hepatorenal syndrome (Fig. 140-1). Overall prognosis is poor unless the liver failure resolves or liver transplantation occurs. Prerenal AKI may develop in individuals with congestive heart failure as the combined result of a decrease in cardiac output and an increase in RVR. Prerenal AKI may also complicate therapy with certain medications, especially diuretics, angiotensin-converting enzyme inhibitors, and nonsteroidal anti-inflammatory drugs. In these situations, the kidney is responding to an altered internal environment. However, if the decrease in RBF is severe or prolonged, ischemic injury may occur.

Table 140-1 Classification and Staging System for Acute Kidney Injury

Stage	Creatinine Criteria	Urine Output Criteria
1	Increase serum creatinine ≥ 0.3 mg/dL (≥ 26.4 μmol) or increase to $\geq 150\%$ to 200% from baseline	< 0.5 mL/kg/hr for > 6 hr
2	Increase serum creatinine to $> 200\%$ to 300% (> 2 - to 3 -fold) from baseline	< 0.5 mL/kg/hr for > 12 hr
3	Increase serum creatinine to $> 300\%$ (> 3 -fold) from baseline or serum creatinine ≥ 4.0 mg/dL (≥ 354 $\mu\text{mol/L}$) with an acute rise of at least 0.5 mg/dL	< 0.3 mL/kg/hr $\times 24$ hr or anuria $\times 2$ hr

Figure 140-1 Kidney Injury in Liver Disease.

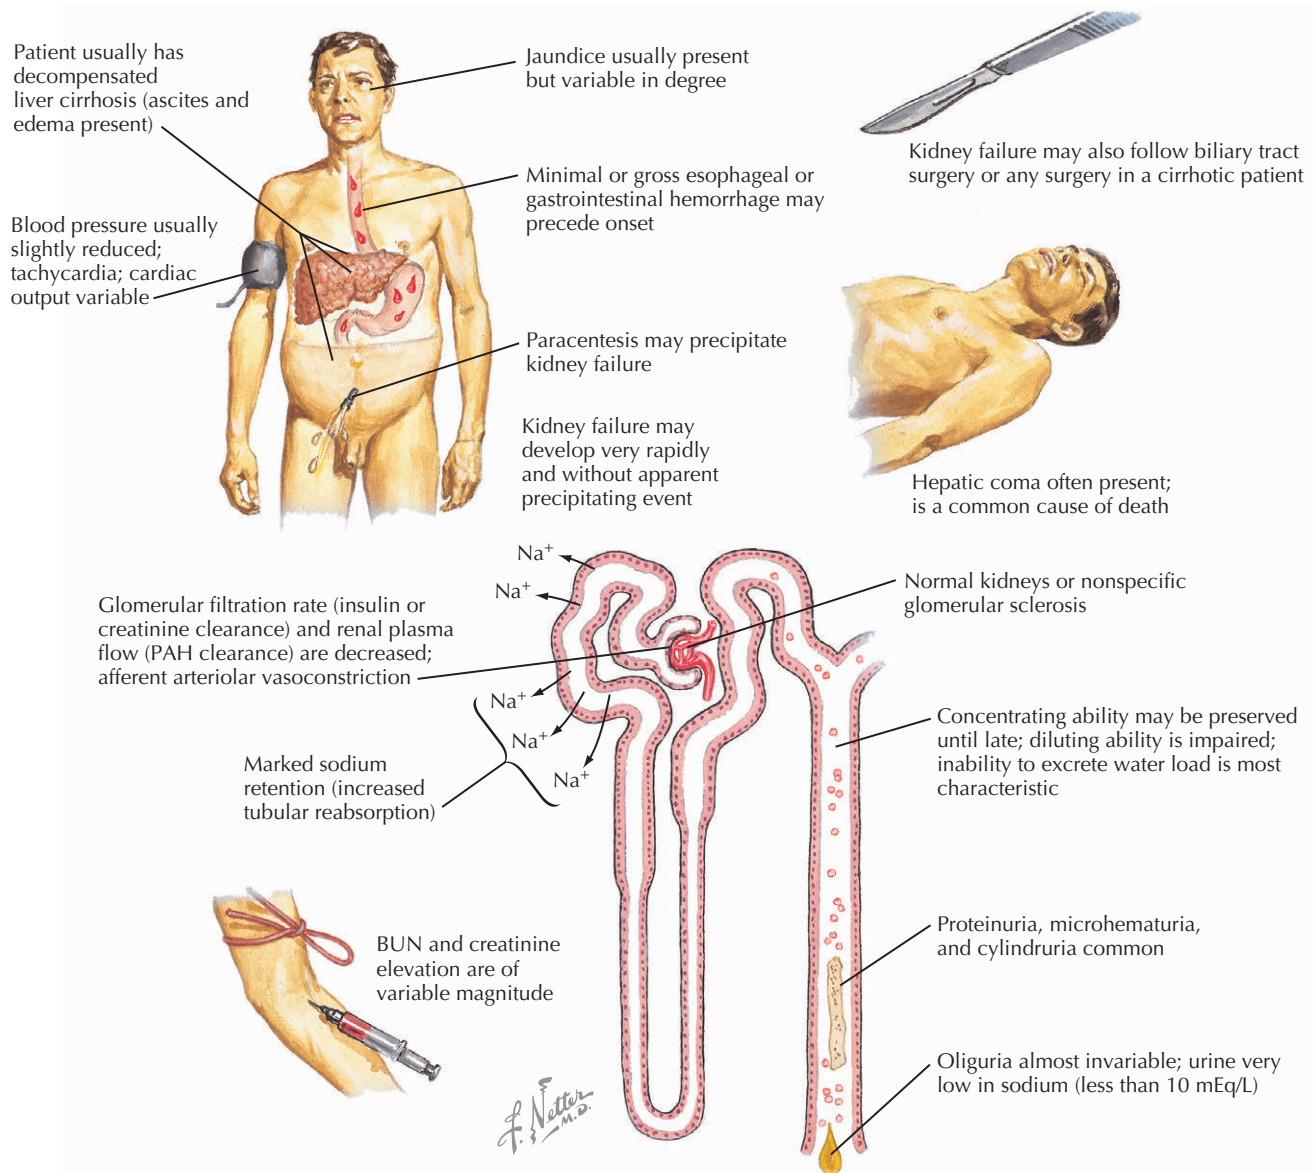

Figure 140-2 Obstructive Uropathy: Etiology.

Postrenal Acute Kidney Injury

Postrenal AKI may result from obstruction at any point along the urinary tract system (Fig. 140-2) and is not an infrequent cause of AKI. Excluding individuals with solitary kidneys and those with significantly impaired renal function due to underlying renal parenchymal disease, ureteral obstruction must be bilateral to produce clinically apparent abnormalities. If the obstruction is partial, urine flow may remain normal as a result of elevated pressures proximal to the site of the obstruction. A calculus, mass lesion, or sloughed papilla in papillary necrosis may cause ureteral obstruction. Papillary necrosis may complicate sickle cell disease, diabetes mellitus, and excessive analgesic

use. Urethral obstruction occurs more commonly in men with prostatic hypertrophy.

Intrinsic Acute Kidney Injury

The pathogenesis of AKI-associated ischemic and nephrotoxic injury is complex. In both ischemic and nephrotoxic AKI, renal tubular epithelial (RTE) cells are injured, and some may undergo necrosis or apoptosis. With severe tubular injury, debris accumulates within tubules and may obstruct fluid flow and compress adjacent peritubular capillaries. Necrosis of the tubular epithelium permits passage of filtrate into the renal interstitium. In most circum-

Figure 140-3 Hemolytic-Uremic Syndrome.**Intravascular coagulation, hemolytic-uremic syndrome, and thrombotic microangiopathy**

Common electron microscopic findings: Deposits (D) and mesangial cell cytoplasmic processes (M) in the subendothelial space; endothelium (E) swollen; both mesangial (MC) and endothelial cells (EN) contain many vacuoles and dilated rough endoplasmic reticulum; lumen (L) narrowed (may be slit-like); red blood cells (RC) may or may not be present; basement membrane (B) often wrinkled; epithelial foot processes (F) partly fused

stances, there is an increase in RVR and decrease in RBF. Finally, the permeability of the glomerular capillary membranes may change, contributing to the AKI. The injured kidney has the capacity to recover. Recent studies indicate that it may be possible to influence the extent to which this occurs.

Clinical Presentation

The clinical course of AKI is highly variable, ranging from a transient, self-limited disturbance of kidney function to prolonged and often life-threatening renal failure. The classic pattern involves three phases: initial, maintenance, and recovery. The initial phase begins with a specific renal insult and continues until functional abnormalities of the kidney develop. The time from injury to renal impairment during the initial stage depends on the severity of the injury. Oliguria (urine volume <500 mL/day) or anuria (urine volume <100 mL/day) may accompany the maintenance phase. In some instances, however, the urine volume remains normal, although the quality of the urine is poor, the GFR is severely reduced, and the blood urea nitrogen (BUN) and S_{Cr} rise. Characteristically, the maintenance phase lasts for 10 to 14 days, depending on the nature of the renal injury, although longer courses have been described. The final phase of AKI is the recovery phase.

If the patient had been oliguric, there may be a dramatic increase in urine volume at a relatively constant rate, ranging anywhere from hours to days. The degree of the diuresis is dependent on the volume status of the individual and inversely related to the duration of the maintenance phase. In nonoliguric individuals, improvement in the quality rather than the quantity of the urine heralds recovery. Late in recovery, glomerular and tubular function is restored, and the renal function returns to or toward the preexisting level. The likelihood of complete renal recovery is influenced by many factors. Poor prognostic indicators include the presence of preexisting renal disease, advanced age at the onset of renal injury, and persistent oliguria. As many as 10% to 15% of individuals do not recover adequate renal function, and chronic kidney disease develops in up to one third of patients.

Differential Diagnosis

Ischemic injury and exposure to nephrotoxic agents account for a significant proportion of cases of AKI among the conditions that may precipitously disrupt renal function. Injury resulting in AKI may involve any or all of the histologic components of the kidney, including glomeruli, tubules, interstitium, and vasculature (Box 140-1).

Postischemic Acute Kidney Injury**Nephrotoxic Acute Kidney Injury**

Sustained episodes of prerenal AKI due to protracted decreases in arterial blood pressure and RBF may evolve into postischemic AKI, in which tubular injury predominates. With profound ischemia, glomerular damage and cortical necrosis may further complicate the clinical picture. Cortical necrosis can also result from intraglomerular microthrombi, as occurs with the hemolytic-uremic syndrome or other types of thrombotic microangiopathies (see Fig. 140-3). Other instances of postischemic AKI complicate severe crushing injuries from trauma, resulting in rhabdomyolysis and myoglobinuria. Nontraumatic rhabdomyolysis with AKI may occur as a side effect of prescription and nonprescription drugs, including cholesterol-lowering agents and cocaine. Heat stress can also precipitate rhabdomyolysis.

AKI is associated with hemolysis and hemoglobinuria. A number of substances (xenobiotics) have been identified as capable of producing significant renal injury. The most common agents causing nephrotoxic AKI are medications, including antibiotics, especially the aminoglycosides, antifungal and chemotherapeutic agents; diagnostic agents such as iodinated radiocontrast media; and environmental substances including organic solvents and heavy metals. Analgesics, certain antibiotics, and several diuretics may be associated with a diffuse acute interstitial nephritis that differs from postischemic and nephrotoxic AKI because of evidence of an allergic reaction. Less frequently intrinsic AKI develops in the setting of multiple myeloma where light chains and uric acid deposit in the renal tubules, resulting in cast nephropathy.

Diagnostic Approach

The diagnosis of AKI requires a careful and systematic approach to identifying and managing potentially reversible conditions. After a careful history and physical examination, urine and plasma measurements are useful for further investigation of the etiology. The urine examination includes a microscopic exam of the urinary sediment and electrolyte measurements. The urine sediment is typically normal in prerenal and postrenal AKI except for the presence of hyaline casts. In intrinsic AKI, the urine sediment is often quite active, with muddy brown granular casts, free RTE cells and casts, white blood cells, and red blood cells.

The urinary sodium concentration and osmolality help to differentiate prerenal failure from AKI due to intrinsic renal disease. In prerenal AKI, the fractional excretions of sodium (FE_{Na}) and urea are low, and the urinary osmolality and specific gravity are high. The urine-to-plasma creatinine ratio (U/P_{creat}) is generally above 20 : 1. In postischemic and nephrotoxic AKI, the urinary sodium is high, the urinary osmolality and specific gravity are closer to that of plasma and, the U/P_{creat} may be less than 20 : 1. Intrinsic AKI is associated with a high FE_{Na} , usually greater than

1% and often more than 3%, which helps to distinguish it from the prerenal causes of AKI. Plasma measurements of electrolytes, BUN, and S_{Cr} indicate the severity of the AKI. These may be accompanied by the appearance of tubular aquaporins and the sodium transporter NHE-3 in the urine.

Renal ultrasonography is highly recommended early in the evaluation of AKI because of the importance of diagnosing postrenal AKI quickly. Less commonly, plain radiographs of the abdomen are performed to look for urinary calculi. Renal biopsy is indicated if the diagnosis of the AKI is in question, if a systemic illness is suspected, and to help guide therapy.

Management and Therapy

Optimum Treatment

The management and therapy of AKI, once largely supportive, now requires more specific attention. To begin, for patients with underlying CKD, the risk for developing AKI requires assessment followed by appropriate actions to minimize the risk. The first step is to estimate the baseline GFR using the formula from the modification in diet renal disease study. The use of the S_{Cr} alone is not acceptable. The risk for AKI increases in stepwise fashion with CKD 3 (GFR 30 to 60 mL/min), CKD 4 (GFR 15 to 30 mL/min), and CKD 5 (GFR <15 mL/min). On this basis, the dose and dosing interval of nephrotoxic agents such as aminoglycoside antibiotics must be adjusted and deficiencies in intravascular volume or systemic hemodynamics corrected. The need for prophylaxis is most obvious in preventing contrast-induced nephropathy (CIN), the third most common cause of hospital-acquired renal failure. CIN develops in about 3% of the general population. The risk for CIN may be as high as 50% in at-risk patient subsets, including those with CKD, diabetes mellitus, or both. Although the decline in renal function is usually reversible, it is associated with an increase in mortality rates.

When AKI occurs, all potentially reversible causes require urgent identification and correction. In prerenal AKI, volume repletion to correct circulatory abnormalities will restore renal function. In all patients, the cessation of nephrotoxic agents is essential. For mild cases of AKI that fail to resolve quickly, conservative medical management is often all that is required. This includes careful monitoring of fluid and electrolyte intake, in addition to prescribing potassium-binding resins and sodium bicarbonate for non-life-threatening hyperkalemia and metabolic acidosis, respectively. For persistent oliguria following volume repletion, loop diuretics are commonly employed, although their use is not associated with improved mortality or renal recovery but may be associated with shorter duration of RRT. There is overwhelming evidence that there is no role for “renal-dose” or “low-dose” dopamine in the prevention

of AKI from any cause, nor does it affect the need for dialysis or mortality.

The use of RRT with either intermittent hemodialysis (IHD) or continuous renal replacement therapy (CRRT) is often essential. The use of CRRT may be associated with better renal recovery than IHD; however, mortality rates are similar. Based on published reports, daily IHD, as compared with alternate-day therapy, is associated with improved survival; nevertheless, the current recommendation is to perform dialysis at least three times per week and to monitor the adequacy of dialysis to ensure that clearance and ultrafiltration goals are achieved. Few parameters are helpful in predicting the severity or prognosis of AKI; however, a prompt diagnosis and an aggressive treatment strategy are mandatory to preserve renal function and to avoid serious complications.

Avoiding Treatment Errors

During the course of AKI, monitoring sequential changes in urine quality rather than urine volume is often more valuable. In this way, the recovery of tubular function may be observed by an increase in the U/P_{urea} ratio and a decrease in the FE_{Na} . At times, a delay in recovery is a result of the superimposition of a state of volume depletion due to overaggressive ultrafiltration and intravascular volume depletion. A fall in blood pressure in a patient with AKI is likely to result in a proportional fall in RBF because of an inability of the injured kidney to compensate by a reduction in RVR. To avoid additional injury, it is important to choose a dialysis modality that minimizes the risk for intradialytic hypotension. This should be part of an overall dialysis prescription, which should include a program of nutritional support. It is important to record the amount delivered versus that prescribed to avoid otherwise unrecognized underdialysis and malnutrition.

Future Directions

The continued high mortality rate in individuals with AKI and the failure of many who survive to recover normal renal function have placed considerable importance on understanding the mechanisms by which the kidney responds to injury. There is considerable interest in the development of one or more biomarkers to judge the events occurring within the kidney. These include kidney injury molecule-1 (KIM-1), neutrophil gelatinase-associated lipocalin (NGAL), and urine interleukin-18 (IL-18). The quest for a pharmacologic therapy that could improve survival has been largely unsuccessful. Additional insight into the details of the cell cycle and the application of the tools of molecular biology may eventually lead to the development of pharmacologic agents that protect the kidney from injury or promote its full recovery. Increasing evidence suggests that at least three mechanisms contribute to the regenerative capacity of the kidney. These

include the ability of RTE cells to differentiate, proliferate, and repopulate the tubule; the possibility that specific renal progenitor stem cells within the kidney serve the same purpose; and the more recent data that bone marrow-derived stem cells may contribute to the regeneration of the renal parenchyma.

Glomerulonephritis

Introduction

Glomerulonephritis refers to a typically inflammatory injury of glomeruli that results in hematuria, proteinuria, edema, hypertension, and azotemia. Of the numerous glomerular diseases, each characterized by its own pathologic features, natural history, and response to treatment, many can present with the same clinical syndrome. For instance, asymptomatic microscopic hematuria is a consequence of several disparate pathologic entities, most commonly thin basement membrane nephropathy and immunoglobulin A (IgA) nephropathy. Thus, when evaluating patients with glomerulonephritis, it is helpful to first determine to which general clinical category they belong, and then to dissect the different diseases within each group as described in Box 141-1.

Etiology and Pathogenesis

There are several pathogenic mechanisms of glomerulonephritis. The most common is an inflammatory glomerular injury that results from immune complex formation or deposition within the glomerular basement membrane or the mesangium. These immune complexes initiate many pathologic pathways, in particular, complement activation, cytokine, and chemokine generation and release. In response, circulating inflammatory cells, including neutrophils, monocytes, and lymphocytes infiltrate the glomeruli and the surrounding tubulointerstitial compartments. Immune deposits may develop in the glomeruli in three basic ways: the deposition of circulating immune complexes (e.g., lupus nephritis), the deposition of antigens with subsequent in situ immune complex formation (e.g., peri-infectious disorders), or the presence of circulating antibodies that react to intrinsic components of the glomerulus (e.g., anti-glomerular basement membrane [anti-GBM] diseases) (Fig. 141-1). The mesangial cell response to injury is marked by proliferation, production, and deposition of extracellular matrix, and, eventually, glomerular scarring. Glomerular endothelial cells are the target of injury in some diseases, such as hemolytic-uremic syndrome and the vasculitides.

Hereditary nephritides, including Alport's syndrome and thin basement membrane disease, are the result of mutations in type IV collagen. Genetically, Alport's syndrome may result from mutations in the $\alpha 5$ chain of type IV collagen (X-linked transmission), or mutations of the

$\alpha 3$ or $\alpha 4$ chains associated with autosomal recessive or dominant patterns of transmission. Thin basement membrane disease, a relatively common autosomal dominant disorder, is also related to mutations of the $\alpha 3$ or $\alpha 4$ chains. Although both syndromes present with asymptomatic glomerular hematuria, they diverge in their natural history. Thin basement membrane disease (also referred to as *benign familial hematuria*) is associated with an excellent long-term outcome, whereas Alport's syndrome causes a progressive loss of renal function. Some kindred with Alport's syndrome may also present with sensorineural deafness, ocular anomalies, mental retardation, or leiomyomatosis.

Clinical Presentation

The clinical expression of disease correlates with the pathologic features; the more aggressive the pathologic injury, the more severe the illness. Some patients present with asymptomatic hematuria and recurrent gross hematuria. Hematuria, defined as more than three red blood cells per high-power field observed in centrifuged urine sediment, can be of either glomerular or nonglomerular origin (Fig. 141-2). Chemical stress on red blood cells as they pass along the nephron result in morphologic changes and dysmorphic red cells. The most diagnostic of these, acanthocytes (Mickey Mouse cells), are virtually pathognomonic of glomerular bleeding. In combination with red blood cell casts, other cylindruria, and proteinuria, these

abnormalities suggest a glomerular as opposed to a urinary tract source of hematuria.

The most common causes of asymptomatic hematuria are listed in Box 141-1. Patients with IgA nephropathy present with one of three syndromes. About half have a history of episodes of macroscopic hematuria associated with an upper respiratory tract infection that may recur, with subsequent episodes of pharyngitis, febrile illness, or heavy exertion. Patients are typically asymptomatic; hypertension and peripheral edema are uncommon. Asymptomatic microscopic hematuria with proteinuria, the second most common presentation, is associated with the worst long-term prognosis. A third presentation is part of the vasculitic syndrome, Henoch-Schönlein purpura, which develops most commonly in children. The postinfectious

nephritic syndrome of IgA nephropathy is differentiated from poststreptococcal glomerulonephritis in that it occurs only 1 to 2 days after the onset of the infection, as opposed to after the 10- to 14-day delay in poststreptococcal glomerulonephritis.

Acute glomerulonephritis usually presents with the sudden onset of proteinuria, hematuria, and urine sediment containing dysmorphic red blood cells, red blood cell casts, and cellular debris. Patients typically have edema, hypertension, oliguria, and renal insufficiency. In the most severe form, rapidly progressive glomerulonephritis (RPGN), the serum creatinine concentration rises in a matter of days to weeks, resulting in profound renal insufficiency. Structurally, RPGNs are usually associated with the formation of glomerular crescents that result from the proliferation of both glomerular epithelial cells and mononuclear phagocytes in Bowman's space. Crescents are not indicative of a specific cause of glomerular injury but may result from many different pathogenetic mechanisms.

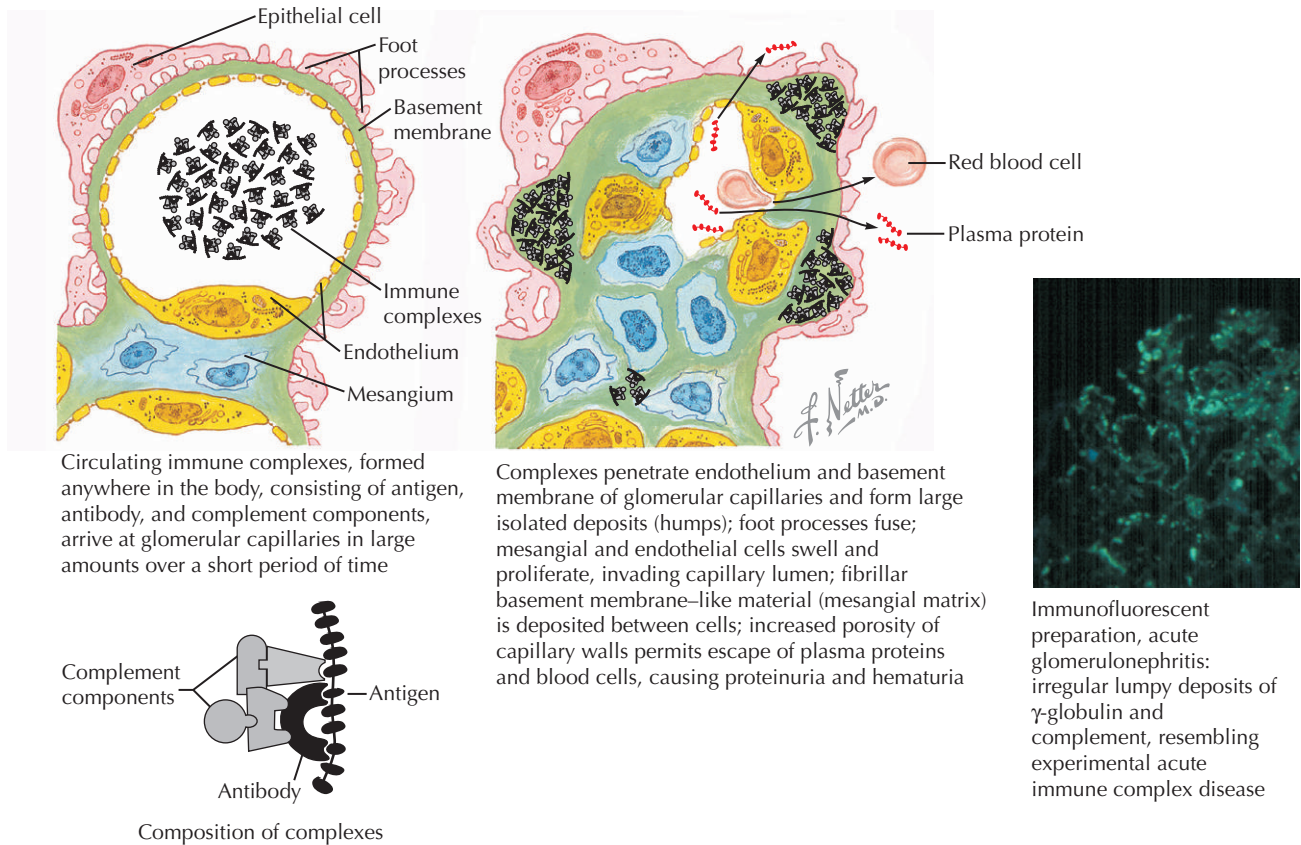

All forms of acute nephritis, including RPGN, may be a consequence of streptococcal or staphylococcal infections or immunologic diseases. The illness is characterized by the sudden onset of edema and by oliguria with heavy proteinuria and hematuria (Fig. 141-3). Hypertension, cardiac enlargement, and pulmonary edema may complicate the clinical course. In the Western world, the types of infections resulting in postinfectious glomerulonephritis have changed so that patients with underlying immunocompromised states, including cirrhosis, malignancy, and transplantation, develop glomerulopathies associated with a variety of gram-negative organisms.

Recently, the role of hepatitis C virus was recognized in the pathogenesis of membranoproliferative glomerulonephritis type I and cryoglobulinemia. A clinical syndrome of mixed cryoglobulins is characterized by purpura, weakness, arthralgias, and in some cases, glomerular disease.

Systemic lupus erythematosus (SLE) is the prototypic cause of acute nephritis associated with immunologic injury. The characteristic renal lesion of lupus is a consequence of the accumulation of immune complexes in the mesangium and along the glomerular capillary wall. Lupus nephritis ranges from almost no pathologic abnormality to a severe diffusely proliferative and crescentic lesion; the clinical spectrum of disease ranges from normal renal function with minimal proteinuria (<1 g/24 hours) to RPGN and severe proteinuria. Almost all patients have hematuria. Other causes of diffuse proliferative glomerulonephritis include IgA nephropathy and membranoproliferative glomerulonephritides.

The most common causes of RPGN associated with crescent formation include the immune complex-mediated diseases, diseases associated with antineutrophil cytoplasmic autoantibodies (ANCA) or with anti-GBM. The presence of pulmonary hemorrhage in addition to anti-GBM-mediated nephritis defines Goodpasture's syndrome. There is a bimodal age distribution of patients with

Figure 141-1 Hypothesis of Pathogenesis of Acute Glomerular Injury by Circulating Immune Complexes (Schematic).

Goodpasture's syndrome with peaks in the third and sixth decades. One third of patients have isolated glomerular disease. Malaise, fatigue, and weight loss are common.

In a patient with a glomerulonephritis, it is most important to determine whether the renal disease is part of a systemic disorder resulting from an infection or is caused by an immunologic disorder. One approach is to determine whether a patient has a pulmonary-renal or dermal-renal syndrome. Pulmonary-renal vasculitic syndromes include Goodpasture's syndrome, the ANCA vasculitides (including microscopic polyangiitis, Wegener's granulomatosis, and Churg-Strauss syndrome), or immune complex vasculitis, especially SLE and cryoglobulinemia. In renal-dermal vasculitic syndromes, the glomerulonephritis is associated with a number of skin manifestations, including petechiae, purpura, hives, livedo reticularis, and ecchymoses. These diseases are usually attributable to SLE, ANCA vasculitis, Henoch-Schönlein purpura, or cryoglobulinemia.

Differential Diagnosis

The differential diagnosis of glomerulonephritis is broad and includes other causes of hematuria and azotemia. Glomerulonephritides account for only about 5% of hematu-

ria in the adult population where urinary tract stones, infections, and malignancies predominate. Azotemia may be caused by tubulointerstitial disease (e.g., acute tubular necrosis or acute interstitial nephritis), thrombotic microangiopathies or urinary tract obstruction. The presence of dysmorphic erythrocyturia, red blood cell casts, and proteinuria more than 500 mg/day are strong clues for a glomerular cause of hematuria. Extrarenal manifestations of disease identified on a thorough review of systems and physical examination provide clues to the presence of systemic infections or autoimmune diseases associated with glomerulonephritis.

Diagnostic Approach

The initial diagnostic approach in anyone with kidney disease is to examine the urine for the presence of glomerular hematuria, proteinuria, or other formed elements. This simple study allows the inclusion or exclusion of many renal processes. Multisystem disease is usually associated with constitutional signs and symptoms of inflammation, including arthralgias, myalgias, fever, and weight loss. The pattern and character of organ involvement provide clues for a differential diagnosis. The eyes, ears,

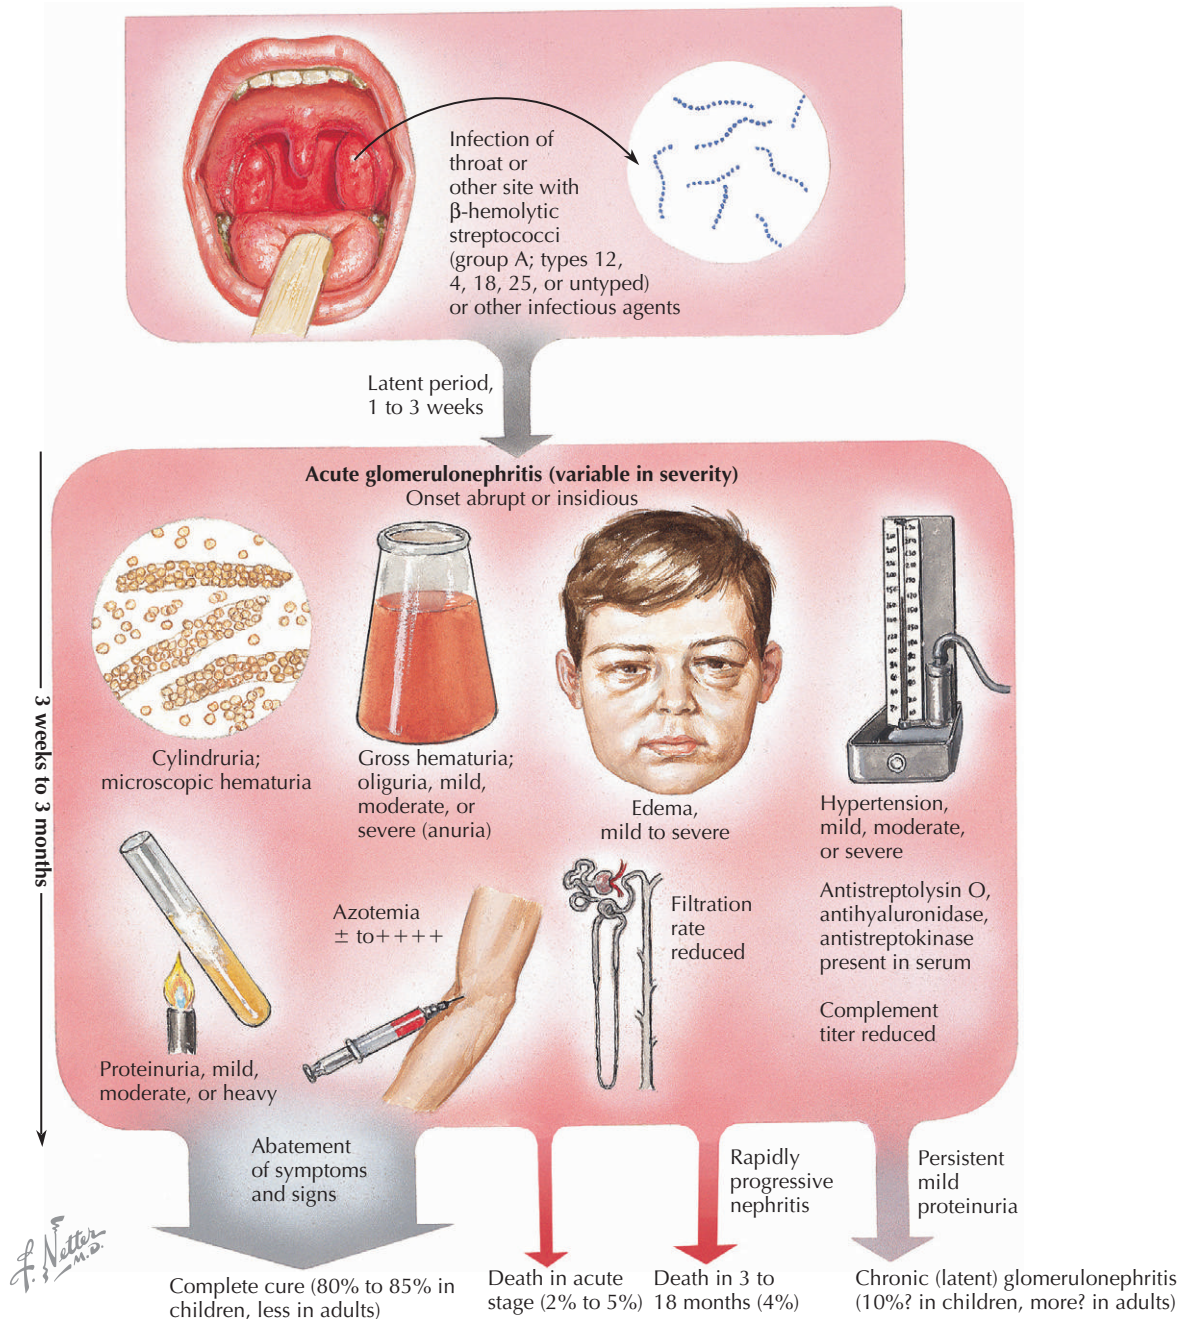

Figure 141-2 Urinary Sediment: Organized Elements.

sinuses, upper respiratory tract, lungs, gastrointestinal tract, central and peripheral nervous system, and skin may be involved in the various vasculitides associated with glomerulonephritis. Serologic tests help in the diagnosis of glomerular diseases. It is possible to separate glomerular diseases on the basis of whether the patient has circulating immune complexes such as cryoglobulins; antibodies to nuclear antigens including anti-double-stranded DNA, ANCA, anti-GBM antibodies, and hypocomplementemia; or evidence for infectious diseases including assays for hepatitis C, hepatitis B, and streptococcal disease, includ-

ing deoxyribonuclease-B and anti-streptolysin O testing (Fig. 141-4).

The evaluation of pathologic features on a renal biopsy specimen is usually required for diagnosis. Light, immunofluorescence, and electron microscopy are used to establish the precise pattern of injury. The definitive diagnosis frequently depends on an integrated synthesis of the clinical features of disease, serologic tests, and pathologic findings. For example, glomerulonephritides associated with proliferative lesions are attributable to infections, lupus nephritis, or IgA nephropathy and require serologic tests

Figure 141-3 Clinical Course of Acute Glomerulonephritis.

to differentiate among them. In addition to its diagnostic value, the renal biopsy also allows estimation of prognosis and treatment options. Generally, a renal biopsy is indicated in any patient with renal disease when the cause cannot be adequately determined by the clinical pattern of disease or laboratory findings, the differential diagnosis results in differing prognoses and treatment, or signs and symptoms suggest intrinsic renal disease that can be diagnosed by the biopsy (Fig. 141-5).

Contraindications to renal biopsy include the presence of a solitary kidney, an uncooperative patient, bleeding

disorders of any kind, severe hypertension, multiple cysts within the kidney, obstructive uropathy, renal neoplasm, and a very thin cortex (usually indicative of end-stage renal disease) in which case a biopsy is no longer useful.

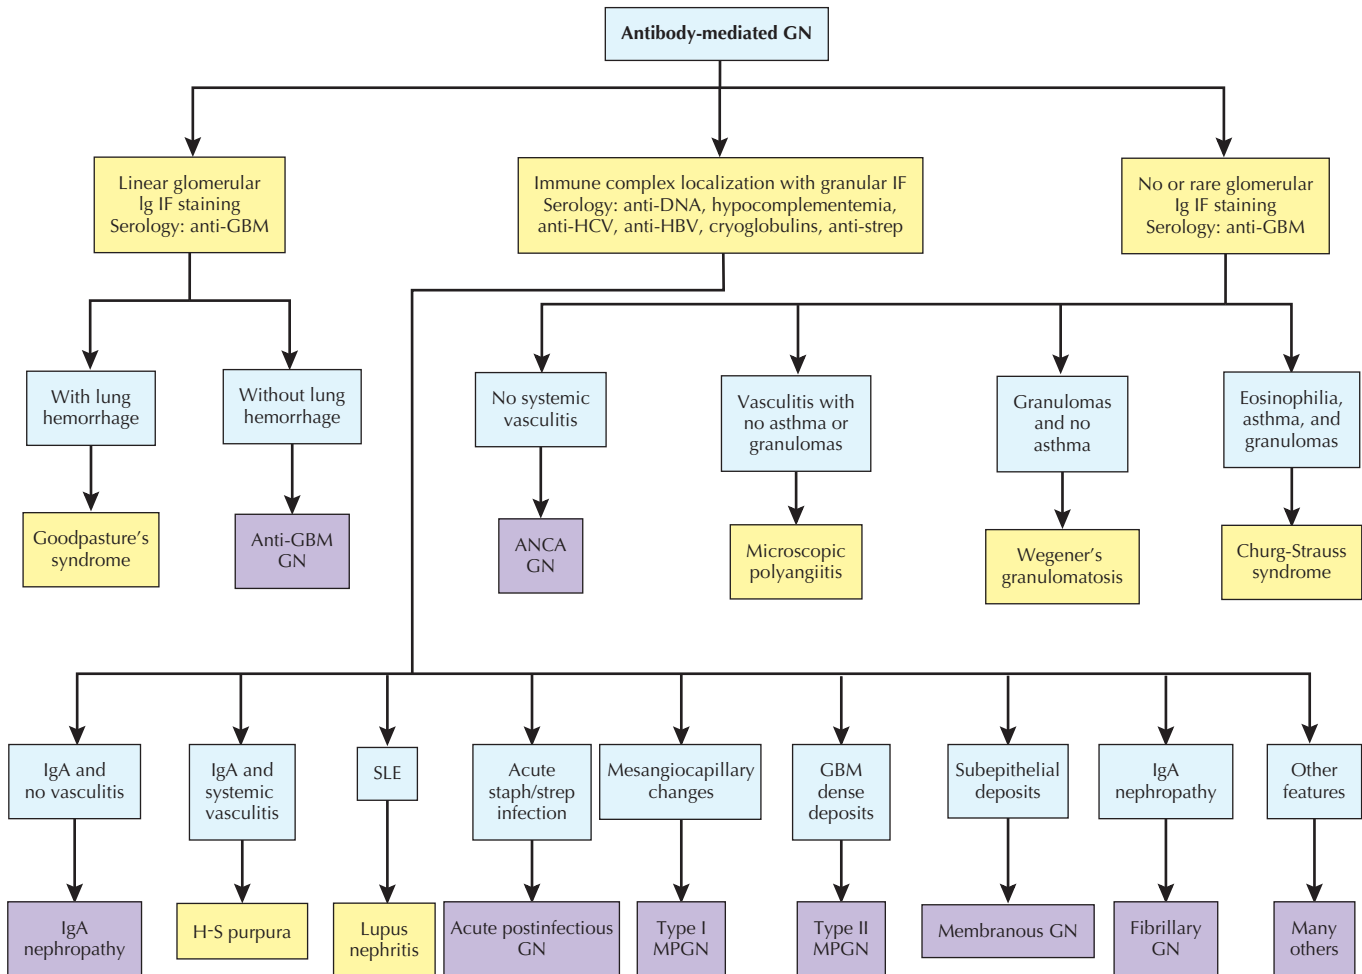

Management and Therapy

Optimum Treatment

All forms of glomerular disease require supportive care. The treatment of hypertension is a cornerstone of therapy.

Figure 141-4 A serologic approach to glomerulonephritis.

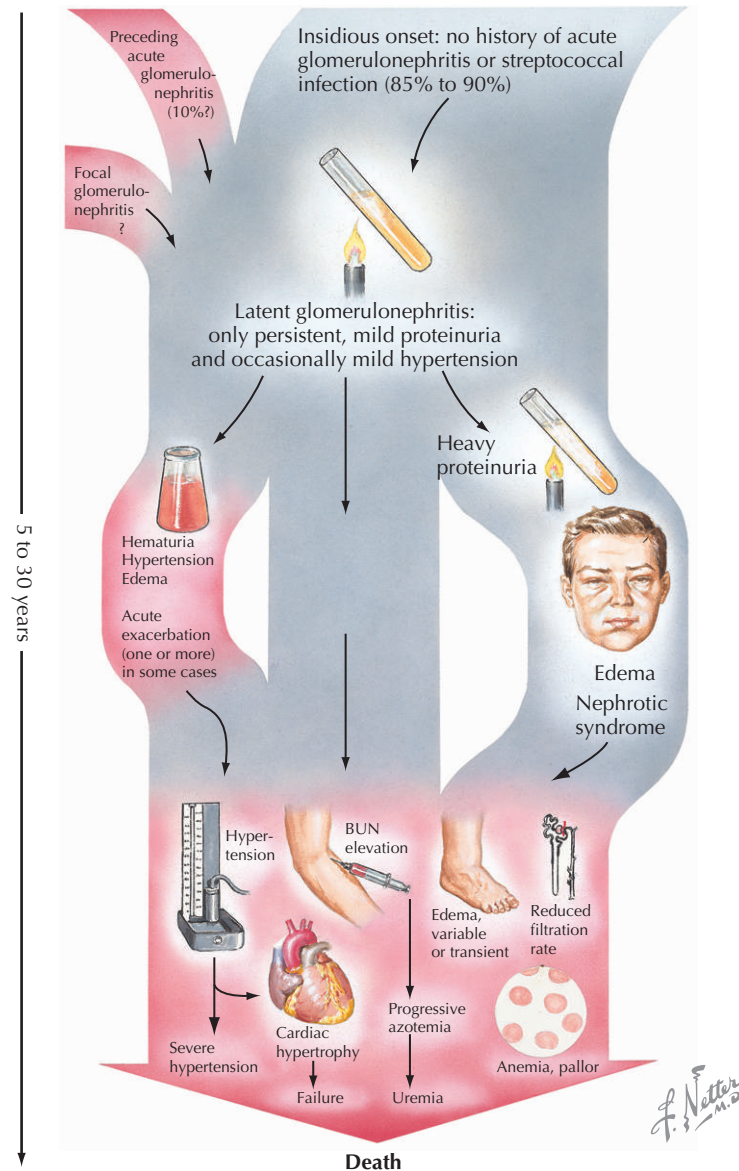

The *purple boxes* denote diseases limited to the kidney; *yellow boxes* denote systemic diseases. ANCA, anti-neutrophil cytoplasmic autoantibody; anti-GBM, anti-glomerular basement membrane; IF, immunofluorescence microscopy; Ig, immunoglobulin; GN, glomerulonephritis; anti-HCV, anti-hepatitis C virus antibodies; anti-HBV, anti-hepatitis B virus antibodies. HBV serologies should include HBV surface antigen, and antibodies to the HBV core antigen; H-S purpura, Henoch-Schönlein purpura, MPGN, membranoproliferative glomerulonephritis; SLE, systemic lupus erythematosus. From Falk RJ, Jennette JC, Nachman PH: *Primary glomerular disease*. In: Brenner BM (ed): *Brenner & Rector's The Kidney*, 6th ed. Philadelphia, WB Saunders, 2004, pp 1293-1380.

Angiotensin-converting enzyme inhibitors or angiotensin receptor blockers are the agents of choice because they control blood pressure, reduce proteinuria, and slow the rate of decline of creatinine clearance. Other supportive measures include management of edema with diuretics, diminution of hyperlipidemia, prevention of osteoporosis from glucocorticoids, and a moderate restriction of protein intake (avoiding protein malnutrition in patients with severe proteinuria).

Some diseases require observation alone, including thin basement membrane disease, Alport's syndrome, and mild glomerular injury. Poststreptococcal glomerulonephritis typically resolves spontaneously, but other peri-

infectious diseases may require specific treatment of the underlying infection, including antiviral therapy in hepatitis C-associated conditions. Glucocorticoid therapy, usually given orally, is useful in patients with many types of acute nephritis, especially those in which renal impairment may ensue. Glucocorticoids are usually started at 1 mg/kg/day of prednisone (<80 mg/day) for 4 weeks, and then rapidly titrated to an alternate-day regime, and discontinued by the end of 3 to 4 months. This approach is used in treating lupus nephritis, ANCA glomerulonephritis, and milder forms of other types of glomerulonephritis. The use of cyclophosphamide is indicated for patients with severe lupus nephritis, anti-GBM disease,

Figure 141-5 Clinical Course of Chronic Glomerulonephritis.

Goodpasture's syndrome, and ANCA glomerulonephritis or vasculitis. The method in which cyclophosphamide is administered has varied, although monthly intravenous doses for at least 6 months have been recommended for the treatment of lupus nephritis. A consolidation treatment is extended for an additional 18 months to preserve a renal remission in severe lupus nephritis. Similarly, both intravenous cyclophosphamide and oral cyclophosphamide have been used in the treatment of ANCA glomerulonephritis. The duration and intensity of therapy must match the intensity and severity of the underlying glomerular-systemic inflammation. Data do not allow for specific recommendations, but generally 6 to 12 months is sufficient for almost all forms of glomerulonephritis.

Some conditions are life threatening as a consequence of pulmonary hemorrhage or RPGN. In these most aggressive forms of disease, induction therapy with intravenous methylprednisolone at a dose of 7 mg/kg (<1000 mg/day) on 3 consecutive days is useful adjunctive therapy. Patients presenting with pulmonary hemorrhage or severe renal failure are treated with plasmapheresis in addition to glucocorticoids and cyclophosphamide. Daily plasma exchange is indicated for patients with anti-GBM disease and Goodpasture's syndrome.

Avoiding Treatment Errors

The outcome of patients with aggressive forms of glomerulonephritis depends on prompt diagnosis and the

early institution of therapy. The lower the serum creatinine at the time of initiation of therapy, the smaller is the risk for progression to end-stage renal disease. Delay in diagnosis and therapy adversely affects long-term outcome in all forms of glomerular inflammation.

Whenever immunosuppressive therapy is instituted, it is important to pay close attention to the prevention and early detection of potential infectious and metabolic complications. The use of high-dose glucocorticoids should be accompanied by measures to prevent bone loss with calcium, vitamin D, and when appropriate, the use of bisphosphonates. Close monitoring is necessary for the early detection and management of steroid-induced diabetes mellitus. The prophylactic use of trimethoprim-sulfamethoxazole should be considered in all patients undergoing therapy with cyclophosphamide. Monitoring of the peripheral white cell count during treatment with cyclophosphamide (especially 2 weeks after an intravenous dose) is necessary to adjust its dosage and avoid severe leukopenia.

Future Directions

Very little is known about the precise pathogenesis of any form of glomerulonephritis, so it is difficult to target therapy on the basis of the pathogenic mechanisms of these disorders. New pharmaceutical agents that target specific portions of the immune system's effector arm, such as cytokines, complement activation, lymphocyte co-stimulatory molecules, and effector immune cells, are under various stages of development. Agents that inhibit T and B cells are available and have been experimentally used in glomerular diseases, including cyclosporine, tacrolimus, and mycophenolate mofetil. The precise role of these agents in the treatment of glomerular disease remains under investigation.

Precisely targeted therapy awaits the understanding of proximate causes of glomerular inflammation, whereas the

ultimate goal will be their prevention. Assessment of populations at risk will require a careful understanding of the genes and environmental conditions that spawn glomerular injury.

Nephrotic Syndrome

Introduction

The nephrotic syndrome represents a diverse group of diseases that share the clinical hallmark of proteinuria of 3.5 g/day per 1.73 m² body surface area or more, accompanied by hypoalbuminemia, edema, hyperlipidemia, and lipiduria. Although the nephrotic syndrome can occur at all ages, certain forms primarily affect children and young adults (minimal change glomerulopathy [MCG] and membranoproliferative glomerulonephritis), and others are more common among older adults (membranous glomerulopathy [MGN]).

Etiology and Pathogenesis

The diseases that present with the nephrotic syndrome have various etiologies and pathogeneses (Fig. 142-1). In general, they can all present as a primary (idiopathic) renal disease or be secondary to an underlying systemic disease. Diabetes mellitus is the most common cause of secondary nephrotic syndrome. Other causes are infections, malignancies, connective tissue diseases, exposure to drugs or environmental agents, and hemodynamic or genetic abnormalities (Table 142-1).

The exact mechanisms leading to the severe proteinuria are poorly understood in most cases of primary and secondary nephrotic syndrome (Fig. 142-2).

Clinical Presentation

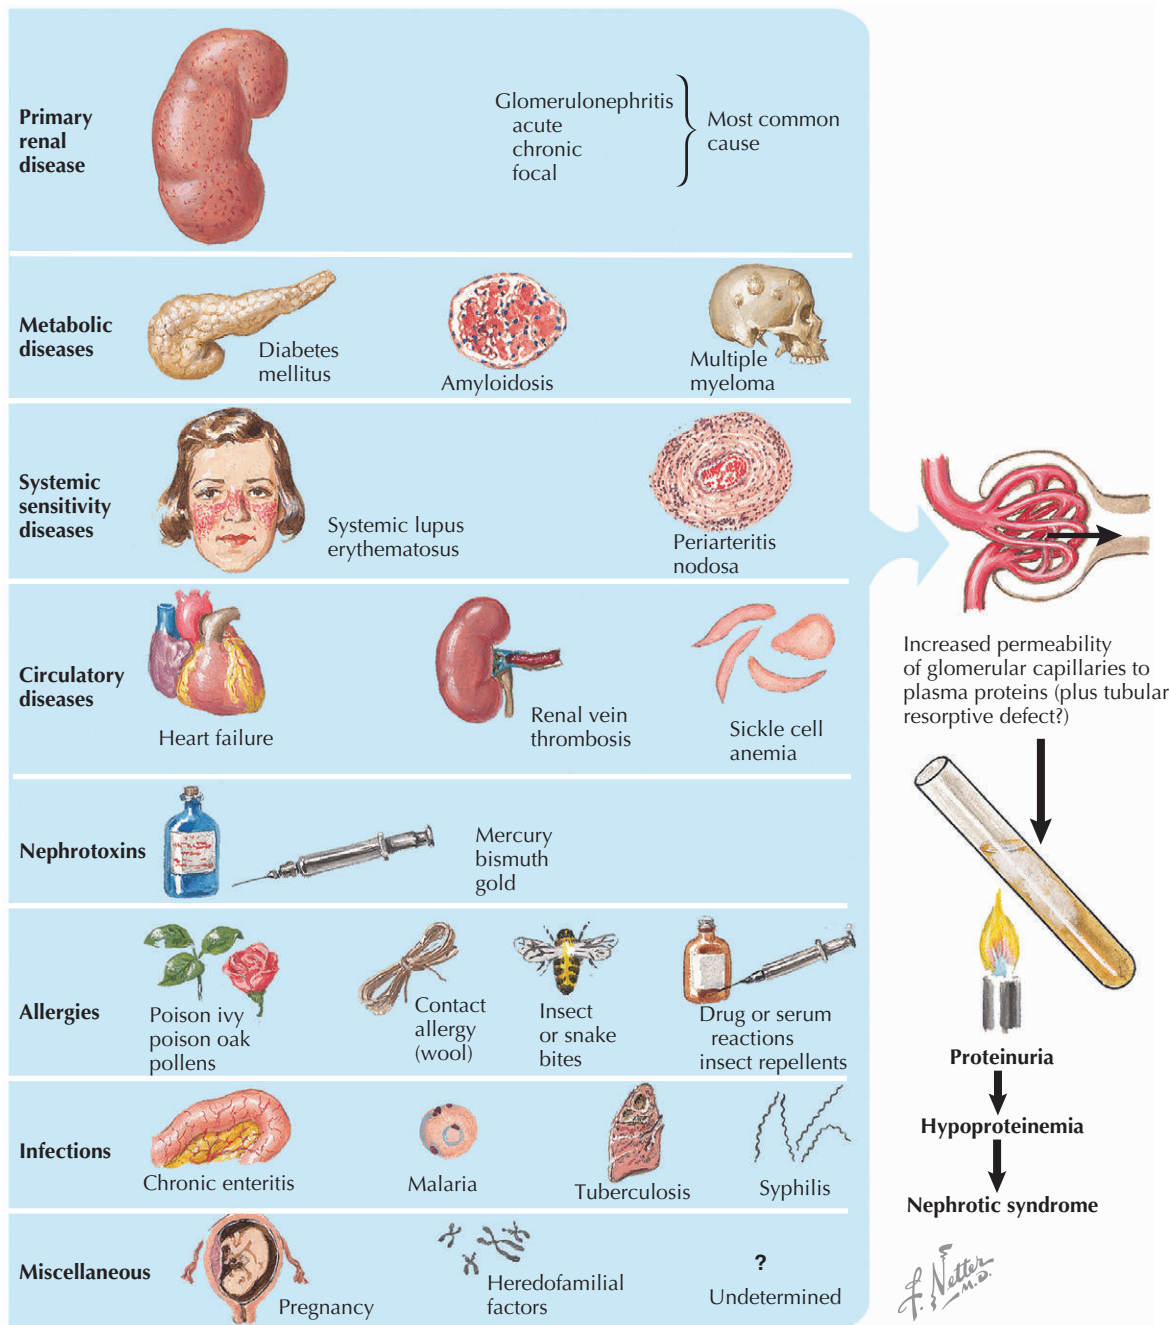

Edema is the most common presenting symptom. Reduced plasma oncotic pressure has long been considered the proximate cause of intravascular depletion resulting in salt and water retention by the kidney (Fig. 142-3). This concept is challenged by the fact that some patients have an increased plasma volume and hypertension. Furthermore, in children with a relapse of MCG, sodium retention may precede the reduction in serum protein concentrations, and natriuresis can start before the hypoalbuminemia has resolved with treatment. Enhanced tubular sodium reabsorption is instead more likely a function of multiple mediator systems, including the activation of the renin-angiotensin aldosterone, sympathetic nervous, and vasopressor systems.

The hypercholesterolemia and hypertriglyceridemia are thought to be the consequence of both increased synthesis and decreased catabolism and may persist well after clinical remission has occurred. Hypercholesterolemia is largely a result of hepatic overproduction of lipoproteins and appears to be stimulated by the fall in oncotic pressure. An acquired defect in the low-density lipoprotein (LDL) receptor results in a diminished clearance of LDL. Lipiduria is reflected by the presence of free lipid droplets, hyalofatty casts, and oval fat bodies in the urine. The latter are sloughed tubular epithelial cells engorged with the excess lipids and lipoproteins in the urine. Hypoalbuminemia is a consequence of urinary losses and of an increased albumin catabolism, whereas hepatic albumin synthesis is increased. Although proteinuria and lipiduria are the hallmark urinary findings of the nephrotic syndrome, microscopic hematuria may be present in patients with focal segmental glomerulosclerosis (FSGS), MGN, and membranoproliferative glomerulonephritis (MPGN).

As a consequence of the urinary losses of immunoglobulins and defects in the complement cascade, nephrotic patients have an increased susceptibility to infection, particularly peritonitis.

Several abnormalities of the coagulation system may result in venous and, less frequently, arterial thrombi. Thrombi may occur in virtually any venous bed but have a predilection for the renal veins. The hypercoagulability is attributed to urinary losses of anticoagulant factors such as proteins C and S and antithrombin III, as well as to intravascular consumption.

Figure 142-1 Multiple Etiologies of Nephrotic Syndrome.

Major Forms of Primary Nephrotic Syndrome

Minimal Change Glomerulopathy (MCG)

MCG is most common in children, accounting for 70% to 90% of nephrotic syndrome cases in children younger than 10 years, and 10% to 15% of primary nephrotic syndrome in adults. MCG has no glomerular lesions by light microscopy and no staining with antisera specific for immuno-

globulins or complement by immunofluorescence microscopy (Fig. 142-4). Electron microscopy reveals effacement of visceral epithelial cell foot processes. Primary MCG is thought to be mediated by an as yet unidentified T-cell lymphokine that increases glomerular permeability to protein. The cardinal clinical feature of MCG is the abrupt onset of the nephrotic syndrome. Hypertension and renal insufficiency, although rare in children, may be seen in older adults.

Table 142-1 Underlying Causes of the Nephrotic Syndrome and Associated Pathologic Findings

Underlying Cause	Disease
Infections	
HIV	Collapsing FSGS
Hepatitis C virus	MPGN > MGN
Hepatitis B virus	MGN > MPGN
Subacute bacterial infections (endocarditis, osteomyelitis)	MPGN, MGN
Malaria	Proliferative glomerulonephritis > MGN
Syphilis	MGN > MPGN
Autoimmune	
Autoimmune thyroiditis	MGN
Systemic lupus erythematosus	MGN, MPGN
Allergic	
Food allergies	MCG
Malignancies

Non-Hodgkin's lymphoma, leukemia	MGN
Solid tumors	MGN
Metabolic and Hemodynamic	
Diabetes mellitus	Diabetic nephropathy
Obesity	FSGS
Sickle cell disease	FSGS
Cyanotic congenital heart disease	FSGS
Congenital pulmonary disease	FSGS
Nephron loss	FSGS
Exposures	
NSAIDs	MCG
Penicillamine, gold	MGN
Heroin, intravenous drug abuse	Collapsing FSGS
Genetic	Familial FSGS

FSGS, focal segmental glomerulosclerosis; MCG, minimal change glomerulopathy; MGN, membranous glomerulopathy; MPGN, membranoproliferative glomerulonephritis; NSAID, nonsteroidal anti-inflammatory drugs.

Focal Segmental Glomerulosclerosis

FSGS is a clinical-pathologic syndrome that likely encompasses diseases of multiple etiologies and pathogenic mechanisms. The incidence of FSGS has increased over the past two decades, and it is the most common cause of nephrotic syndrome among African Americans. FSGS may be a primary renal disease, or it may be associated with a variety of other conditions (see Table 142-1). On histology, it is characterized by focal and segmental glomerular sclerosis. Although many specimens have nonspecific patterns of sclerosis, at least three major structural variants are recognized (Fig. 142-5).

The perihilar variant is characterized by sclerotic lesions that have a predilection for the glomerular perihilar segments and are accompanied usually by hyalinosis and adhesions to Bowman's capsule. There is no staining for immunoglobulins or complement by immunofluorescence microscopy. Electron microscopy reveals focal foot process effacement.

The collapsing glomerulopathy occurs in HIV nephropathy, with intravenous drug abuse, or as an idiopathic

process. The characteristic feature is focal segmental or global collapse of glomerular capillaries with obliteration of capillary lumens. Visceral epithelial cells that overlie collapsed segments usually are enlarged and contain conspicuous resorption droplets.

The glomerular tip lesion variant is characterized by consolidation of the glomerular segment that is adjacent to the origin of, and may project into the lumen of, the proximal tubule. Visceral epithelial cells adjacent to the consolidated segment are enlarged and contain clear vacuoles and hyaline droplets.

The pathogenesis of FSGS is poorly understood. Many theories suggest that podocyte injury is a component of the pathogenic process. FSGS may result from the loss of nephrons, which causes compensatory intraglomerular hypertension and hypertrophy in the remaining glomeruli, although data from long-term studies of uninephrectomized individuals have demonstrated either none or only a small increase in mild proteinuria and systolic hypertension. An as yet poorly characterized permeability factor has been described in some patients with primary FSGS, especially in those with recurrent FSGS after transplantation.

Figure 142-2 Pathophysiologic Factors in the Etiology of Nephrotic Edema.
ADH, antidiuretic hormone.

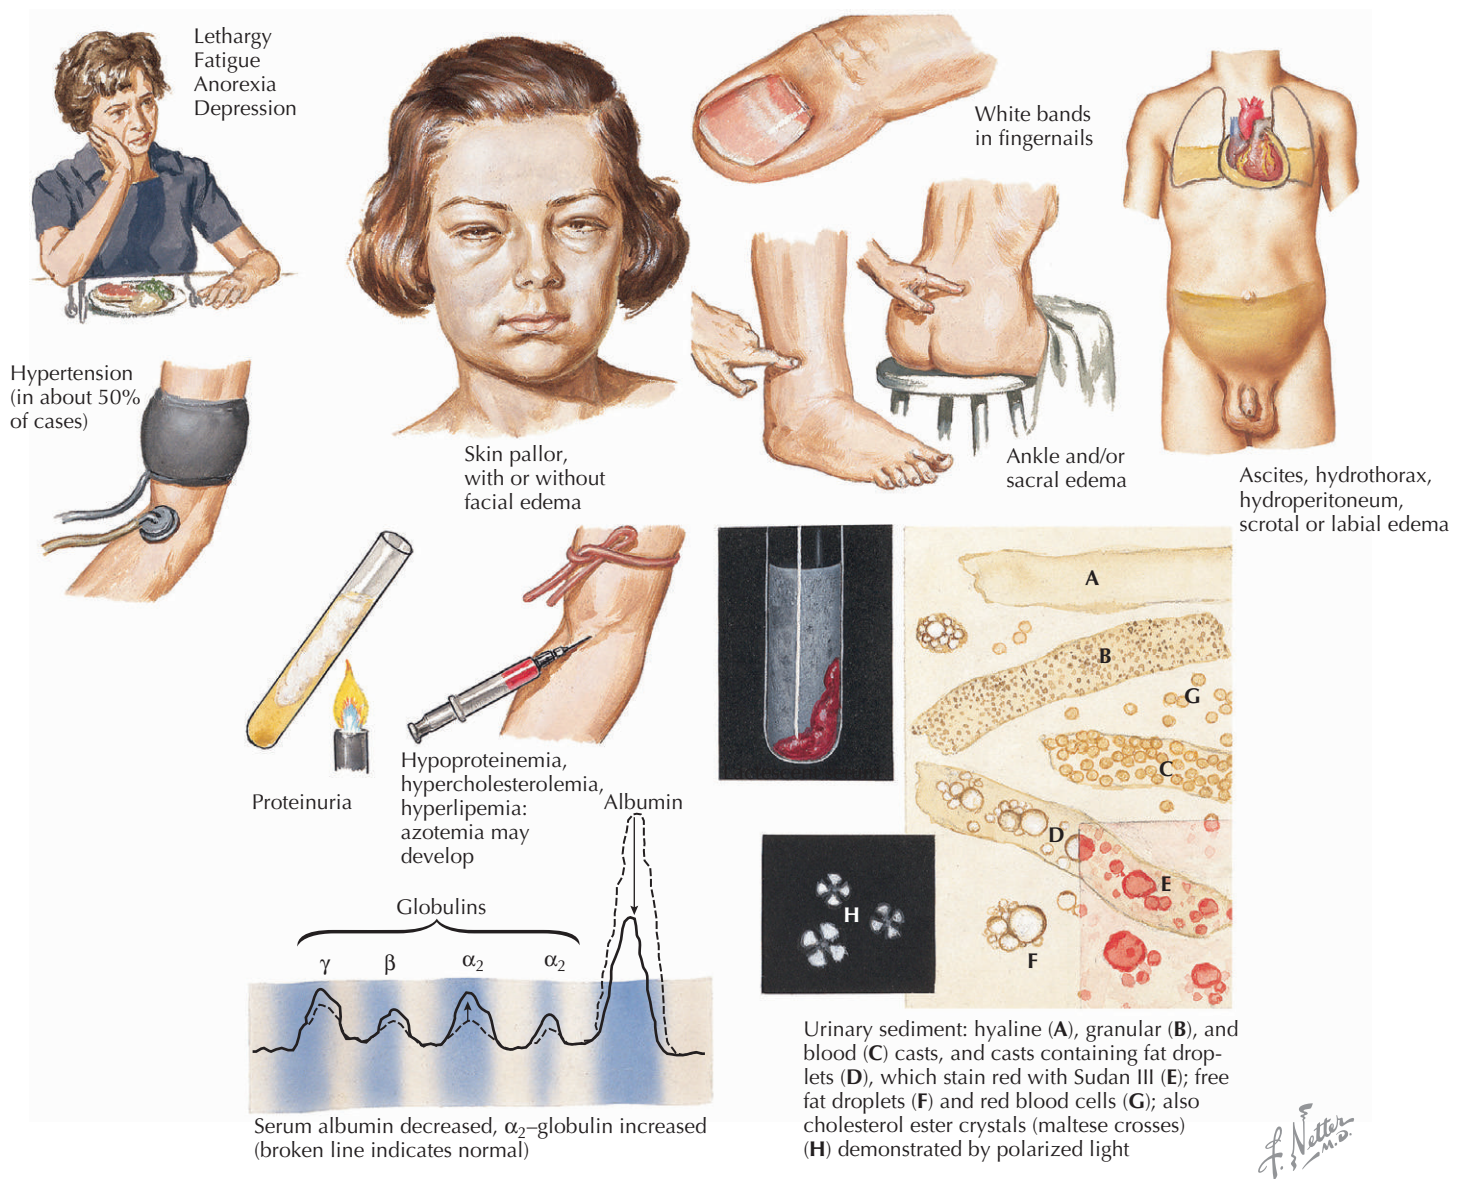

Microscopic hematuria occurs in more than half of FSGS patients, and about one third of patients present with some degree of renal insufficiency or hypertension. The collapsing variant often presents with more severe proteinuria and renal insufficiency and carries a poorer prognosis than the perihilar variant. The glomerular tip lesion variant often presents with rapid onset of edema similar to MCG.

Membranous Glomerulopathy (MGN)

MGN, the most common cause for nephrotic syndrome in white adults, is uncommon in children. The peak incidence

is in the fourth or fifth decade. It occurs as an idiopathic (primary) or secondary disease (see Table 142-1). Infectious and autoimmune causes are more frequent in children, whereas underlying malignancies are found in 20% to 30% of patients older than 60 years. The characteristic histologic abnormality is diffuse global capillary wall thickening associated with subepithelial immune complex deposits, in the absence of significant glomerular hypercellularity (Figure 142-4). By immunofluorescence microscopy, there is diffuse global granular capillary wall staining for immunoglobulin and complement. In idiopathic MGN, the nature of the antigens involved in the subepithelial

Figure 142-3 Clinical and Laboratory Findings that May Be Present in Nephrotic Syndrome.

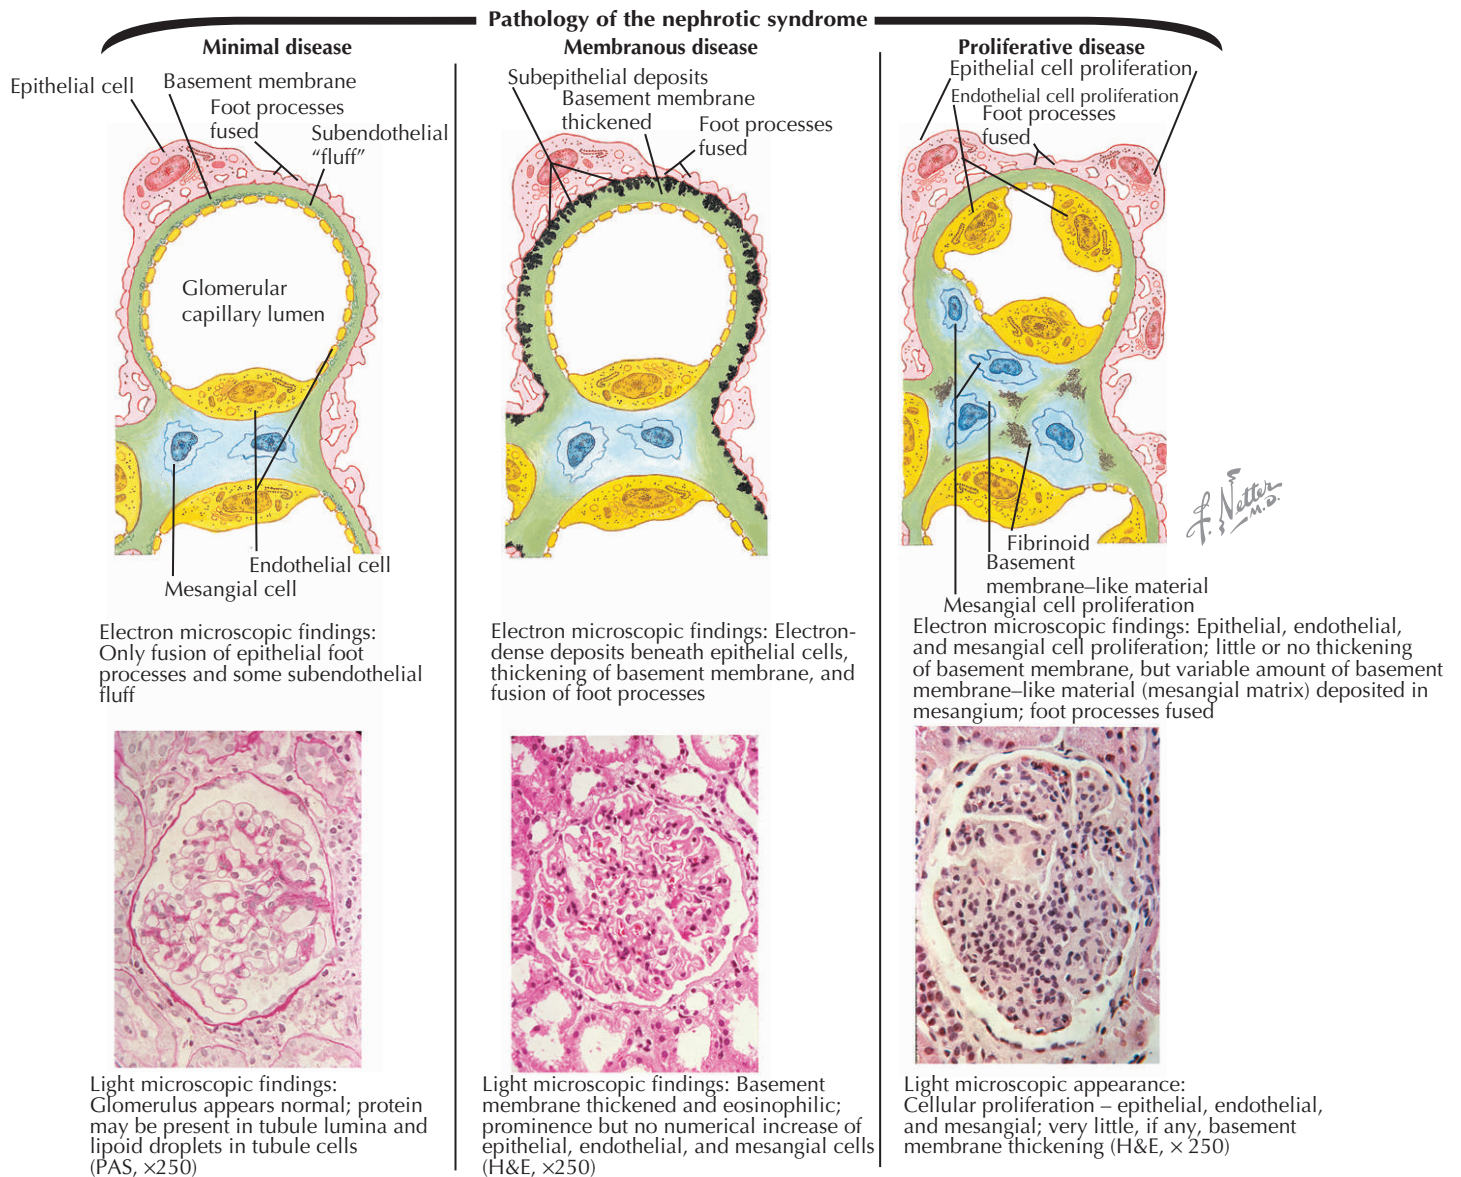

immune complexes is unknown. The immune complexes activate the complement pathway, leading to the formation of the C5b-C9 membrane attack complex and injury to the epithelial cells. Patients usually present with normal or slightly decreased renal function. If progressive renal insufficiency develops, it is usually relatively indolent, resulting in end-stage renal disease in 25% of patients. Twenty-five percent of patients may have a complete spontaneous remission of proteinuria within 5 years.

Membranoproliferative Glomerulonephritis

Type I MPGN is characterized by diffuse global capillary wall thickening and endocapillary hypercellularity with

infiltrating mononuclear leukocytes and neutrophils. Immunofluorescence microscopy reveals a characteristic pattern of peripheral granular to band-like staining for complement, especially C3, and usually immunoglobulins. Electron microscopy demonstrates prominent subendothelial immune complexes with associated subendothelial mesangial interposition. The identity of the antigens involved in the immune complexes is unknown in most cases.

Type II MPGN, also named *dense deposit disease*, is characterized by discontinuous electron-dense bands within glomerular basement membranes. Immunofluorescence microscopy demonstrates intense capillary wall band-like staining for C3, with little or no staining for immunoglobulin. These pathologic findings suggest that the

Figure 142-4 Pathology of the Nephrotic Syndrome.

deposited immune complexes or complement results in the proliferation of mesangial and endothelial cells and the recruitment of inflammatory cells, including neutrophils and monocytes.

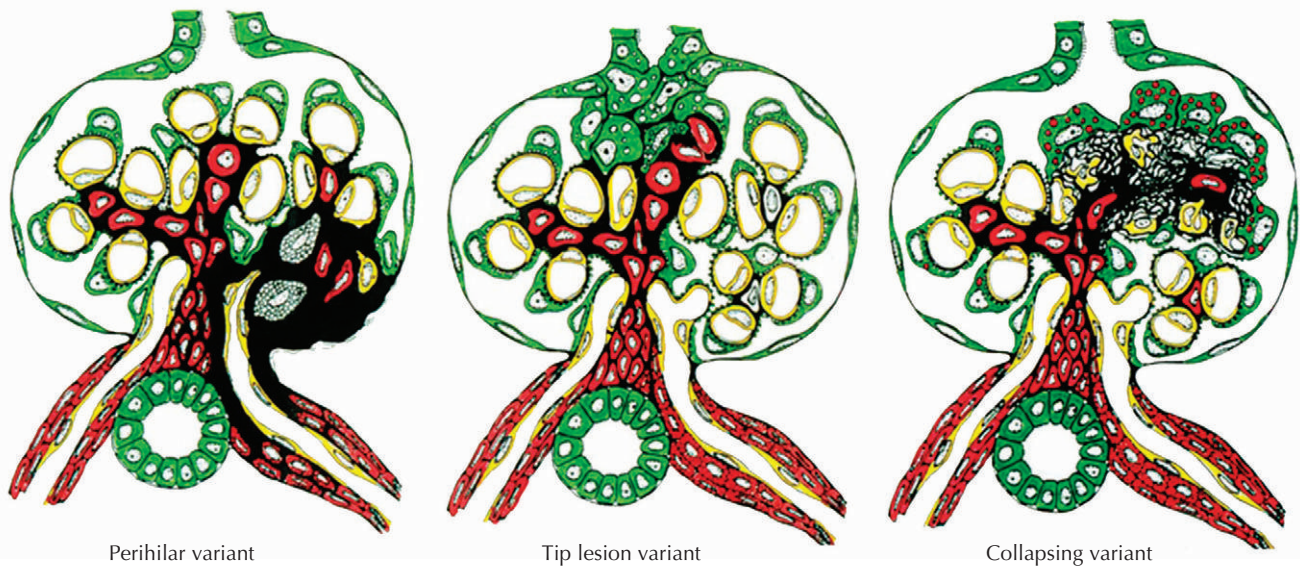

Hypocomplementemia is a frequent feature of all types of MPGN. Complement activation occurs through the classic pathway initiated by immune complex formation in type I MPGN and by the alternate pathway in type II MPGN. C3 nephritic factor, an autoantibody that binds to C3 convertase and prevents its inactivation, is found in more than 60% of patients with MPGN type II.

The clinical features of all forms of MPGN are usually that of the nephrotic syndrome, but about 30% of patients (especially patients with type II) present with an acute nephritic syndrome with hematuria, hypertension, and renal insufficiency. In general, one third of patients with

type I MPGN have a spontaneous remission, one third have progressive disease, and one third have a disease process that will wax and wane but never completely disappear. The prognosis for type II disease is worse than that for type I, and clinical remissions are rare. MPGN is associated with hepatitis C virus infection (and the presence of cryoglobulins), other infections, and autoimmune diseases.

Differential Diagnosis

In the evaluation of patients with proteinuria, nonglomerular causes such as functional or transient proteinuria and orthostatic proteinuria should be excluded. These types of proteinuria rarely exceed 500 mg/day.

Figure 142-5 Histologic Variants of Focal Segmental Glomerulosclerosis.*Courtesy of Charles Jennette, MD.***Diagnostic Approach**

The diagnosis of the nephrotic syndrome begins with quantifying the proteinuria using a 24-hour urine collection measurement of protein and creatinine excretion. The excreted creatinine verifies the adequacy of the collection; the normal 24-hour creatinine excretion is 20 to 25 mg/kg/day for males and 15 to 20 mg/kg/day for females.

Unless an underlying systemic disease is evident, a renal biopsy is required in adults to establish the specific diagnosis of the nephrotic syndrome and assess the severity and acuity of the renal disease. A detailed history and serologic workup that includes testing for hepatitis B and C, HIV, syphilis, antinuclear antibody, cryoglobulins, and hypocomplementemia are essential in evaluating secondary forms of nephrotic syndrome. Based on the clinical presentation, testing for chronic infections such as subacute bacterial endocarditis is necessary. The search for occult malignancies is warranted, especially for older adults.

Management and Therapy**Optimum Treatment**

Treatments aimed at the reduction or elimination of proteinuria is essential to the management of nephrotic syndrome. In most forms of the disease, even a partial reduction in proteinuria is associated with a beneficial effect on outcome. For this reason, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, or both deserve consideration in all adult patients, with upward dosage titration as tolerated (avoiding hypotension and hyperkalemia).

The management of edema requires dietary restriction of sodium intake and the judicious use of diuretics. An

overzealous diuresis is contraindicated because intravascular depletion, hypotension, and acute renal failure may result.

The hyperlipidemia of the nephrotic syndrome predisposes to atherosclerotic cardiovascular disease and may contribute to the progression of renal disease. The treatment of hyperlipidemia is difficult; the most useful agents are the HMG-CoA reductase inhibitors and bile acid sequestrants.

The treatment of secondary forms of nephrotic syndrome depends on the underlying disease process. When associated with the use of medications such as nonsteroidal anti-inflammatory drugs, the proteinuria may resolve with cessation of the offending agent. Similarly, peri-infectious nephrotic syndrome typically responds to treatment of the underlying infection.

For the primary diseases that cause the nephrotic syndrome, various therapies apply depending on the pathologic diagnosis.

Minimal Change Glomerulopathy

MCG is treated primarily with corticosteroids. Proteinuria abates in more than 90% of children within 4 to 6 weeks but may take up to 15 weeks in adults. After the clinical response to initial treatment, as few as 25% of patients have a long-term remission, 25% to 30% have infrequent relapses (one per year or less), and the remainder have frequent relapses, steroid dependence, or steroid resistance. Frequently, relapsing or steroid-dependent nephrotic patients may require the use of cyclophosphamide. Cyclosporine may lead to a partial or complete remission in up to 90% of patients with steroid-resistant MCG, but relapses are frequent once the drug is discontinued.

Focal Segmental Glomerulosclerosis

The treatment of patients with FSGS remains controversial. Although some older studies suggested that only 15% of patients responded to corticosteroids, more recent reports suggest that 40% to 55% of adult patients may attain some form of remission with the prolonged use of high-dose corticosteroids. The data currently available do not take into account a careful assessment of the risk-benefit ratio of such treatments. Cyclosporine therapy has been used with varying degrees of success and is complicated by an elevated rate of relapse.

Membranous Glomerulopathy

Because of the variable course of MGN, the choice of therapy must be individualized based on an assessment of each patient's risks for progressive disease. A pooled analysis of randomized and prospective studies demonstrated a lack of benefit of corticosteroids alone in inducing a remission of the nephrotic syndrome or on renal survival of patients. The current approaches shown to lead to complete or partial resolution of proteinuria include the use of chlorambucil or cyclophosphamide in combination with corticosteroids or cyclosporine. The rate of relapse after discontinuation of cyclosporin is high.

Membranoproliferative Glomerulonephritis

The treatment of patients with type I MPGN is based on the underlying cause of the disease process. In children, corticosteroid therapy improves renal survival. The addition of anticoagulant therapy with dipyridamole, aspirin, and warfarin is of questionable benefit. Unfortunately, evidence for an effective therapy for type II MPGN is currently very limited.

Avoiding Treatment Errors

Whenever glucocorticoids are prescribed in the management of nephrotic syndrome, it is important to implement measures to reduce the risk for osteoporosis with calcium, vitamin D, and when appropriate, bisphosphonate therapy. The optimal dose of cyclosporine in the management of nephrotic syndrome is not well established. To avoid the adverse effects of cyclosporine therapy, it is advisable to initiate treatment at a modest dose (about 2 mg/kg/day in two divided doses) and titrate the dose up while monitoring drug levels and the development of hypertension, hyperlipidemia, and a decrease in glomerular filtration rate (GFR). Several formulations of cyclosporine are currently available. Because of their different pharmacokinetic profiles, switches from one formulation to another may be accompanied by significant changes in drug levels and adverse effects, and are best avoided.

Future Directions

Recent advances in genetics have vastly increased our definition of the molecular anatomy of the glomerular podocytes and the role of these cells in pathogenesis of nephrotic syndrome. Advances in diagnosis and treatment will depend on a better understanding of the precipitating agents (e.g., infections or toxins for secondary forms) and the pathogenetic mechanisms involved. Current research holds the promise of more specifically targeted therapies that will avoid the need for aggressive immunosuppression.

Osteoarthritis

Introduction

Osteoarthritis (OA) is the most common form of arthritis, affecting about 21 million adults in the United States. Symptomatic knee and hip OA is the leading cause of joint replacement surgery, disability, and diminished quality of life among older individuals. The onset of OA before the fifth decade is unusual, and prevalence increases with age. Before the age of 50 years, men with OA outnumber women, but after this age, women are more likely to have OA than men, particularly at the hand and knee.

OA may be the final common pathway of many different disease processes. Although commonly defined radiographically, radiographic change can exist without corresponding symptoms. The causes of pain and disability from OA are complex and include comorbid conditions, muscle weakness, and psychosocial factors, as well as radiographic severity.

Etiology and Pathogenesis

Formerly regarded as primarily a disorder of articular cartilage, OA affects the entire joint, including cartilage, subchondral bone, ligaments, synovium, and surrounding muscle. The earliest pathologic changes are increased hydration and loss of proteoglycan content of cartilage, with subchondral bony thickening or sclerosis. With progression, cartilage frays or fibrillates with the development of focal ulcerations, sometimes leading to exposure of subchondral bone. Growth of bony osteophytes, a hallmark of the condition, occurs at joint margins, and mild synovitis may also ensue. Laxity of ligaments and weakness of surrounding muscle, formerly believed to be the result of disuse, may actually precede some of these disease processes (Figs. 143-1 and 143-2).

The cause of these events is unknown, but risk factors for the occurrence and progression of OA have been identified, although their relative importance may vary for different populations and for different joints. For example, increased body mass index is associated with knee and hand OA, but less strongly with hip OA. Further, these associations may be stronger in women, in whom weight loss has been shown to decrease the risk for developing symptomatic knee OA. The role of hormonal status and bone mineral density in OA is complex, with the incidence of OA in women increasing greatly with the onset of menopause. Genetics may account for as much as 65% of OA. Other risk factors include joint injury, occupational

and sports physical demands, and possibly quadriceps weakness.

Clinical Presentation

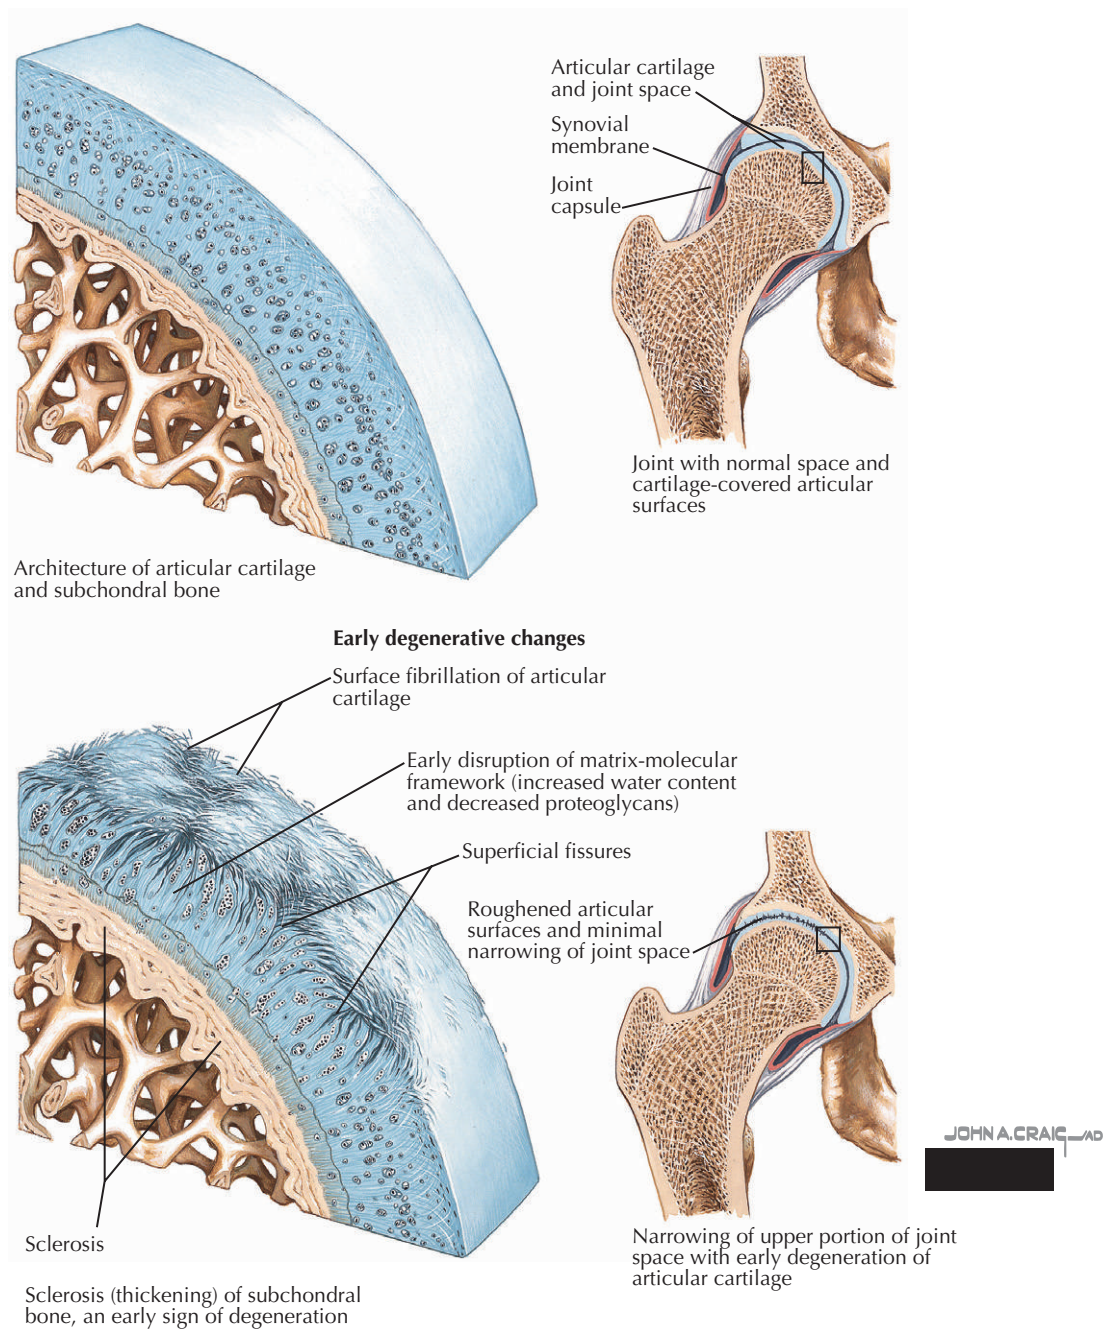

OA has a characteristic joint distribution with symptoms dependent on the joint involved (Fig. 143-3). The most commonly involved joints are the knees, hands, feet, hips, and spine. The usual presenting complaint in OA is pain, initially activity related, with pain at rest occurring with advanced disease. Stiffness after inactivity (gel phenomenon) is prominent, but morning stiffness is of shorter duration and intensity than in systemic inflammatory arthropathies.

On clinical examination, the affected joint demonstrates hard, bony enlargement with or without soft tissue swelling, crepitus, tenderness, and limited range of motion. Synovial fluid, when present, is typically noninflammatory or only mildly inflammatory, and may have associated calcium pyrophosphate crystals.

Clinical Involvement: Knee

Knee OA is characterized by insidious onset of pain, gelling, limited motion, and difficulty with walking, transferring, and stair climbing (Fig. 143-4). Physical examination reveals crepitus and bony enlargement with pain along the medial or lateral joint line with or without effusion. Varus deformity is not uncommon, and flexion deformity

Figure 143-1 Normal Joint and Articular Surface; Early Degenerative Changes.

and joint instability are signs of severity. Quadriceps weakness may occur early and may contribute to progression.

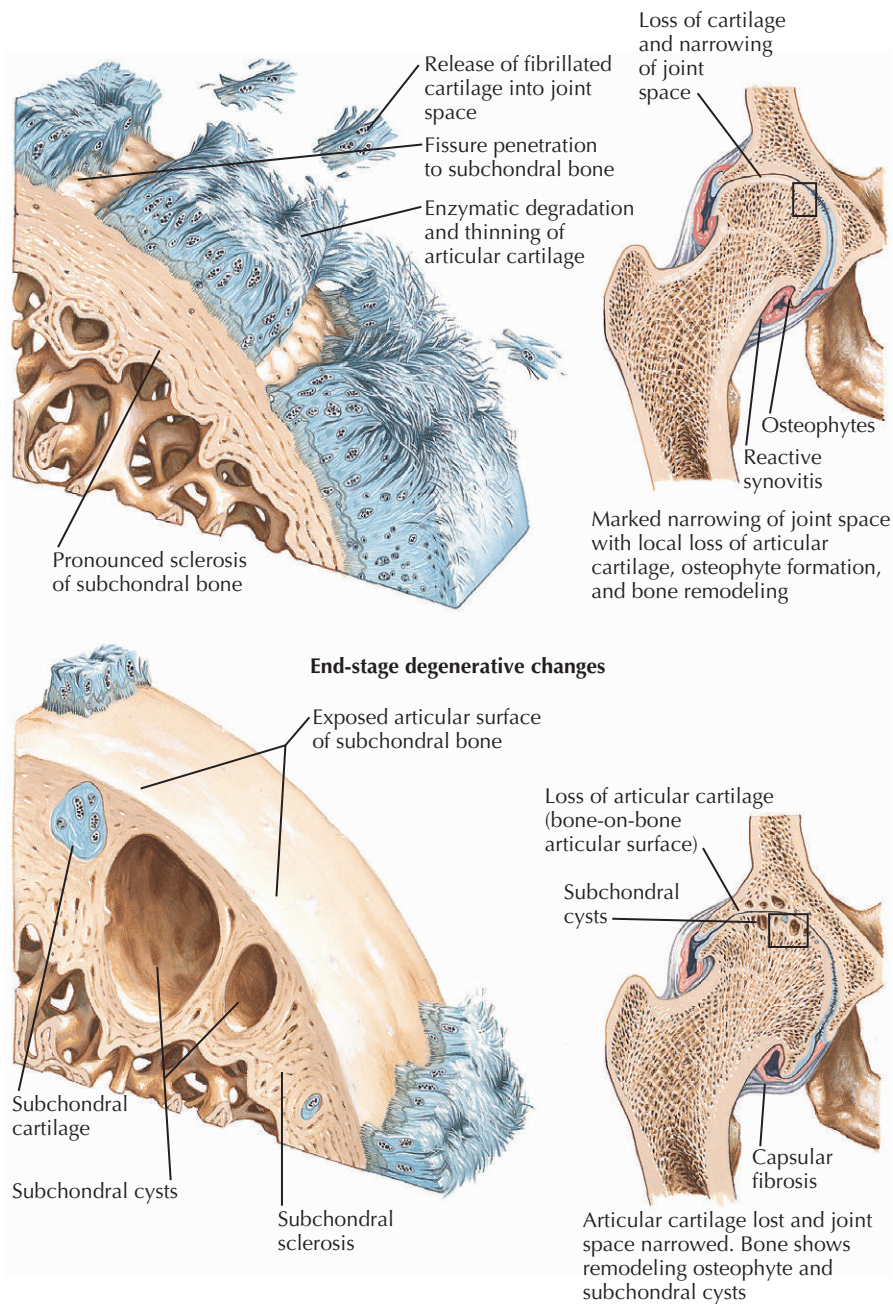

Clinical Involvement: Hip

Hip OA usually presents with groin pain, but pain can be felt in the thigh, buttock, or knee. Pain and limitation of motion in walking, bending, and transfer can be severe. On examination, painful limitation of internal rotation can be

an early sign. Deformity and limitation of hip flexion indicate advanced disease (Fig. 143-5).

Clinical Involvement: Hand

Bony enlargement of the distal interphalangeal joints (Heberden’s nodes) and proximal interphalangeal joints (Bouchard’s nodes) can begin with an acute inflammatory phase, but the joints may become less symptomatic after

Figure 143-2 Advanced and End-Stage Degenerative Changes.

the initial inflammation has subsided. A subset of patients may have erosive osteoarthritis of hand joints, which presents as episodes of inflammation, pain, and swelling. Involvement of the first carpometacarpal joint can be associated with significant pain and limited function (Fig. 143-6). Bilateral involvement of multiple joints within and across joint groups is frequent. Metacarpophalangeal joints are affected more commonly than previously recognized; nonetheless, prominent involvement of these joints in the OA process should prompt consideration of secondary causes (see “Differential Diagnosis”).

Clinical Involvement: Spine

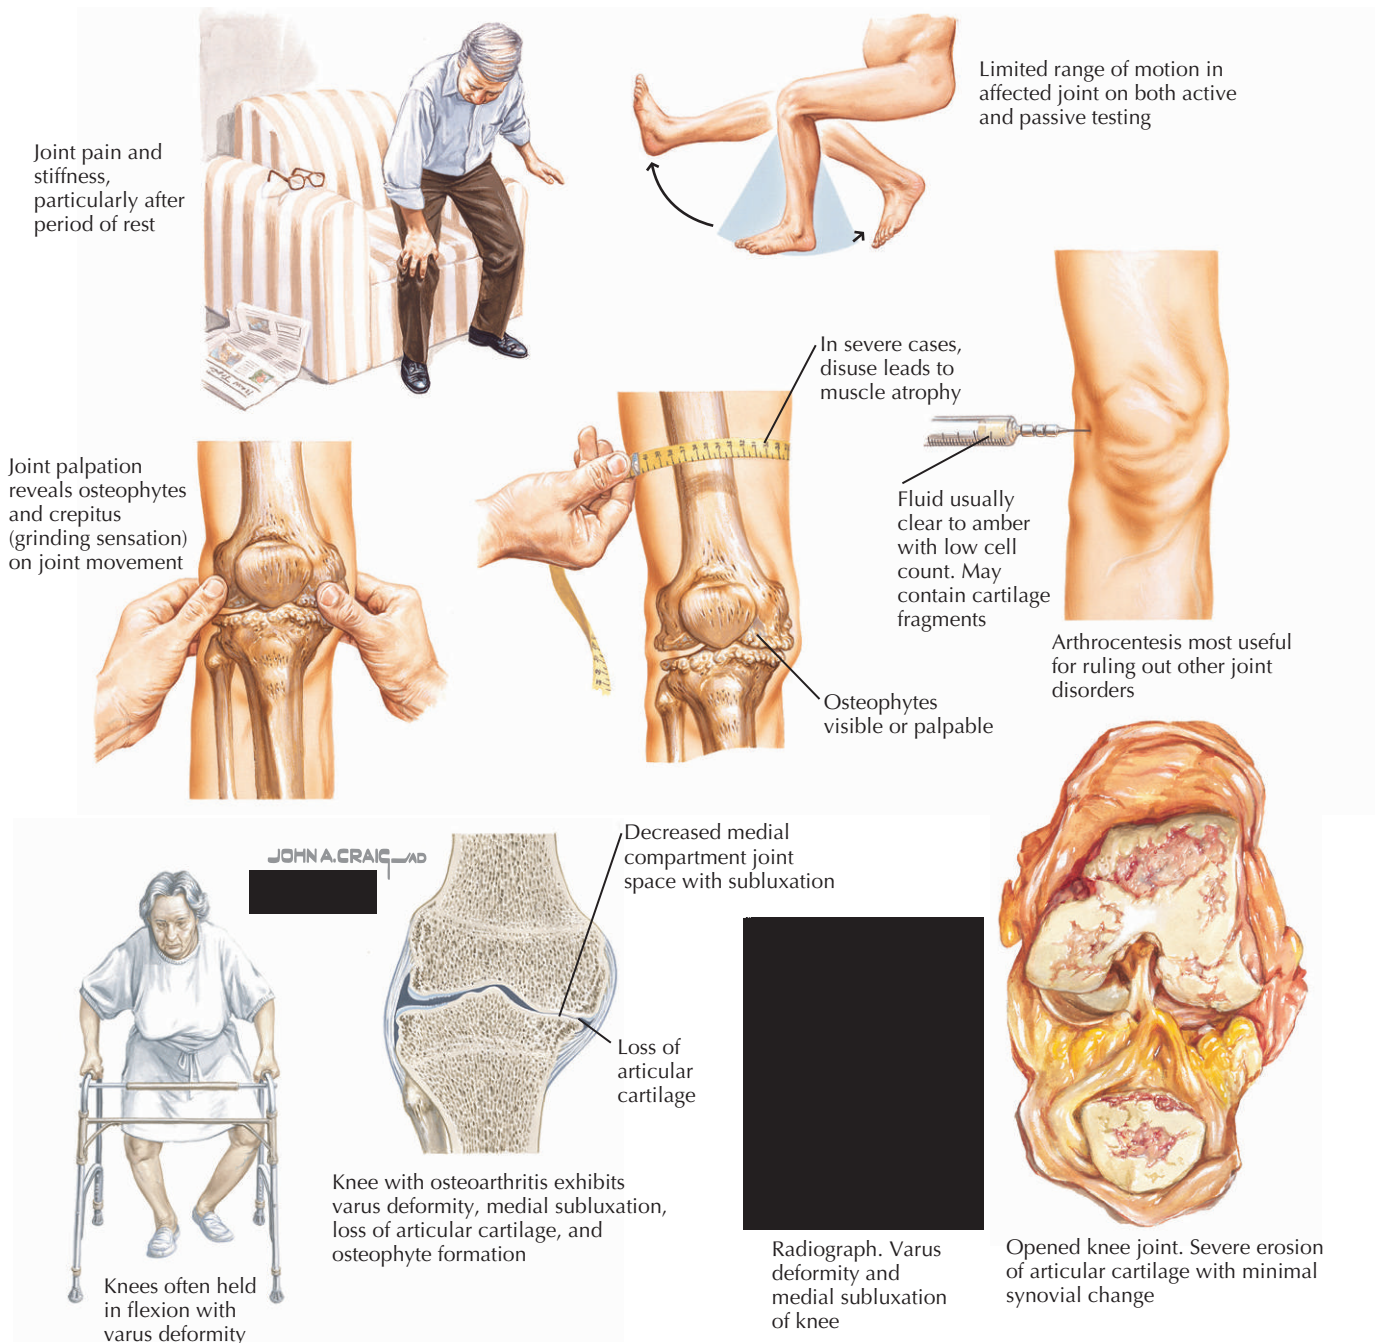

Radiographic OA in the cervical and lumbar spine, frequently with degenerative disk disease, is very common in those older than 45 years, but may not be associated with symptoms. Clinical symptoms in the cervical spine can include pain in the neck and occiput, with radiation down the arm, weakness, or paresthesia occurring from compression of cervical nerves from osteophytic encroachment on intervertebral foramina. An analogous process can occur in the lower thoracic and lumbosacral spine.

65-74	74.5	44.2	13.8	3.5

Figure 143-4 Clinical Findings.

Differential Diagnosis

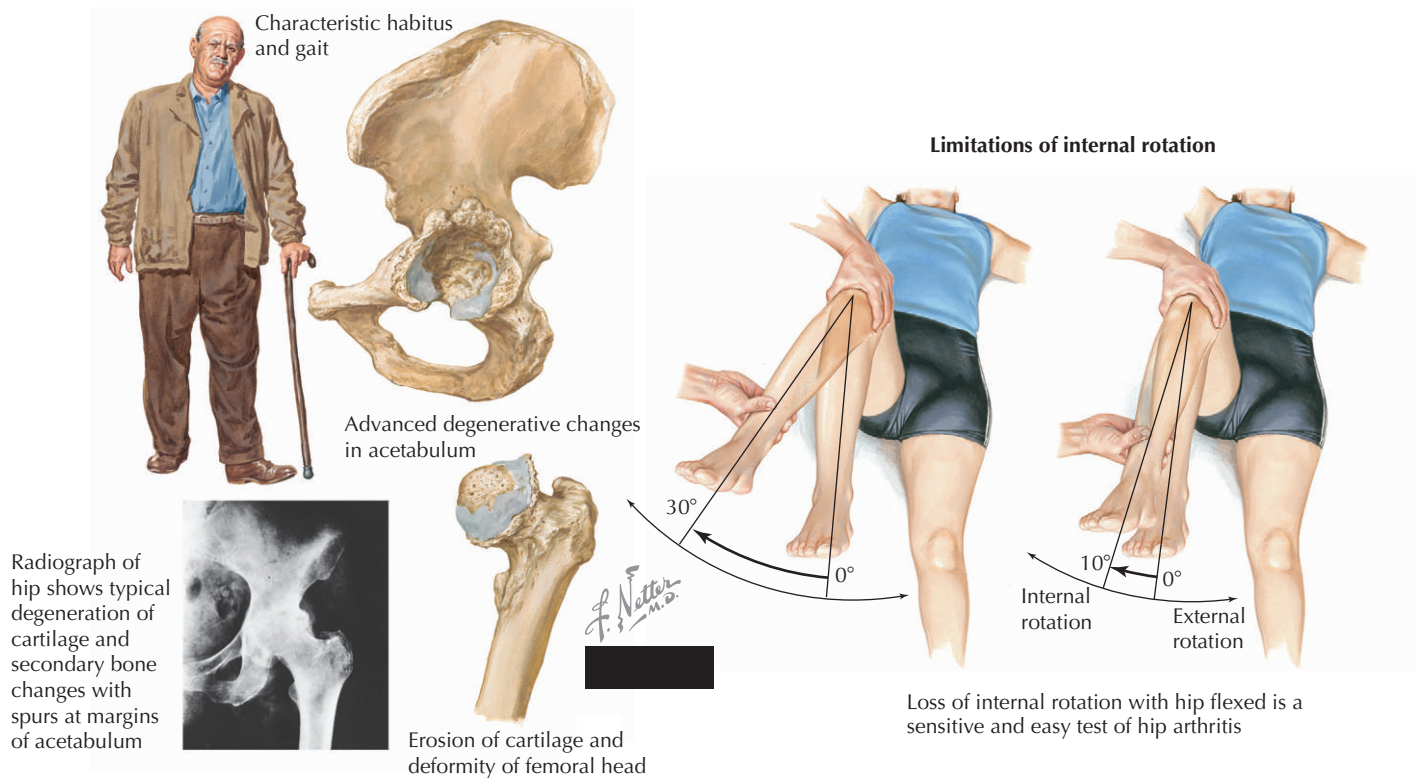

General

Diagnosis of OA is usually made clinically, but other disorders need to be considered, depending on the joints involved. OA in individuals younger than 45 years frequently has an antecedent cause, such as hereditary conditions, prior trauma, or congenital or developmental conditions such as Legg-Perthes disease. OA typically has an insidious onset; an acute onset should prompt investigation for crystal arthropathies, infection, or trauma. OA

does not have systemic inflammatory features nor prolonged morning stiffness. If these are present, systemic inflammatory arthropathies such as rheumatoid arthritis, systemic lupus erythematosus, malignancy, or infection should be considered.

Hip Osteoarthritis

Patients may mistakenly refer to the lumbar spine, pelvis, or greater trochanter as the “hip.” The differential diagnosis of hip OA thus includes fracture, avascular necrosis,

Figure 143-5 Hip Joint Involvement in Osteoarthritis.

inflammatory arthropathies, and pathologies involving the lumbar spine and pelvis or surrounding structures. Trochanteric bursitis is characterized by discomfort in the hip region, particularly with stair climbing and lying on the offending side. Palpation over the greater trochanter reproduces the patient's pain, and groin pain and painful limitation of hip rotation are absent. Low back pain with radiation, weakness, numbness, and paresthesia help differentiate hip OA from lumbar spine disorders.

Hip fracture usually presents acutely after trauma, but in the frail and osteoporotic patient, it can occur without such history. Clinical suspicion should be high in such patients, particularly if severe pain on hip motion or a posture of hip flexion and external rotation are present. Avascular necrosis of the hip should be considered in the patient with sickle cell disease, diabetes mellitus, a history of corticosteroid use, or alcohol.

Hand Osteoarthritis

Because hand OA is common, especially in women, hand complaints should be evaluated with the purpose of eliminating an accompanying, superimposed inflammatory condition. Involvement of the metacarpophalangeal joints with significant soft tissue swelling should suggest an

inflammatory arthropathy, such as rheumatoid arthritis or calcium pyrophosphate dihydrate deposition. Involvement of the metacarpophalangeal joints with bony enlargement can occur in hand OA, but such findings may also indicate other disorders, such as hypothyroidism, hemochromatosis, hyperparathyroidism, or calcium pyrophosphate dihydrate deposition.

Foot Osteoarthritis

Involvement of the first metatarsophalangeal joint in the foot may mimic gout if sufficient erythema and swelling exist. Involvement of multiple metatarsophalangeal joints may indicate inflammatory arthropathy, such as rheumatoid arthritis, particularly if accompanied by prolonged morning stiffness and involvement of the small joints of the hands.

Diagnostic Approach

There are no definitive tests for OA, and the diagnosis remains a clinical one. A thorough history and physical to elicit the presence of other conditions should be performed. Unless clinical suspicion exists for a systemic inflammatory arthropathy or systemic autoimmune condi-

Figure 143-6 Hand Involvement in Osteoarthritis.

tions, there is little purpose in measuring rheumatoid factor, antinuclear antibodies, or other serologic tests. Assessment of complete blood count, electrolytes with glucose and creatinine, and liver function tests should be checked before beginning pharmacologic therapy, especially in the older individual with comorbid medical conditions. In cases of atypical appearance of the hands, particularly with involvement of the metacarpophalangeal joints, evaluation for hypothyroidism and hemochromatosis may be warranted.

Radiographs typically show osteophytes, joint space narrowing, sclerosis of subchondral bone, cysts, and joint deformity. They can confirm a diagnosis and exclude others, particularly in those cases with an unclear clinical picture or when alternate diagnoses, such as inflammatory

arthropathy, hip fracture, avascular necrosis, infection, or malignancy, may exist. In the erosive variant of OA, radiographs may show central erosion and “gull deformity” of the interphalangeal joints. Radionuclide scans, magnetic resonance imaging, and other modalities may be useful in certain situations, but are not routinely needed in clinical practice.

Management and Therapy

Optimum Therapy

There is no cure for OA, nor are there pharmacologic agents available at this time that definitively affect the underlying pathologic process. Optimal medical management

consists of nonpharmacologic modalities and pharmacologic agents to relieve pain and improve function and health-related quality of life, with the goal of avoiding complications of therapy. In more severe cases, surgical intervention, particularly joint replacement, can be effective. Recently, similar guidelines for the treatment of hip and knee osteoarthritis were published by the American College of Rheumatology and the European League against Rheumatism.

Nonpharmacologic Therapy

Physical and occupational therapy should be mainstays of the treatment approach of most patients with OA. Assessment of gait disturbances, leg length discrepancy, and functional and other difficulties is critical in developing an individualized treatment plan. Ambulatory aids, orthotics, splints, and other assistive devices can alleviate pain and improve function by correcting malalignment, distributing weight more evenly to decrease stress on a particular joint, and altering abnormal joint biomechanics. Instruction in joint protection and energy saving techniques, aerobic exercise, muscle strengthening, and range-of-motion exercises can help the patient regain, maintain, or improve function. Weight loss should be prescribed for overweight OA patients and can be more effective in combination with exercise in reducing pain.

Pharmacologic Therapy

If the above measures prove insufficient, pharmacologic therapy (oral, topical and intra-articular) can be considered.

Acetaminophen and nonopioid analgesics, such as tramadol, can be helpful in the patient with mild to moderate or intermittent pain. Nonsteroidal anti-inflammatory drugs (NSAIDs) can be used in those in whom acetaminophen is ineffective. However, the potential for serious side effects, including gastrointestinal ulceration and bleeding, exacerbation of hypertension, and fluid retention, particularly in older individuals with comorbidities, limit their use. Although selective cyclooxygenase-2 inhibitors provided analgesia similar to traditional NSAIDs and were less likely to be associated with gastrointestinal ulceration and bleeding, concerns about their renal and cardiovascular safety have restricted their availability and utilization. Opioids should be reserved for those with severe pain that cannot be controlled otherwise.

The use of glucosamine and chondroitin, nutraceuticals that have demonstrated possible symptom- and disease-modifying properties in OA, remains popular but controversial. A recent clinical trial showed that the combination of glucosamine and chondroitin may be effective in relieving moderate to severe pain from knee osteoarthritis.

Other studies have had mixed results. Topical methylsalicylate, capsaicin, and NSAIDs can be useful as adjunctive or sole therapy in some patients.

Intra-articular corticosteroid therapy can relieve pain and inflammation in patients with OA. The need for repeated corticosteroid injections should prompt reevaluation of the medical regimen and consideration of surgical intervention. Intra-articular hyaluronan can be administered in a series of injections for knee OA; although no definite disease modification has been shown for such agents, there may be a pain-relieving effect that can last several months.

With improved imaging methodology to measure cartilage loss, several agents have been studied recently to evaluate their effect on OA disease progression. Two trials have suggested that glucosamine sulfate may be associated with less joint space narrowing than placebo in knee OA. Other agents aimed at inhibition of catabolic processes in the joint and bone turnover, including diacerein, doxycycline, and bisphosphonates, have been or are currently under evaluation for their potential to modify the disease process. Future studies will reveal their significance and usefulness in clinical practice.

Avoiding Treatment Errors

Treatment errors in OA include (1) failure to recognize superimposed inflammatory arthritis, such as rheumatoid arthritis or gout, which would prompt different therapy; (2) inadequate attention to effective nonpharmacologic interventions such as weight loss, exercise, lifestyle modification, and biomechanical and assistive devices; (3) use of medications with a poor safety profile in susceptible individuals; and (4) failure to recognize potential drug interactions between OA therapy and concomitant medications. For example, the use of NSAIDs in older individuals and in those with cardiac, hepatic, or renal disease can be particularly problematic. Because of the risk for gastrointestinal ulceration with the use of NSAIDs, prophylactic therapy for ulcers should be considered as concomitant therapy in many patients. Use of any pharmaceutical should prompt careful periodic evaluation for side effects such as renal, electrolyte, hepatic, and gastrointestinal toxicity.

Future Directions

Therapy in OA at this time modifies symptoms without altering the underlying disease process, which may have progressed considerably by the time symptoms occur. The goals of future research are to develop better means to identify individuals at increased risk for OA for early intervention and to develop interventions to influence the disease process. Avenues for exploration in this regard include genetics, advanced imaging such as magnetic

resonance imaging, and biomarkers in serum, urine, and synovial fluid. For those in whom OA has already progressed, future research also endeavors to improve techniques and materials for joint replacement and to develop new ways to grow, modify, and implant cartilage into diseased joints.

The authors provide 10 key recommendations for the treatment of hip OA, based on evidence from literature and expert opinion.

Low Back Pain in Adults

Introduction

Low back pain is a common and remitting ailment for most adults. About 80% of adults have an episode sufficiently severe that they cannot do their usual daily activities for at least 1 day at some time in their lives. About 8% of individuals have an episode in a given year, and about 3% to 4% have the very disabling syndrome of chronic low back pain. Most patients with low back pain can be treated at the primary care level.

Etiology and Pathogenesis

Adult vertebrae are complex anatomic and biomechanical structures (Fig. 144-1). Usually, these structures function extraordinarily well under various loads, postures, and torque, and after mild to moderate trauma. Most back pain occurs in the lumbar area, and 95% of intervertebral disk problems occur at the L-2 through L-5 areas.

The pain generator for most cases of back pain is unclear. The annulus fibrosus of the intervertebral disk is richly innervated, and many cases of back pain are undoubtedly diskogenic. Facet joints, ligaments, and muscles can all cause chronic back pain. Leg pain is more likely to be related to pressure on the intervertebral disk, but can occur as a result of bone spurs or pressure on the nerve roots related to spinal stenosis. Sciatica is generally defined as radiation of pain to the level of the knee or below. Classic diskogenic pain is more prominent in the leg than in the back. In spinal stenosis, a variation of nerve root impingement, the patient's thigh pain becomes worse on walking or prolonged standing (pseudoclaudication). The pathogenesis of pseudoclaudication appears to relate to a congenitally narrow spinal canal combined with bony overgrowth around the facet joints.

More than 85% of cases of acute back pain are not related to sciatica, spinal stenosis, or serious causes such as malignancy or abdominal aortic aneurysm. Cases of non-specific chronic back pain are usually the most difficult to manage and require a great deal of skill in both communicating with patients and coordinating care.

Clinical Presentation

Because most patients have a relatively nonspecific diagnosis, it is important to identify the minority of patients

who do have a specific cause of their back pain. Patients with acute back pain generally present after 2 weeks of symptoms. The onset of the pain is usually not substantial trauma; most often, it occurs with activities of daily living such as lifting, bending, or twisting. Often, patients are fearful that the cause of their back pain is serious and will result in chronic pain or permanent disability. Eliciting these fears by asking, "What do you think is causing your back pain?" can lead to productive reassurance.

Differential Diagnosis

The history should include a search for red-flag factors, described below, relating to the patient's back pain in order to make the correct diagnosis and rule out important, potentially correctable, causes of back pain.

Cauda Equina Syndrome

In the cauda equina syndrome, the acute onset of urinary retention or fecal incontinence, loss of anal sphincter tone, and perianal anesthesia are typical and may occur with bilateral leg weakness. Immediate magnetic resonance imaging (MRI) and referral to an orthopedic surgeon or neurosurgeon is indicated. The etiology is most commonly related to a metastatic malignancy and rarely to a large central disk herniation.

Infectious Diskitis and Osteomyelitis

Back pain associated with fever, sweats, and weight loss may occur with infectious diskitis or osteomyelitis. These patients generally have an elevated erythrocyte sedimenta-

Figure 144-1 Lumbosacral Spine and Ligaments.

tion rate and may be immunocompromised or have a nidus of infection, such as a chronic urinary tract infection. Plain film radiographs have only about a 70% sensitivity in the early phases of diskitis.

Metastatic Cancer

Progressive and unrelenting back pain can be a sign of prostate, breast, or lung cancer. Multiple myeloma may also initially present as back pain. A history of cancer other than skin cancer in the previous 5 to 10 years requires plain film radiographs, measurement of erythrocyte sedimentation rate, or advanced imaging such as bone scan, MRI, or computed tomography (CT) scan.

Trauma

Trauma, especially in a patient with or at risk for osteoporosis, should raise concern regarding fracture.

Ankylosing Spondylitis and Other Syndromes

Pain made worse with morning stiffness in younger men and relieved by exercise may be indicative of ankylosing spondylitis, an uncommon but important cause of back pain.

Back pain may occasionally present as referred pain from an abdominal or retroperitoneal source. This may

include the burning pain of early shingles (herpes zoster), back pain secondary to an abdominal aortic aneurysm, or pyelonephritis.

The red-flag syndromes described previously are very important to recognize because some causes of back pain may lead to an irreversible neurologic deficit. The chance of a patient presenting with back pain having one of these serious red-flag problems is low in an ambulatory practice but is higher in emergency room settings or tertiary care centers.

A brief evaluation for yellow flags is also indicated. These social factors include litigation through personal injury or worker compensation, intense preoccupation with the pain, or anger toward the employer, all of which may indicate a worse prognosis from back pain. The presence of one of these factors does not indicate that the patient is malingering. The physician's perspective should

be attuned to encouraging improved functioning and psychosocial support.

Diagnostic Approach

The physical examination can be brief in most cases. Examination of the abdomen may pick up bruits or pulsating masses in cases of abdominal aneurysm; this is especially important in males older than 50 years with a smoking history and other signs of atherosclerosis. Palpation of the back can sometimes find tender areas or trigger points. Usually, these findings are quite nonspecific; however, it is important to touch the part of the patient that hurts in order to assure the patient that he or she is receiving a thorough evaluation. Examination of the knee and ankle jerk reflexes can pick up nerve root impingement (Figs. 144-2, 144-3, and 144-4). Testing of dorsiflexion foot

 <p>L5-S1 disk; 1st sacral nerve root</p>	 <p>Over sacroiliac joint, hip, posterolateral thigh and leg to heel</p>	 <p>Back of calf; lateral heel, foot and toe</p>	 <p>Plantar flexion of foot and great toe may be affected; difficulty walking on toes</p>	 <p>Gastrocnemius and soleus</p>	 <p>Ankle jerk diminished or absent</p>
 <p>Massive midline protrusion Coccygeal</p>	 <p>Lower back, thighs, legs, and/or perineum depending on level of lesion; may be bilateral</p>	 <p>Thighs, legs, feet, and/or perineum; variable; may be bilateral</p>	 <p>Variable paralysis or paresis of legs and/or bowel and bladder incontinence</p>	 <p>May be extensive</p>	 <p>Ankle jerk diminished or absent</p>

strength can assess the L-4 to L-5 nerve root. The ankle-jerk reflex assesses L-5 to S-1. More than 90% of nerve root impingements occur at one of these two levels. The dorsum of the foot may have hypoesthesia in impingement of the L-4 to L-5 disk space.

The straight-leg-raising sign is relatively specific but not very sensitive for nerve root impingement. For this maneuver, the leg is elevated passively, and when positive, the patient has pain on the affected side that radiates to the level of the knee or below.

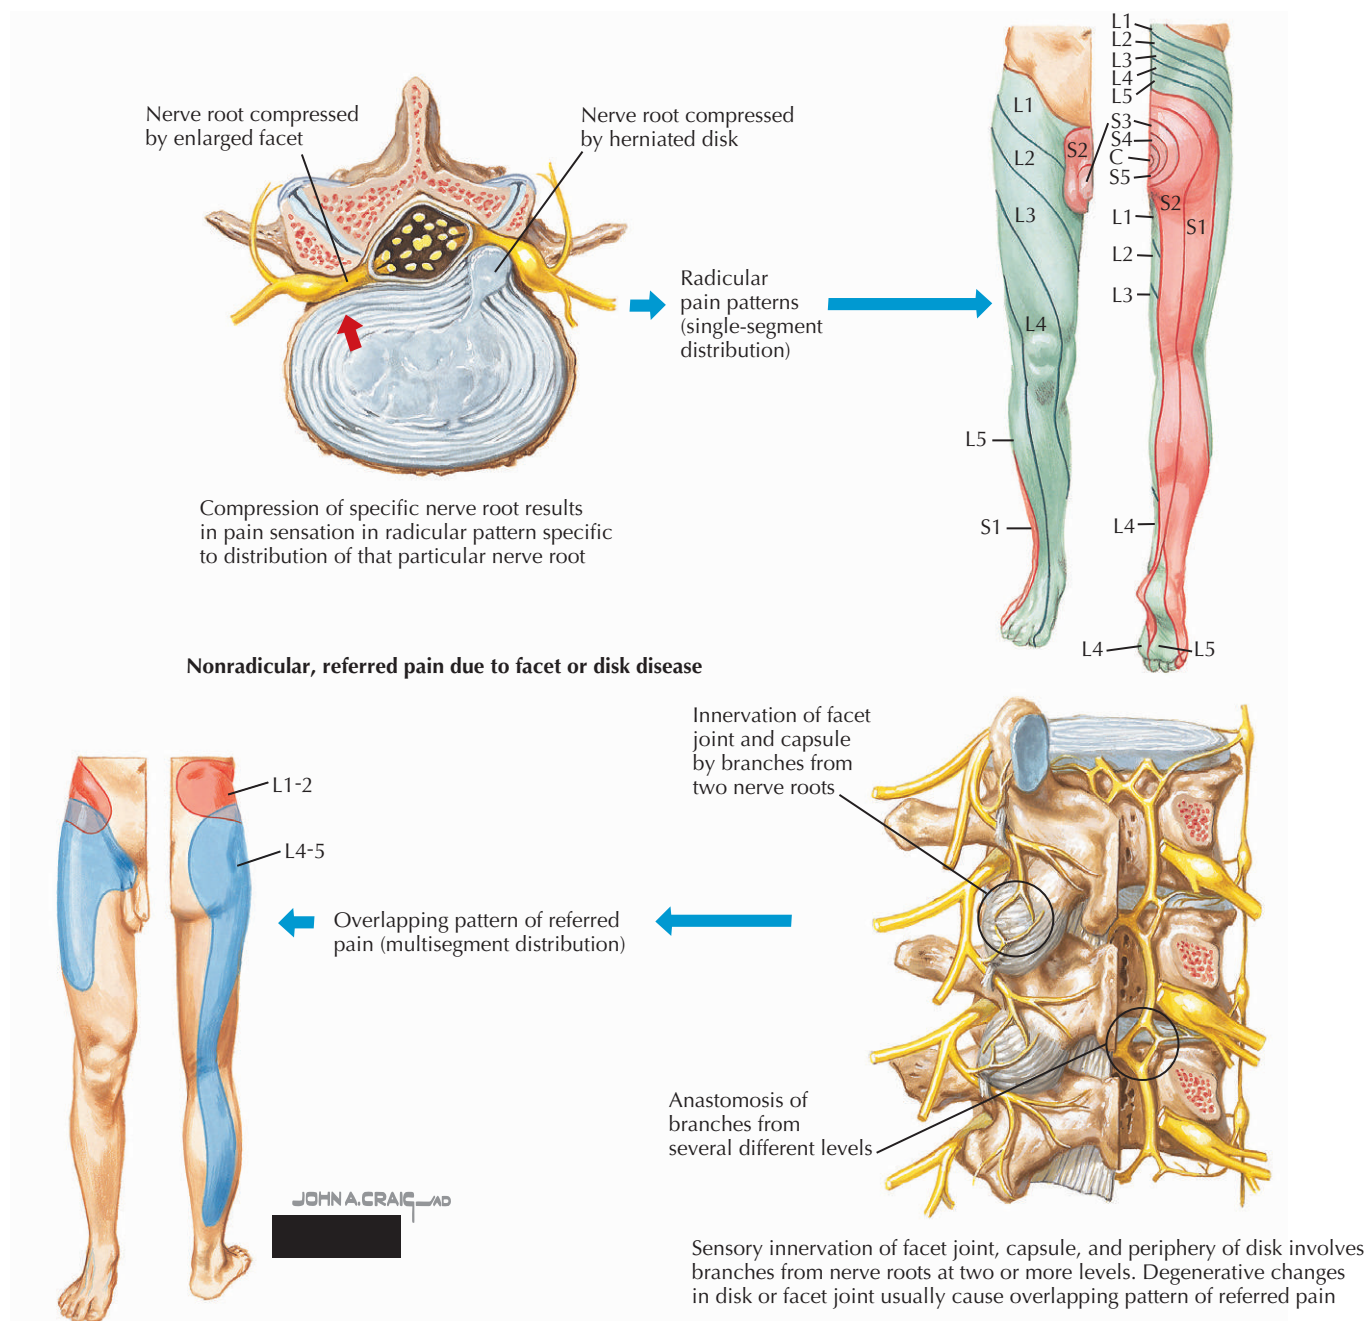

Rectal examination is indicated when there is concern about carcinoma of the prostate gland (prolonged pain,

older men) or potential cauda equina syndrome (bilateral leg weakness, incontinence, or retention of urine or stool).

Exaggerated pain behavior and reproduction of pain by pressing on the top of the head (axial loading, which transmits essentially zero force to the lumbar spine) are associated with a strong psychological component to pain. These patients tend to do poorly with surgery and require greater attention to psychosocial issues.

Most patients do not require immediate imaging studies. Lumbar spine radiographs are indicated when there is concern regarding trauma, in the presence of red flags, or

Figure 144-4 Pain Patterns in Lumbar Disease.

if the patient has not attained functional recovery within 4 to 6 weeks. There is no consensus regarding indications for advanced techniques such as CT or MRI. Such tests should be urgently performed when there is concern regarding metastasis or infection. In general, such advanced imaging techniques are indicated only when a red flag is present or an operation is under active consideration. Although these tests are highly sensitive, nonspecific findings are common, herniated disks may be found in 20% to 30% of asymptomatic individuals. MRI evidence of spinal

stenosis has been demonstrated in more than 20% of individuals older than 60 years without symptoms.

Management and Therapy

When a serious cause of low back pain is found (metastatic malignancy, diskitis), specific treatment is urgently indicated. However, this is unusual, and most cases of non-emergent back pain can be divided into three broad

categories: nonspecific back pain, nerve root impingement related to herniated disk, and spinal stenosis.

Nonspecific Low Back Pain

More than 80% of patients present with nonspecific or mechanical low back pain. This lack of specificity is often frustrating for both doctors and patients. It is important to provide patients with an explanatory model of what is going on with their back so that they can live with their symptoms and know that, given the natural history of back pain, they will likely improve. Patients often relate well to phrases such as “it’s like a flu in your back” or “strained ligaments” because these common syndromes have a relatively benign prognosis.

Ninety-five percent of patients with nonspecific acute back pain (less than 2 months of symptoms) return to their usual daily functioning within 3 months of conservative treatment.

Optimum Treatment

Reassurance, appropriate analgesia, and advice to resume usual daily activities as quickly as possible are the most effective treatments. Bed rest for more than 48 hours appears to be counterproductive. Acetaminophen, nonsteroidal anti-inflammatory drugs, and, possibly, a muscle relaxant provide adequate symptom relief for most patients. Those with very severe initial symptoms may benefit from a short course of a narcotic analgesic. It is important to encourage patients to return to work as quickly as possible because prolonged time off work appears to worsen rather than improve back-related disability. A note or conversation with a patient’s supervisor regarding avoiding heavy lifting or awkward postures for a designated period can be helpful and is often indicated. Patients often benefit from a telephone call or return office visit within 2 weeks. If the patient is off work after 2 weeks, more specific treatment such as a physical therapy referral may be in order. Spinal manipulative therapy may be performed by doctors of chiropractic medicine, osteopathic physicians, and some physical therapists. Randomized trials of spinal manipulation have yielded somewhat conflicting results; more recent studies have demonstrated marginal, if any, benefit when compared with conventional conservative medical therapy.

Herniated Lumbar Disk

Diagnostic clues of a herniated disk include true sciatica and presence of suggestive neurologic findings (Fig. 144-5). In the absence of red flags, a supportive approach is indicated. Ninety percent of patients with sciatica improve with conservative therapy over a 3-month period.

Optimum Treatment

Some patients benefit from a brief (1 to 2 days) period of bed rest. Patients often are quite fearful of resuming usual activities, and a physical therapy referral may be helpful to coach the patient to maintain activities such as walking, even when uncomfortable. If a patient has persistent predominant leg pain as the primary back symptom, especially if combined with asymmetrical reflexes or mild weakness in dorsiflexion of the foot, limited evidence suggests that the patient may benefit from an advanced imaging technique and consideration of operative microdiscectomy.

Spinal Stenosis

Cohort studies have demonstrated that, over several years, one third of patients stay the same, and one third worsen. Some patients become severely impaired with nearly constant pain and limited ambulation.

Optimum Treatment

Analgesics and physical therapy may offer only modest benefit. Because walking is often limited by the nature of the disease, swimming or stationary bicycling may be helpful. Surgical decompression appears to offer substantial relief of leg symptoms and improved walking distance, although most patients continue to have back pain and some limitation in walking distance. Older age leads to greater risk for cardiac complications at the time of surgery.

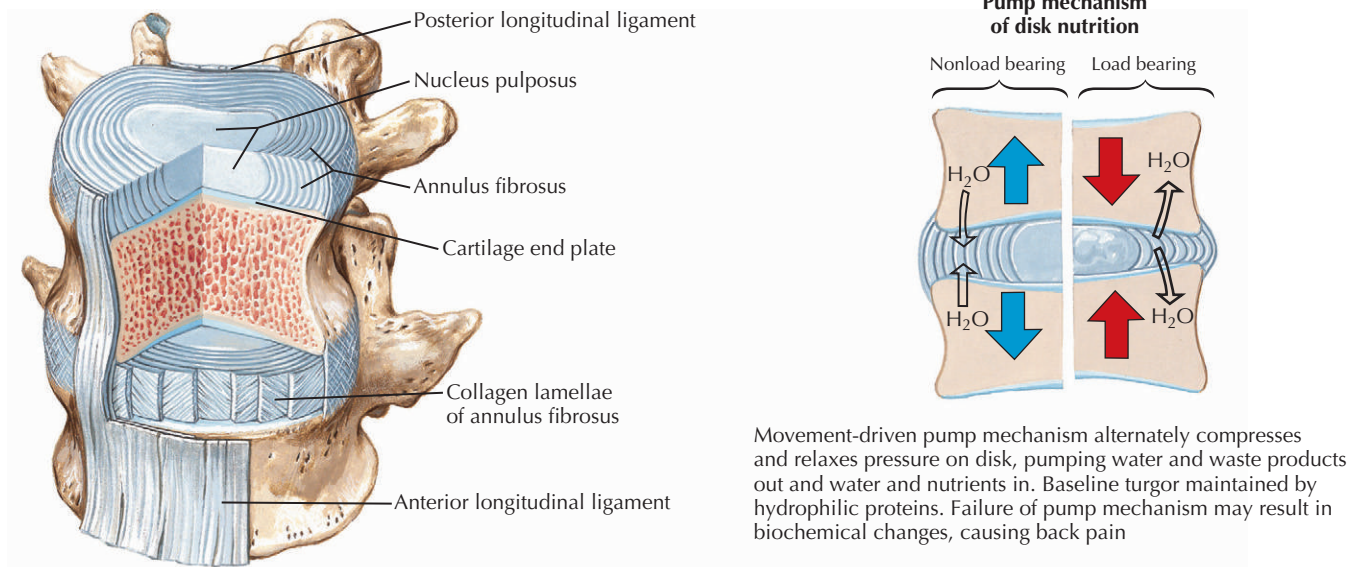

Chronic Back Pain

Many patients with chronic low back pain have no radiculopathy or anatomic abnormalities that clearly explain their symptoms. Patients with 2 months of continuous symptoms have more than a 50% chance of having significant back symptoms 1 to 2 years later. No single therapy appears to be beneficial for their symptoms. Lumbar spinal fusion may provide some relief, but it is a significantly morbid procedure with high failure rates, which provides relief of symptoms in less than half of patients. After an acute episode of worsened back pain is resolved, chronic back pain patients who can adhere to an exercise regimen (as recommended by a physical therapist) have less back pain and fewer exacerbations.

Optimum Treatment

Intensive exercise regimens reduce pain and improve functioning. As noted earlier, reinforcement of exercise needs to take place on an ongoing basis. Tricyclic antidepressant medications or antiseizure medications such as gabapentin are useful adjuncts. Long-term opioid therapy is favored by some authorities. One small, randomized trial showed that opioids reduced pain; however, activity levels were not improved, and side effects such as sedation and constipation may be substantial. Patients with disabling chronic

pain may benefit from referral to a multidisciplinary pain center.

Avoiding Treatment Errors

Problems with back pain care can occur in nonrecognition of serious pathology, such as not imaging a patient with a history of severe low back pain and a history of breast cancer. Errors are also common through provision of *too many* diagnostic tests or recommendation of inappropriate treatments. When patients with nonspecific back pain

receive an MRI, they may be told they have degenerated or bulging disks, when in fact they have a typical imaging test for age, resulting in markedly increased anxiety and fear of activity. Recommendation of therapies for which there is limited evidence of benefit, such as intradiskal electrothermal therapy or prolonged courses of traction, may also result in wasted time, additional cost, and exposure to complications. One must also be cautious in recommending surgical intervention for chronic back pain because the patient rarely obtains long-term benefit and often requires subsequent procedures.

Future Directions

The use of an initial clinical diagnostic evaluation and a stepped care approach to back pain can reduce provider and patient frustration and result in improved outcomes, including improved functional status and earlier return to work. Basic research in identifying the pain generator in a larger portion of cases will improve diagnosis and better guide treatment. Randomized trials, currently underway, should give clinicians better information regarding which patients may benefit from discectomy, spinal fusion, and spinal decompressive surgery.

This is an excellent overall review of diagnostic and treatment options.

EVIDENCE

1. Assendelft WJ, Morton SC, Yu EI, et al: Spinal manipulative therapy for low back pain. A meta-analysis of effectiveness relative to other therapies. *Ann Intern Med* 138:871-881, 2003.

This very complete review and meta-analysis indicates that spinal manipulation is not superior to conventional medical treatments, but may be helpful in some circumstances.

2. Atlas SJ, Keller RB, Wu YA, et al: Long-term outcomes of surgical and nonsurgical management of sciatica secondary to lumbar disc herniation: 10 year results from the Main Lumbar Spine Study. *Spine* 30:927-935, 2005.

In this long-term cohort study, patients receiving surgical treatment for sciatica had greater improvement in symptoms than patients who chose nonoperative treatments. However, at 10 years, the work and disability outcomes were similar regardless of treatment chosen. This is the best evidence at present until new randomized trials are reported.

3. Hayden JA, van Tulder MW, Tomlinson G: Systematic review: Strategies for using exercise therapy to improve outcomes in chronic low back pain. *Ann Intern Med* 142:776-785, 2005.

Exercise of longer duration and programs that were individually tailored to the patient had the greatest benefit. The magnitude of benefit for the best-performing exercise regimens was both clinically and statistically significant.

4. Jamison RN, Raymond SA, Slawby EA, et al: Opioid therapy for chronic noncancer back pain. A randomized prospective study. *Spine* 23:2591-2600, 1998.

This article describes one of the very few true randomized controlled trials of opioid use for nonmalignant pain. Pain scores were improved by opiates, but patient functional status was not.

Fibromyalgia

Introduction

Fibromyalgia is a chronic disorder occurring predominately in females; the female-to-male ratio is 10 : 1. It is characterized by pain amplification (manifest as widespread pain) and psychological distress (manifest as fatigue, poor sleep, and in some patients, anxiety, depression, and numerous somatic complaints) (Fig. 145-1). Fibromyalgia overlaps with other illnesses that remain unexplained after usual clinical and laboratory assessment, such as chronic fatigue syndrome, irritable bowel syndrome (IBS), temporomandibular joint pain, and other regional pain syndromes. Advances in our understanding of the genetic, neurophysiologic, neuroendocrinologic, and environmental events that underlie the development of such illnesses are impelling a unifying reclassification as central sensitivity syndromes (CSS) (Box 145-1).

Otherwise unexplained chronic pain and fatigue are extremely prevalent in the general population in the United States and Europe, especially among women and persons of lower socioeconomic status: regional pain, 20%; widespread pain, 11%; fibromyalgia by American College of Rheumatology (ACR) criteria, 3% to 5% in females and 0.5% to 1.6% in males; and chronic fatigue, about 20%. Fibromyalgia may develop in both children and older persons.

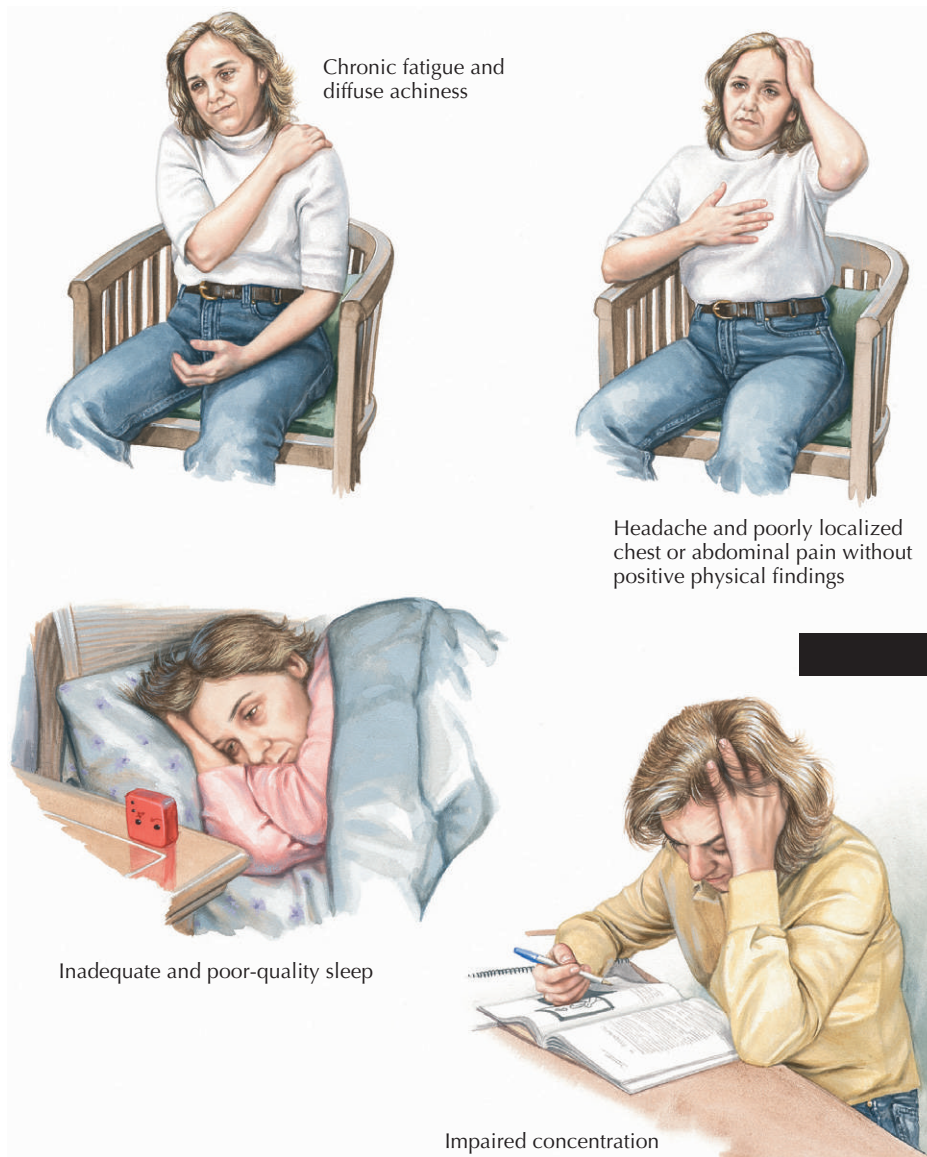

Etiology and Pathogenesis

Although many of the biologic and psychological variables that contribute to chronic pain and fatigue in fibromyalgia and other CSS have been identified, clinical expression of illness in fibromyalgia is best viewed from the perspective of the biopsychosocial model, in which health status and outcomes are influenced by the interaction of a series of biologic, psychological, and sociologic variables.

Biologic Elements

Biologic elements in fibromyalgia that were so lacking for most of this century, such as structural pathology in muscles, have recently been identified and partially characterized. These include gender, genes, central and peripheral mechanisms of pain amplification, abnormal sleep, and dysregulation of the stress response system. Female gender is a likely modifier of the interaction between genetic and environmental factors that influence vulnerability to pain amplification and psychological distress. For example, compared with males, females exhibit higher pain sensitivity; lack certain pain inhibitory mechanisms; exhibit greater

sympathetic nervous system, neuroendocrine, and psychological responses to stressful or aversive stimuli; and are at greater risk for chronic pain conditions. The number of specific genetic variants that influence vulnerability to pain amplification and psychological distress is expanding exponentially as a result of high-throughput genetic analyses. The neurophysiologic and neuroendocrinologic bases for pain amplification involve multiple abnormalities in pronociceptive and antinociceptive pathways in the central nervous system. These include glial activation; increased levels of inflammatory cytokines and excitatory amino acids; decreased availability of serotonin, norepinephrine, and enkephalins; and deficiency of biogenic amines that normally regulate the release of substance P, to list a few. Nonrestorative sleep is related to intrusion of α waves into the brain's electrical field during restorative stage 3 and 4 non-rapid eye movement sleep and to several other well-characterized sleep abnormalities. Dysregulation of the stress response system is manifest by hypofunctional sympathetic reflex response to stressors and by abnormalities of the hypothalamic-pituitary-adrenal axis as well as other neuroendocrine axes, including growth hormone secretion in response to exercise.

Figure 145-1 Faces of Fibromyalgia.

Psychological (Cognitive-Behavioral) Variables

Psychological distress, especially in association with depression, anxiety, post-traumatic stress disorder, and personality disorders, is prevalent in fibromyalgia and other CSS. When vulnerable individuals who express various combinations of genetic susceptibility haplotypes encounter environmental situations of unrelieved stress and distress, functional alterations of the stress response system may result. Other psychological variables that play a role in the overall symptomatology and clinical impact of fibromyalgia include pain beliefs and attributions regarding environmental causation of the illness, pain behaviors,

hypervigilance, coping strategies, and the degree of perceived self-efficacy for pain control.

Sociologic (Environmental and Sociocultural) Variables

Sociologic variables consist of experiences influenced by life and culture that interact with gender and genetic vulnerabilities in the clinical expression of fibromyalgia, such as psychosocial experiences during childhood, family support, work environment, job satisfaction, and ethnologic factors. Particularly important with respect to the development of chronic pain in adulthood are adverse

Box 145-1 Currently Proposed Members of the Central Sensitivity Syndromes

Fibromyalgia (overlaps strongly with chronic fatigue syndrome)
 Irritable bowel syndrome (includes functional dyspepsia)
 Temporomandibular disorders
 Myofascial pain syndrome, regional soft tissue pain syndrome
 Periodic limb movements in sleep
 Multiple chemical sensitivity
 Female urethral syndrome, interstitial cystitis (possibly may also include vulvodynia)
 Post-traumatic stress syndrome
 Depression

experiences during childhood, such as poor family environment or childhood sexual abuse, as has been particularly well studied in IBS.

Clinical Presentation

Fibromyalgia presents with widespread pain, fatigue, subjective weakness, insomnia, and in many patients, depression and anxiety, “like I have flu all the time.” Pain radiates diffusely from the axial skeleton and is localized to muscles and muscle-tendon junctions of the neck, shoulders, hips, and extremities. The pain may be described as “exhausting,” “miserable,” or “unbearable,” and there often is the complaint that even gentle touch is unpleasant (allodynia). Fatigue may dominate the clinical picture. Cognitive complaints, such as difficulties with concentration and memory, may be prominent. Many patients express numerous somatic complaints that remain unexplained after careful clinical assessment. Significant functional impairment in activities of daily living is usually present, as is deconditioning due to lack of exercise. Indeed, there often is fear and avoidance of exercise because of exacerbation of symptomatology following excessive activity on “good days.” Fibromyalgia frequently coexists with inflammatory disorders of defined structural pathology, such as systemic lupus erythematosus (SLE), rheumatoid arthritis, ankylosing spondylitis, Crohn’s disease, and ulcerative colitis. Optimum therapeutic outcomes require recognition and treatment of both fibromyalgia and associated disease.

As in IBS, patients with more severe fibromyalgia may exhibit a history of childhood abuse, major psychosocial stressors, post-traumatic stress disorder, personality disorder, or major depressive disorder. Such patients require counseling and psychiatric consultation. Prognosis varies among three fairly distinct subsets of patients. Adaptive copers, many of whom do not seek care for fibromyalgia, do well with respect to self-reported pain, disturbed sleep, and fatigue. Interpersonally distressed patients also respond to a comprehensive interdisciplinary therapeutic approach.

Table 145-1 Differential Diagnosis of Fibromyalgia

Major Disorder Group	Selected Specific Disorders
Rheumatologic	Systemic lupus erythematosus* Rheumatoid arthritis, Sjögren’s syndrome* Polyarticular osteoarthritis, degenerative spondylosis Polymyalgia rheumatica* Polymyositis, statin myopathy Regional pain syndromes* Osteomalacia Hypermobility syndromes
Neurologic	Carpal tunnel syndrome* Cervical radiculopathy* Metabolic myopathies Multiple sclerosis*
Chronic infection	Cervical cord compression Subacute bacterial endocarditis Brucellosis Hepatitis HIV
Endocrine	Hypothyroidism* Diabetes mellitus type 2 Hyperparathyroidism
Neoplastic	Metastatic (e.g., breast, lung, prostate) Myeloma
Psychiatric	Pain disorder associated with psychological factors* (formerly, somatoform pain disorder) Somatization disorder (hysteria, Briquet’s syndrome)

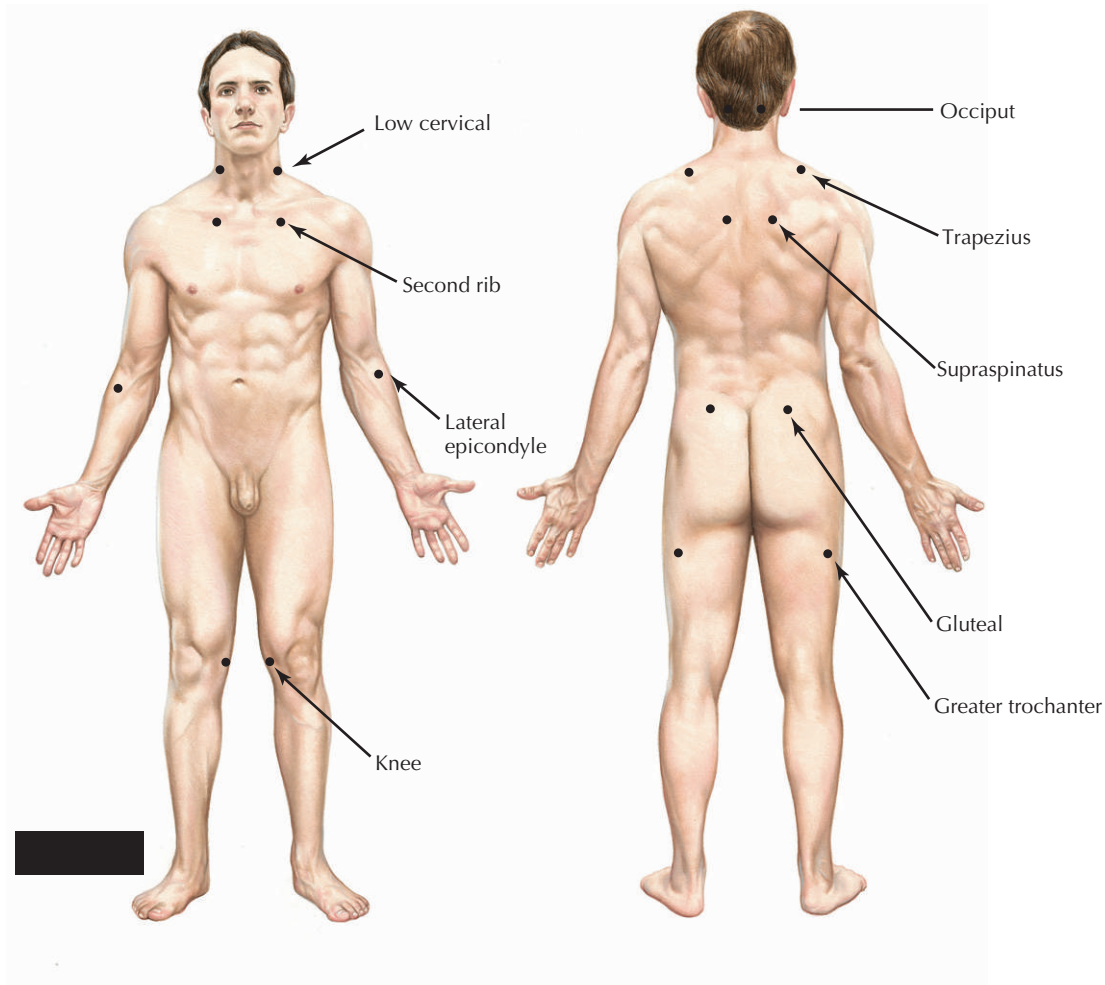

*Common alternative diagnoses.

From Winfield JB: *Fibromyalgia*. In Dale DC (ed): *ACP Medicine*. New York, WebMD Professional Publishing, 2006, pp 1412-1418.

Dysfunctional patients, who exhibit high levels of pain, anxiety, functional impairment, and a history of opioid dependence, respond poorly to therapeutic intervention, as do patients with pending litigation.

Differential Diagnosis

Although the differential diagnosis of fibromyalgia is broad (Table 145-1), extensive diagnostic testing should not be done unless the patient exhibits objective signs of structural disease on physical or neurologic examinations. It is not helpful clinically to distinguish fibromyalgia from chronic fatigue syndrome (refer to Chapter 6) or the many regional pain syndromes. However, giving patients a name for their illness has therapeutic value in that it enables them to concentrate on getting better, rather than on continuously searching for a cause and a cure.

Figure 145-2 Fibromyalgia Tender Points.

Diagnostic Approach

There are no generally accepted diagnostic criteria for fibromyalgia, although the ACR classification criteria designed and validated for selection of research subjects provides a reminder for two key features: widespread pain and painful tender points (Fig. 145-2) on physical examination. In practice, consider fibromyalgia when a patient presents with widespread pain for longer than 3 months, fatigue associated with usual daily activities, poor sleep, and multiple symptoms that cannot be easily explained. Except for painful tender points (perhaps five is sufficient), the physical and neurologic examinations will be unremarkable unless coexisting disease is present. Routine diagnostic testing should be limited to a few screening tests to exclude or confirm the presence of diseases that can be confused with fibromyalgia or that frequently coexist with fibromyalgia (Box 145-2).

Key Elements in the History

- Assess the onset, location, and nature of pain, together with ameliorating and exacerbating factors.

Box 145-2 Routine Diagnostic Testing

Complete blood count and differential
 Creatine kinase
 Thyroid-stimulating hormone (TSH)
 Erythrocyte sedimentation rate (ESR)
 Antinuclear antibodies (ANAs)
 Rheumatoid factor

Other tests that may be considered:

Laboratory sleep assessment if sleep does not improve with usual conservative measures

Consider screening with a serum transferrin saturation and a serum ferritin concentration in patients aged 40-60 years because diffuse arthralgias and myalgias have been described in patients with hemochromatosis

Pressure algometry (dolorimetry) to assess pressure pain detection thresholds at four tender points associated with fibromyalgia (i.e., both lateral epicondyles, midpoints of the trapezii) is useful both as an aid in diagnosis and as a semiquantitative guide to therapy. Normal values are ≥ 4 kg/cm²

- Inquire about sleep quality, impairment in activities of daily living, ongoing and past stressors, feelings of anxiety or depression, marital adjustment, and perceived levels of social support. Recognition of difficulties in these areas is essential in the overall management of fibromyalgia.
- Ask “how was your childhood?” This inquiry often reveals adverse childhood experiences, such as abuse, that have increased the patient’s vulnerability to chronic pain (consequences of abuse are not limited to children; adult domestic violence is an important antecedent of fibromyalgia).
- Determine the presence of regional pain syndromes that overlap with fibromyalgia and frequently coexist in the same patient, such as temporomandibular joint pain, IBS, and chronic pelvic pain.
- Inquire about previous treatment for pain and insomnia, which can guide the physician in developing a therapeutic plan. Dependency on opioids and unsuccessful prior referrals to multidisciplinary pain centers suggest a poor prognosis.
- Ask about use of complementary and alternative medicine (CAM). Some CAM agents are not safe, and many have the potential to interact with conventional medicines.

A simple self-report form that incorporates validated scales for physical and psychological health status; visual analog scales for pain and fatigue, cognitive performance, and self-efficacy; and a checklist of current symptoms can be completed in just a few minutes in the waiting room. Easily adaptable to a busy practice, such information is invaluable in the comprehensive assessment of fibromyalgia.

Physical Findings

With the exception of painful tender points, the physical and neurologic examinations are normal in the absence of comorbid disease. Pressure algometry at several fibromyalgia tender point sites to assess pain detection threshold (normal is about 4 kg/cm²) at the initial visit and in follow-up visits provides a guide to therapeutic response. Moreover, algometry can serve as an effective starting point for patient education regarding the nature of their illness.

Diagnostic Testing

Although there are no specific laboratory test abnormalities in fibromyalgia, limited screening for commonly associated disorders and for other diseases that can cause pain and fatigue is useful. These include antinuclear antibody, complete blood count, erythrocyte sedimentation rate or C-reactive protein, thyroid-stimulating hormone, creatine kinase, aspartate aminotransferase, and alanine aminotransferase. Tests for viral infection, autonomic dysfunction (tilt-table test), nerve conduction velocity

and electromyography, and imaging studies are usually unnecessary.

Diagnostic Pitfalls

Missed diagnosis of coexisting disease: Do not automatically attribute all symptoms to fibromyalgia, and remember that patients with fibromyalgia can develop intercurrent diseases. Fibromyalgia frequently coexists with other disorders of defined structural pathology, such as SLE or rheumatoid arthritis, and optimum therapy requires recognition of both fibromyalgia and comorbid disease.

Excessive diagnostic testing: Conversely, avoid large-scale diagnostic testing based on symptoms alone, which is both nonproductive and a potential barrier to optimum therapeutic outcome.

Failure to recognize coexisting nociceptive or neuropathic pain: Identify pain generators (e.g., coexisting osteoarthritis or degenerative disk disease with sciatica) that exacerbate fibromyalgia and must be treated separately.

Failure to recognize symptom exaggeration and malingering: In situations of potential secondary gain, such as personal injury litigation, the physician may encounter symptom exaggeration and overt malingering. For example, certain otherwise healthy claimants are well informed regarding the location of tender points. Firm pressure over the trapezii or posterior thorax with a stethoscope, rather than a finger, can provide insight in such cases.

Management and Therapy

General Considerations

Four principles govern the treatment of fibromyalgia: (1) validation of distress, (2) diagnostic and therapeutic conservatism, (3) an individualized combination of pharmacologic and nonpharmacologic measures, and (4) *care* rather than *cure*. Validation of the patient’s symptoms and distress begins with the initial history and physical examination. Comments like “it’s all in your mind” or “there is nothing really wrong with you” serve only to perpetuate illness and may constitute an insurmountable barrier to treatment. An overarching goal of therapy is the promotion of self-efficacy—the patient’s firmly held belief that he or she can control symptoms of pain and fatigue.

Although much current treatment is empirical, abundant data from randomized controlled trials suggest that pain, fatigue, nonrestorative sleep, depression, and anxiety respond to a multifaceted therapeutic approach combining drug therapy with physical, psychological, and behavioral interventions. Consultative referral to a rheumatologist familiar with fibromyalgia is indicated when the diagnosis is unclear, when fibromyalgia is complicated by comorbid

autoimmune or musculoskeletal disease, and when response to therapy is poor. Psychiatric referral is essential for comorbid psychosis and for severe depression with suicidal ideation.

Optimum Treatment

Drug Therapy

For the diffuse pain of fibromyalgia, initial therapy with low-doses of a tricyclic agent (TCA), for example, 10 to 50 mg amitriptyline at bedtime, improves pain, sleep, and overall sense of well-being in about one third of patients, but patient acceptance may be limited by anticholinergic and sedative effects. Selective serotonin reuptake inhibitors, such as fluoxetine or citalopram, and dual-action serotonin-noradrenaline reuptake inhibitors, such as venlafaxine and duloxetine, are of proven efficacy for pain control irrespective of comorbid depression and may be used in combination with a TCA (at initiation of therapy, carefully monitor patients for worsening depression and suicidal thoughts). Addition of an antiepileptic drug, such as gabapentin, topiramate, tiagabine, or pregabalin, is indicated in patients with severe allodynia and hyperalgesia. Centrally acting skeletal muscle relaxants (e.g., cyclobenzaprine, baclofen, tizanidine) generally are less effective. Topical capsaicin is useful when gently massaged into painful areas twice a day. Opioids generally should be avoided, but a subset of patients can achieve a reasonable quality of life and maintain daily functioning in no other way. Pain from comorbid disease is treated in a stepwise fashion with nonsteroidal anti-inflammatory drugs with or without opioid or nonopioid analgesics.

Fatigue generally improves with effective treatment of pain, depression, and sleep disturbances in combination with a graded aerobic exercise program. Modafinil may benefit patients in whom overwhelming fatigue is a persistent complaint. Sleep disturbances should be managed aggressively, beginning with instruction in the elements of good sleep hygiene. Most patients require medication, such as alprazolam, cyclobenzaprine, temazepam, trazodone, or doxepin, either singly or in combination with a nonbenzodiazepine hypnotic, such as zolpidem, zaleplon, or esopiclone. Clonazepam or ropinirole at bedtime is effective for frequently comorbid restless legs syndrome. A formal sleep study is indicated when the simple measures described previously are ineffective. Comorbid depression also requires aggressive pharmacologic management, perhaps in conjunction with formal or informal psychotherapy.

Nonpharmacologic Management

Many nonpharmacologic treatments are of proven benefit with respect to physical capacity, pain reduction, and global well-being and should be combined with drug therapy. Effective modalities include graded aerobic exercise, medi-

tation, yoga, biofeedback training alone or in combination with relaxation training and aerobic exercise, psychotherapeutic counseling, and participation in support groups. Efficacy may be limited by poor motivation, however. High-intensity fitness programs, trigger-point injections, ultrasound, laser therapy, sphenopalatine blocks, vegetarian diets, magnet therapies, manipulative therapy, and referral to anesthesia pain clinics either have no place in the treatment of fibromyalgia or are of questionable benefit.

Treatment in Older Persons and Children

Treatment of diffuse pain in older persons and in children requires special approaches. Accurate pain assessment and effective management are difficult in older persons, who fear diagnostic testing, may be reluctant to report pain, have lower self-efficacy, and use fewer cognitive coping methods. In the pediatric population, unexplained diffuse or localized pain is most common in preadolescent to adolescent girls, often in association with incongruent affect; disproportionate impairment of performance in school; and psychological distress in the patient, the family, or both. Medications should be discontinued, and a program of aerobic exercise should be instituted. A psychological evaluation and psychotherapy may be necessary in some cases. Fortunately, most children do well.

Avoiding Treatment Errors

Failure to recognize pseudoaddiction: Be aware that drug-seeking behavior may be a sign of inadequate symptom control (pseudoaddiction) rather than drug dependency.

Iatrogenic exacerbation: An unsympathetic, uninformed physician who is dismissive of fibromyalgia as a diagnostic entity or who fails to validate suffering can be a major perpetuating factor in this illness.

Converting an acute injury into a chronic pain condition: In the management of an acute injury, for example, a neck strain incurred in a minor traffic accident avoid diagnostic waffling, open-ended referral for physical therapy, prolonged release from work, prescription of a neck brace, and use of the term *post-traumatic fibromyalgia*.

Future Directions

Future directions are rapidly being defined by enormous progress in four areas. First, it is now recognized that fibromyalgia and multiple other regional pain disorders, such as IBS and chronic headaches, frequently coexist, share common pathophysiologic features, and can all be classified as CSS. Second, pain amplification and psychological distress have been identified as the two primary pathways of vulnerability in such disorders. Third, we have a much deeper understanding of the neurophysiologic

mechanisms and pathways that underlie pain amplification. Finally, high-throughput genotyping methods are giving us profound insights into both the genetic contributions to chronic pain and psychological disorders and the bases for individual differences in clinical disease expression. Progress in these areas will impel clinician acceptance of fibromyalgia and related syndromes as “real” diseases and will provide a rational guide for improved therapy and drug development.

Gout

Introduction

Crystal arthropathies are diseases caused by precipitation of the phlogistic crystals within the synovial or tenosynovial spaces. *Phlogism* is the capability of a biologic compound to produce inflammation when present in its crystalline form within the body. In the musculoskeletal system, the most common phlogistic crystal is sodium urate, which produces the disease gout. This chapter discusses the pathophysiology of the formation of uric acid crystals within synovial spaces, the different clinical presentations of gout, and the respective therapies for these entities.

Etiology and Pathogenesis

The cumulative incidence of gout over a 20-year follow-up period is about 8%, with a male predominance. The risk for an acute attack of gout relates to the serum level of uric acid, the risk increasing as the serum urate level rises. At a serum urate level of 9 mg/dL, the risk for developing gout is about 5 times that in a person with a normal serum uric acid level. Although most patients have an elevated serum uric acid level, this value may be falsely low, particularly during an acute exacerbation of the disease, when uric acid is being consumed within the synovial spaces by the crystallization process.

Uric acid forms as a consequence of the purine breakdown biochemical pathway and is eliminated primarily by renal excretion and secretion. Elevation of the serum uric acid concentration and resultant gout occurs by one of the following three etiologies: uric acid underexcretion by the kidney, genetic defects causing overproduction of uric acid, or high cell turnover.

Underexcretion by the kidney causes 85% to 90% of cases of clinical gout. In some cases, underexcretion is due to a presumed genetic defect in renal handling of uric acid. Underexcretion of uric acid may also occur as a result of tubular renal disease (with normal creatinine clearance) or any disease that results in a decrease in overall renal function. Drugs and ingestions decreasing renal excretion of uric acid, such as thiazide and loop diuretics, cyclosporine, ethambutol, alcohol, lead, and low-dose aspirin, all may lead to underexcretion and hyperuricemia.

Genetic defects in the biochemical purine elimination pathway resulting in overproduction of uric acid cause 5%

of cases of clinical gout (Fig. 146-1). Increased activity of PRPP synthetase (alcohol use also results in increased activity of this enzyme) and partial or complete deficiency of the purine scavenger pathway enzyme HGPRT are the most common enzyme abnormalities causing this mechanism of hyperuricemia. Complete deficiency of the HGPRT enzyme results in Lesch-Nyhan syndrome with its neurologic sequelae. Lesch-Nyhan syndrome is seen almost exclusively in children.

High cell turnover states resulting in the overproduction of uric acid in patients with normal purine pathway biochemistry (secondary gout) can occur in a variety of settings. Most notable are in the presence of hematologic malignancies, particularly multiple myeloma in elderly patients; during chemotherapeutic treatment of malignancies (either hematologic or metastatic carcinoma) or during the onset of treatment of pernicious anemia; and with exfoliative skin disorders such as psoriasis (see Fig. 146-1).

Clinical Presentation

Acute Gout

Classic acute gout usually involves the metatarsophalangeal joint of the great toe. This acute monoarthritis, known as podagra, occurs with an abrupt onset usually in the early morning hours. Erythema, warmth, and acute pain occur over the dorsal aspect of the joint and may involve the extensor tendons and surrounding tissue. The pain is usually quite severe and out of proportion to the clinical exam, and patients frequently describe podagra as the

Figure 146-1 Purine Elimination Biochemical Pathway.

worst pain they have ever experienced. Patients describe not being able to tolerate a thin bed sheet or cool air moving over the top of the involved joint. Without treatment, the attack may last from 5 to 7 days, and resolve with scaling of the superficial dermis over the involved joint. Recurrent attacks are common and may occur as frequently as monthly or sporadically, with attacks every few years.

Acute gout may affect any joint in the body. Most commonly involved are the knees, wrists, shoulders, and metacarpophalangeal and proximal or distal interphalangeal finger or toe joints. The axial skeleton, including the hips, is less commonly involved, but acute gout has been reported in the sacroiliac joints and the sternoclavicular joints. Attacks may be limited to tenosynovial sheaths alone and may be confused with other causes of tendonitis, particularly overuse musculoskeletal syndromes. Polyarticular attacks involving two or more joints or tendons are not uncommon and may mimic other systemic rheumatic diseases. Fever and malaise are common in polyarticular acute gout, but less so in monoarticular attacks.

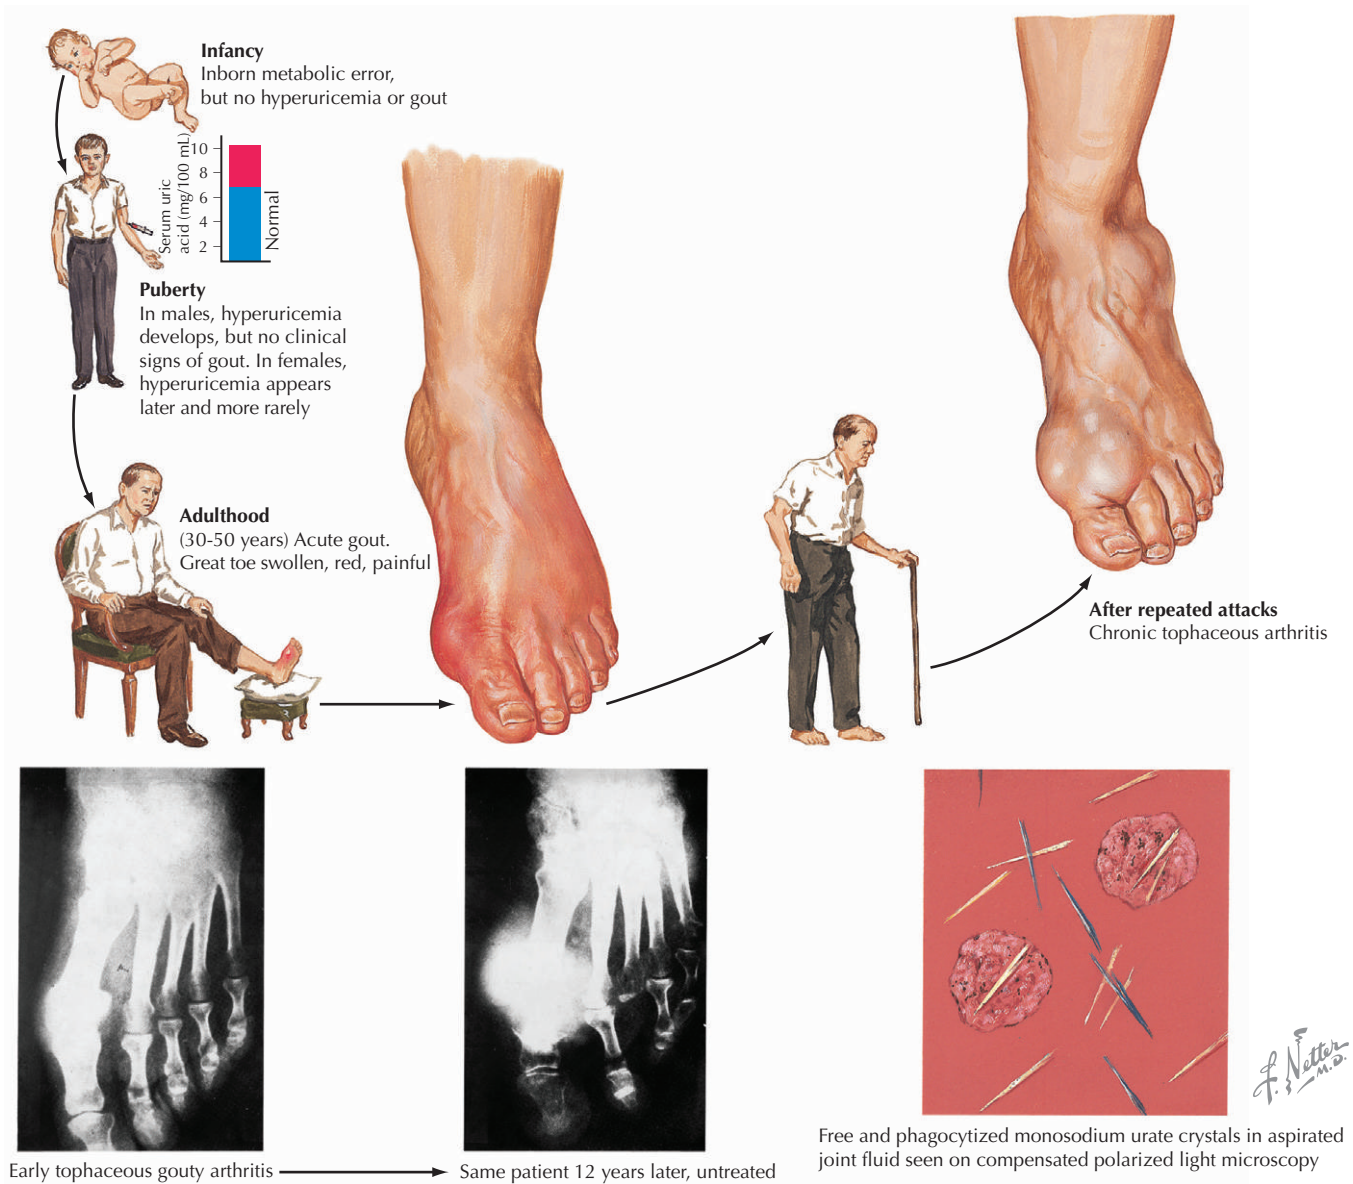

On physical exam, the patient usually cannot move the affected joint or tendon without severe pain. Tendon involvement can be elicited by stretching the suspected muscle-tendon unit without moving the underlying joint. Large tense joint effusions are common in knees, shoulders, or ankles during an acute gout attack. Occasionally, a posterior popliteal cyst (Baker cyst) may form as a result of acute gout in the knee and then, in some cases, rupture down the posterior calf and mimic the physical findings of deep venous thrombosis.

Laboratory findings during the acute attack may include an elevated white blood cell count with a left shift, elevated sedimentation rate (sometimes greater than 100 mm/hr, Westergren method) and increased levels of other acute-phase reactants such as ferritin and C-reactive protein. Synovial fluid contains large numbers of polymorphonuclear leukocytes and may appear grossly purulent. Serum uric acid may be normal and is of no value in the diagnosis of gout. Radiographs are almost always normal other than illustrating soft tissue swelling and effusion in the larger joints, unless the involved joint has had damage from recurrent attacks or the patient has chronic gout.

Chronic Gout

Patients present with a chronic, sometimes deforming, arthritis affecting hands, wrists, feet, knees, and shoulders (Fig. 146-2). It can produce ulnar deviation, swan neck deformities, and other hand and foot deformities, and as a result, can commonly be misdiagnosed as rheumatoid arthritis. Patients may describe episodic acute attacks of swelling, redness, and pain in the involved joints or a more indolent history of chronic swelling and pain. On physical examination, common findings are of chronic synovitis, most often involving the hands and feet and usually asymmetrical (unlike rheumatoid arthritis). Joint deformities and decreased range of motion may be present.

Laboratory evaluation can compound the confusion with rheumatoid arthritis because 20% to 25% of patients with chronic gout have a positive serum rheumatoid factor.

Figure 146-2 Gouty Arthritis: Natural History.

Serum uric acid is usually elevated but may be normal. The sedimentation rate is usually modestly elevated. Radiographs show erosive destructive disease similar to rheumatoid arthritis, but an experienced bone radiologist may discern more cystic periarticular erosions with new bone formation that help distinguish the findings of chronic gout from rheumatoid arthritis.

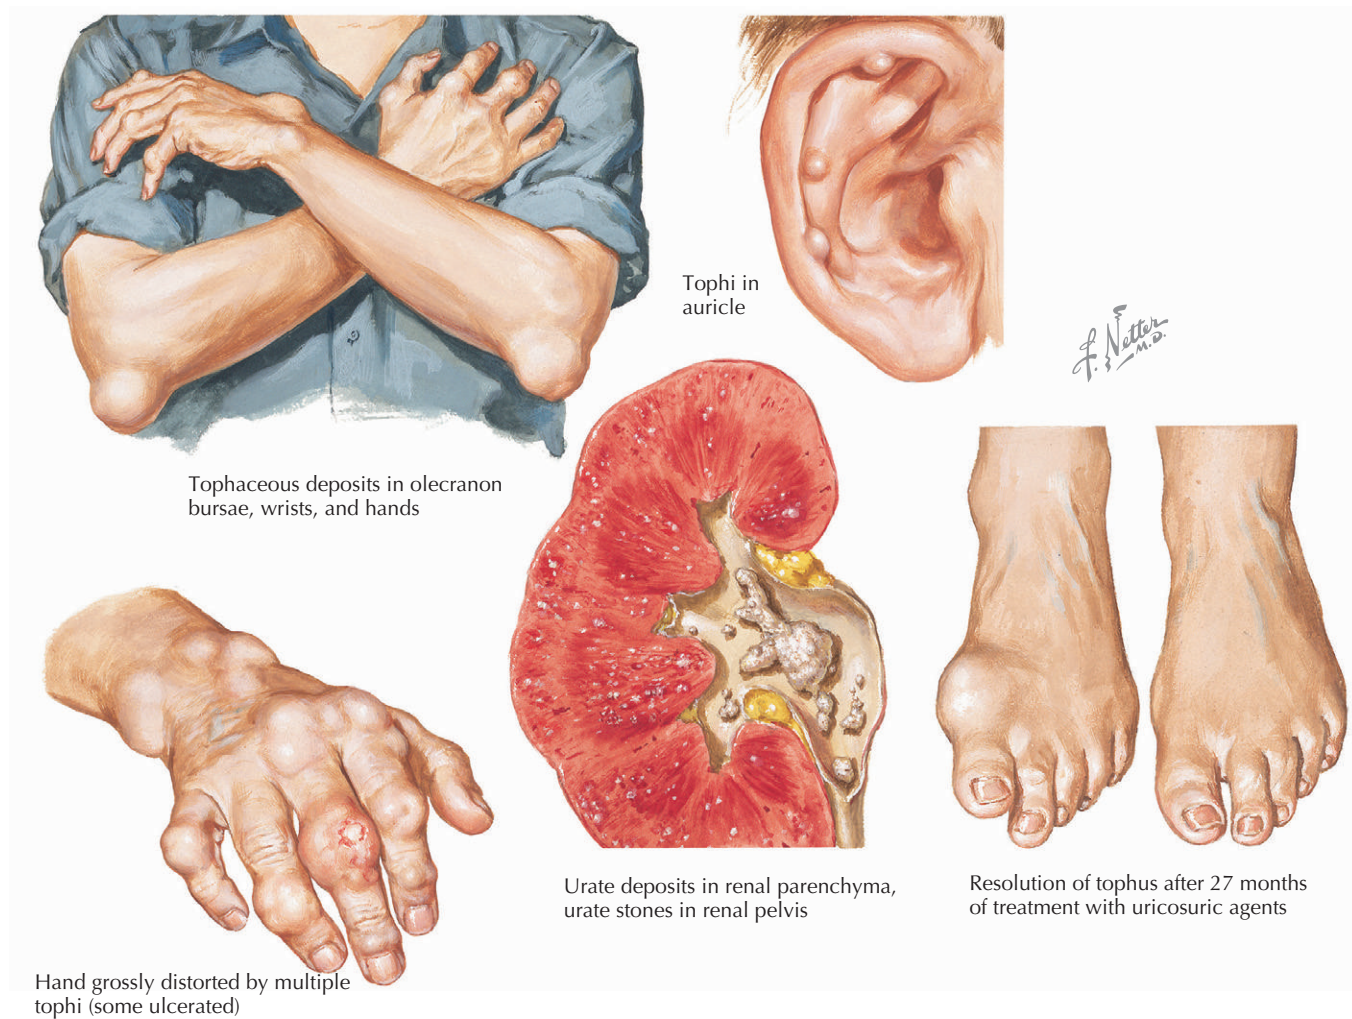

Tophaceous Gout

Some patients, almost always with the chronic form of gout, develop subcutaneous deposits of uric acid known as *tophi*. These deposits form nodules, usually over the extensor surfaces of the elbows, in the Achilles tendons, over the extensor surfaces of the hands and feet, and within the

pinnae of the ears (Fig. 146-3). Their appearance on physical examination is identical to that of rheumatoid nodules, and they can only be distinguished by the presence of uric acid crystals when examined with cross-polarized compensated microscopy. Crystals can be found in joint aspirates or biopsy samples of nodules. Patients who abuse homemade alcohol (moonshine) made by using older-model automobile batteries containing lead may develop a severe form of tophaceous gout known as *saturnine gout*.

Differential Diagnosis

The most common mistake in acute gout is to miss a septic joint. This can be avoided by prompt arthrocentesis of any acutely inflamed joint. If uric acid crystals are seen, the

Figure 146-3 Tophaceous Gout.

diagnosis is confirmed because it is extremely uncommon for bacteria and uric acid crystals to be present in the same joint. Occasionally, the HLA-B27 diseases, particularly Reiter's syndrome, may present in the same manner as acute gout. Tophaceous gout has very commonly been diagnosed as rheumatoid arthritis because, as mentioned earlier, the nodules appear clinically identical to rheumatoid nodules and 20% of patients with chronic gout are rheumatoid factor positive. This mistake can be avoided by aspirating a nodule, which in gout will contain pure uric acid.

Diagnostic Approach

Diagnosis of any of the forms of gout can only be made by demonstration of negatively birefringent, needle-shaped uric acid crystals in synovial, tenosynovial, or nodule fluid obtained by aspiration of the involved joints, tendons, or subcutaneous nodules. In acute gout, these crystals are both extracellular and intracellular within polymorphonuclear

leukocytes. In chronic and tophaceous gout, free uric acid crystals may be present without any inflammatory cell reaction. Most commercial laboratories are able to examine synovial fluid under crossed-polarized compensated microscopy, and uric acid crystals remain observable in synovial fluid samples for up to 7 days. Planar bone radiography may be helpful in establishing a diagnosis of gout.

Management and Therapy

Acute Gout

Nonsteroidal anti-inflammatory drugs (NSAIDs) remain the mainstay of treatment of the acute attack. Indomethacin was the first of this group to be used for acute gout. The typical initial dose is between 100 mg and 200 mg/day orally in divided doses, depending on the severity of the attack and the weight of the patient. Some relief of symptoms should occur within 2 hours. The dosage should be decreased gradually over 3 to 4 days as the acute gout

resolves. Other NSAIDs, such as naproxen (500 mg, 2 to 3 times daily) or ibuprofen (800 mg 4 times a day), are also effective. Aspirin is contraindicated because it produces increased serum uric acid at onset of usage. Long-acting NSAIDs with delayed time to steady-state concentrations (e.g., piroxicam and nabumetone) should be avoided. NSAIDs should be avoided in patients with preexisting renal disease with altered renal hemodynamics, in whom hyperkalemia and deterioration of renal function may be precipitated. The newer cyclooxygenase-2 selective NSAIDs are equivalent in efficacy to the nonspecific NSAIDs in acute gout.

If NSAIDs are contraindicated, patients can receive oral colchicine. There is no current role for intravenous administration of colchicine for acute gout. Colchicine is effective in acute gout, and a clear response to this drug may be valuable in supporting the diagnosis. However, doses close to toxic levels are needed. For this reason, the following regimen is usually recommended: 1.2 mg initially, followed by 0.6 mg every 2 hours until there is either diarrhea or vomiting or the patient obtains relief of pain. The total dose required usually ranges between 4 and 8 mg. Relief may not occur for some hours after the toxic features have developed and may not be complete.

Intra-articular injection of steroids can be used if both colchicine and NSAIDs are contraindicated. Oral steroids may also be considered for those patients who have too many joints involved for intra-articular injections.

Chronic Gout and Recurrent Acute Gout

Patients with chronic gout or episodic recurrent acute gout should receive prophylactic treatment with agents that lower serum uric acid. The decision to use these drugs in episodic acute gout should be based on an individual patient's desires because some patients will tolerate four to five attacks yearly and use only NSAIDs during each attack, whereas others prefer long-term prophylaxis. Low purine diets are unpalatable and rarely tolerated as a method to lower serum uric acid. Uric acid-lowering agents should never be started during an acute attack because they will worsen and prolong the course of the attack. Patients with episodic acute gout should be asymptomatic for at least 4 to 6 weeks before uric acid-lowering agents are begun. Patients with chronic gout should take an NSAID or daily colchicine (0.6 mg twice daily) when prophylactic treatment is started.

The choice of prophylactic agent is based on whether the patient is an underexcretor or overproducer of uric acid. Ninety percent of patients with gout are underexcretors of uric acid and should receive the less toxic uricosuric agents. Allopurinol is reserved for overproducers of uric acid. A 24-hour urine collection for uric acid will establish which group the patient is in. Therapy should be based on the urine uric acid excretion level determined. A serum uric acid level should be determined at onset of

prophylaxis and used as a guide to adjust dosing of the drug chosen, with a goal of lowering the serum uric acid to the range of 5 to 7 mg/dL. Historically, colchicine (0.6 mg twice daily) has been added to any prophylactic regimen to prevent breakthrough attacks.

Probenecid, the original uricosuric agent, is used as initial therapy in patients who underexcrete uric acid. It acts by inhibiting reabsorption of urate from the renal tubule and thus increasing urinary urate excretion. It is contraindicated in patients with nephrolithiasis and is not effective in patients with decreased renal function. Its effect is decreased by the concurrent administration of aspirin. The initial dose is 500 mg twice daily, and the drug is available in a combination form with 0.6 mg of colchicine. Sulfapyrazone (200 mg twice daily), also an effective uricosuric drug, may be used in lieu of probenecid. Angiotensin receptor-blocking antihypertensive drugs such as losartan also act as uricosuric agents and are a convenient way to treat hypertension and gout with a single agent.

Allopurinol, which is rapidly metabolized to oxypurinol, acts by inhibiting the enzyme xanthine oxidase, thereby reducing the production of uric acid. It should be used only in overproducers of uric acid or when uricosuric agents are contraindicated or ineffective. The initial dose should be 100 mg/day, and depending on the risk of precipitating acute gout, the dose can then be increased each week by 100 mg/day until a dose of 300 mg/day is reached. Occasionally, dosages approaching 600 mg/day are required in patients who have genetic causes of overproduction of uric acid. The main complications of using allopurinol are allergic reactions, which may range from a minor skin rash to a severe, life-threatening toxic epidermolysis with interstitial nephritis. About 30% of patients beginning allopurinol develop a rash. If a rash is observed, allopurinol should be immediately discontinued. The dose should be reduced in the presence of renal insufficiency (by about 100 mg/day for a 30-mL/minute decrease in creatinine clearance).

Tophaceous Gout

The goal of therapy for tophaceous gout is to reduce serum uric acid and mobilize and dissolve the nodular deposits of uric acid. This is accomplished by using uricosuric agents with allopurinol in patients who can tolerate this regimen. These patients do not require 24-hour urine collection for uric acid because both classes of drugs are employed in combination. Allopurinol is instituted first with a 6-week interval before beginning the uricosuric agent. After the tophaceous deposits have disappeared (this may take years), the uricosuric agent may be stopped.

Future Directions

Newer, nonpurine xanthine oxidase inhibitors without the cutaneous side effects of allopurinol are in trials, as are

uricases that convert uric acid to water, carbon dioxide, and hydrogen peroxide. Because of the peroxide radicals, these agents are still too toxic for clinical use. It is hoped that, in the future, therapies will be developed that result in increased metabolism of uric acid and improved outcomes in patients with a propensity to develop gout.

Calcium Crystal Diseases

Introduction

Crystal arthropathy disease, in addition to gout, can be caused by precipitation of the phlogistic crystals of calcium pyrophosphate and the basic calcium phosphate (BCP) group of crystals within the synovial or tenosynovial spaces. Although each of these crystals produces a distinct clinical syndrome, they share the common phlogistic potential to induce local inflammation within affected joints. The focus of this chapter is on calcium pyrophosphate and the BCP diseases, but it is important to note that many other types of crystals have been seen within synovial spaces by crystallography and cross-polarized compensated microscopy. These range from calcium oxalate in patients with primary oxalosis or on hemodialysis, cholesterol and lipid liquid crystals, to cryoglobulins, hemoglobin, cystine, and Charcot Leyden crystals. In some cases, these rare crystals almost certainly cause a primary inflammatory response, but in other cases, they may just be epiphenomena to other primary disease processes.

CALCIUM PYROPHOSPHATE DEPOSITION DISEASE

Etiology and Pathogenesis

Calcium pyrophosphate deposition disease is a disease caused by precipitation of crystals of calcium phosphate dihydrate (CPPD) within the synovial, tenosynovial, or cartilaginous spaces. Unlike uric acid crystals, which almost always produce clinical inflammation, CPPD crystals may deposit in cartilaginous tissue, particularly in elderly patients, and produce no apparent clinical symptoms. These deposits appear within the joint spaces on routine radiographs of knees or wrists in about 30% of patients older than 80 years and in 10% of patients between the ages of 60 and 75 years. Only a small percentage of these patients have any of the clinical manifestations of CPPD that are described later. The biochemical mechanism or defects producing the articular deposits of calcium pyrophosphate have yet to be established. Despite the lack of understanding of the pathophysiology of CPPD, certain diseases have an absolute association with the entity and should be pursued as coexisting whenever a patient first presents with clinical manifestations of CPPD. These can be remembered as the five Hs: hyperparathyroidism, hemochromatosis, hypothyroidism, hypomagnesemia, and hypophosphatasia. Early appearance of CPPD (before age 40 years) may be associated with any of these conditions,

or in some cases may be the result of a rare inherited familial form of CPPD.

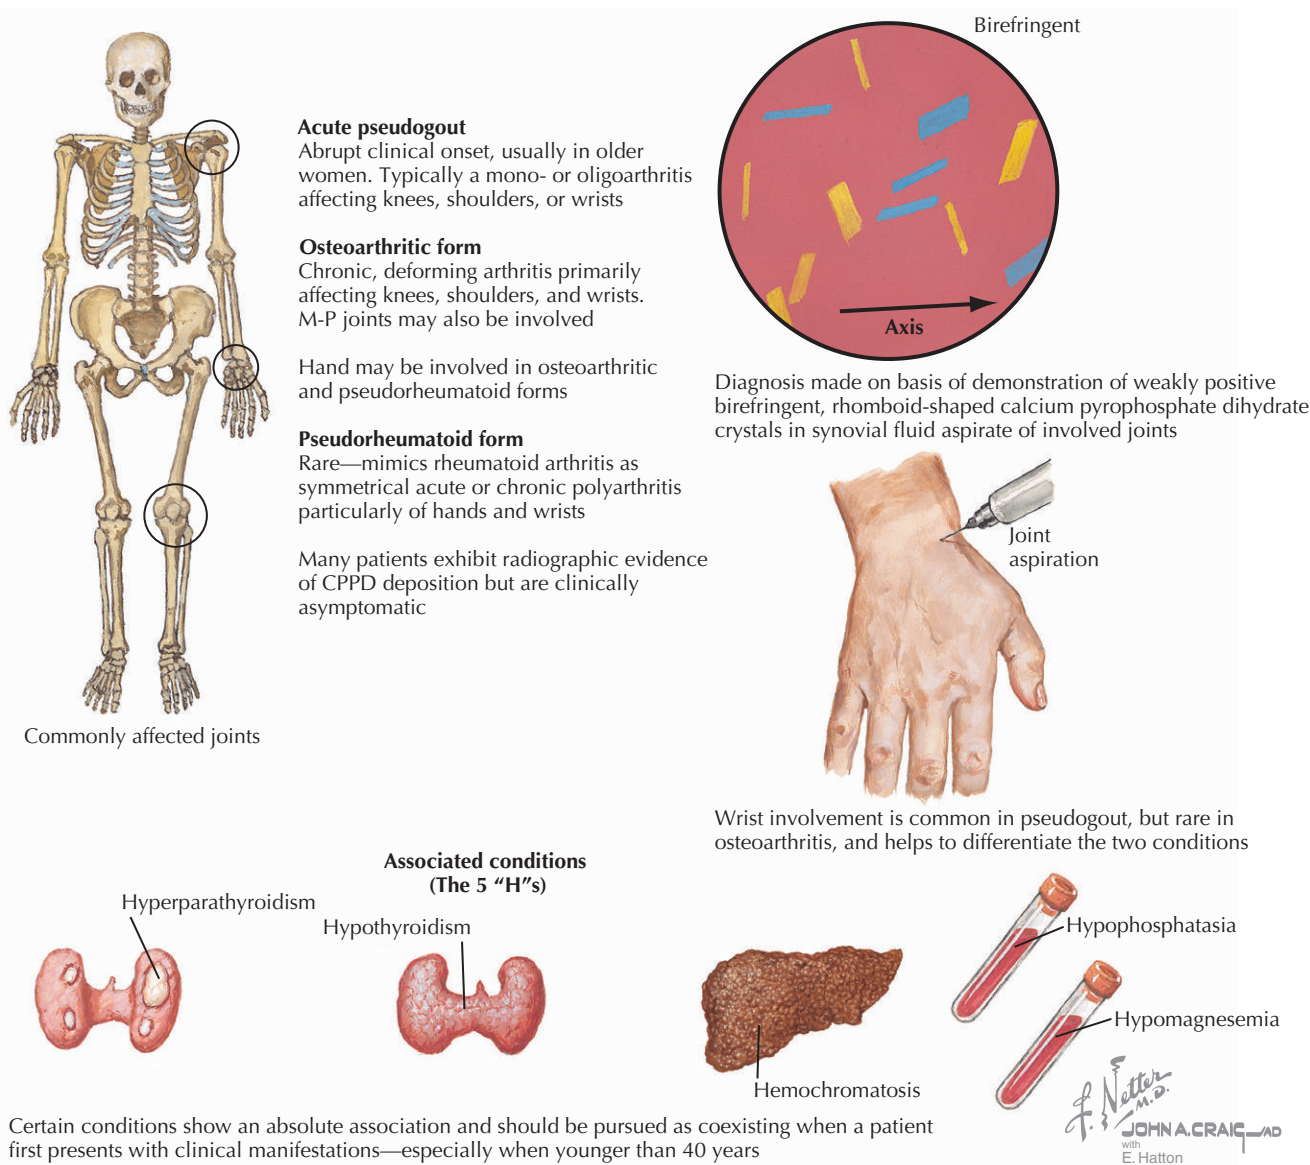

Clinical Presentation

Acute Pseudogout

Classic acute CPPD is known as *pseudogout* because of the abrupt clinical presentation of an acute monoarthritis or oligoarthritis. This form of CPPD affects older women preferentially and usually occurs in the knees, shoulders, or wrists (Fig. 147-1). Its presentation mimics that of gout (although it rarely affects the toes and fingers) or septic arthritis.

On physical exam, as in gout, the patient usually cannot move the affected joint without severe pain. Large tense joint effusions are common in knees or shoulders during the acute attack. Patients will have redness and heat over the joint and may have a low-grade fever. Laboratory findings during the acute attack may include an elevated white blood cell (WBC) count with a left shift, elevated sedimentation rate, and increased levels of other acute-phase reactants such as ferritin and C-reactive protein. The synovial fluid is usually mildly to moderately inflammatory, containing mostly polymorphonuclear leukocytes. Synovial fluid may appear grossly purulent. Radiographs may or may not show chondrocalcinosis within the involved joint (Fig. 147-2).

Figure 147-1 Pseudogout.

Osteoarthritic Calcium Phosphate Dihydrate

Patients with the osteoarthritic form of CPPD present with a chronic, sometimes deforming, arthritis primarily affecting the knees, wrists and shoulders, and metacarpophalangeal joints. Patients may describe episodic acute attacks of swelling, redness, and pain in the involved joints or a more indolent history of chronic noninflammatory pain. The physical examination reveals changes consistent with osteoarthritis, with joint crepitance, deformities, and decreased range of motion of the involved areas. The knee may have valgus deformities (“windswept knees”) instead of the more common varus deformities seen in pure osteoarthritis. Because the wrist is almost never involved in pure osteoarthritis, when wrist deformities are present in a patient with other areas of osteoarthritis, the diagnosis of

CPPD should be considered. Laboratory evaluation is generally not helpful. The sedimentation rate is usually normal. Radiographs of involved joints usually show osteoarthritis, although the presence of chondrocalcinosis, particularly in the wrist ulnar triangular fibrocartilage, may be helpful to discriminate this form of CPPD from routine osteoarthritis.

Pseudorheumatoid Calcium Phosphate Dihydrate

This rare form of CPPD can mimic rheumatoid arthritis. The presentation is a symmetrical acute or chronic polyarthritis, particularly of the hands and wrists. Serum rheumatoid factor may sometimes be positive. Occasionally, patients with this form of CPPD may be quite ill, with fever, polyarticular inflammation, and sedimentation rates

above 100 mm/hr (Westergren method). Radiographs (particularly of the hands) may discriminate this entity from classic rheumatoid arthritis.

Differential Diagnosis and Diagnostic Approach

Diagnosis of any of the forms of pseudogout can only be made by demonstration of weakly positively birefringent,

rhomboidal calcium pyrophosphate dihydrate crystals in synovial fluid obtained by aspiration of the involved joints. Most commercial laboratories can examine synovial fluid under cross-polarized compensated microscopy. However, unlike uric acid crystals, calcium pyrophosphate crystals may remain observable in synovial fluid samples for only 48 to 72 hours before redissolving, making prompt examination of synovial fluid mandatory. These crystals are much smaller than uric acid crystals (about one fourth the

diameter of a neutrophil) and may be shed into the synovial fluid as a result of another process that is primarily responsible for the joint inflammation. For this reason, the presence of calcium pyrophosphate crystals (even intracellular) in synovial fluid cannot entirely rule out the possibility of coexistent infectious arthritis. And, if the time from joint aspiration to examination of synovial fluid is prolonged, the lack of calcium pyrophosphate crystals does not rule out a role for CPPD. If a high clinical index of suspicion for infectious arthritis is present, the patient should be managed for bacterial arthritis until culture results return. Serum calcium, phosphate, and thyroid-stimulating hormone levels should be obtained in all patients with the first presentation of CPPD, and genetic markers for hemochromatosis should be pursued in the appropriate clinical situation (if other findings suggestive of hemochromatosis are present).

Management and Therapy

Acute Pseudogout

The most effective, least toxic therapy for acute pseudogout involving one or two joints is local intra-articular corticosteroid injection. A long-acting steroid preparation such as triamcinolone hexacetonide should be used. These crystalline branched-chain esters of cortisol will be present and have anti-inflammatory effects within the synovial space for 2 to 3 months. Patients with acute polyarticular pseudogout should be treated with rapidly acting nonsteroidal anti-inflammatory drugs (NSAIDs). Long-acting NSAIDs with delayed time to steady-state concentrations (piroxicam and namebutone) should be avoided. The newer cyclooxygenase-2 selective NSAIDs have not been studied for use in acute pseudogout. Low-dose oral prednisone with subsequent rapid taper may be employed in patients in whom NSAIDs are contraindicated. Oral colchicine does have some beneficial effect in acute pseudogout but should be reserved for the rare patient who cannot receive any of the other therapies discussed previously.

Osteoarthritic Calcium Phosphate Dihydrate

Patients with the osteoarthritic form of chronic disease should be managed similarly to any patient with osteoarthritis. Because of the inflammatory basis of the arthropathy, NSAIDs (not acetaminophen) should be used as first-line agents. Oral corticosteroids are usually not effective, and surgical joint replacement may be required if severe joint destruction is present.

Pseudorheumatoid Calcium Phosphate Dihydrate

Patients with pseudorheumatoid disease may be tried on an NSAID as initial therapy but frequently require moder-

ate doses of oral corticosteroids for control of their joint disease. Unlike true rheumatoid arthritis, this form of CPPD tends to occur in the form of acute attacks that spontaneously resolve after weeks to months, thus allowing for episodic use of corticosteroids.

Future Directions

The therapies for control of CPPD disease are less than optimal. Because the biochemical defects that result in the formation of calcium pyrophosphate dihydrate crystals are unknown, no preventative pharmacologic agents are available for this condition. Ongoing research into the biochemistry and physical chemistry of CPPD should result in effective control of this disease, similar to what has already been achieved in the management of gout.

BASIC CALCIUM PHOSPHATE CRYSTALS

Etiology and Pathogenesis

BCP crystals (previously thought to be only calcium hydroxyapatite) have been isolated from patients with calcific periarthritis, tendonitis, bursitis, and occasionally acute monoarthritis. On rare occasions, they have been associated with a chronic arthritis or periarthritis, but in these cases, it is not completely clear whether their presence is causative or an epiphenomena. BCP crystals are not birefringent and can only be reliably identified by transmission or scanning electron microscopy. They are much smaller than sodium urate or CPPD. Their crystalline shape and chemical formula depend on the calcium-to-phosphate-to-water ratio (Table 147-1).

The pathogenic mechanism of how and whether these crystals cause an inflammatory response is inconclusive. In some cases (discussed later), such as hydroxyapatite pseudopodagra and Milwaukee shoulder syndrome, high intrasynovial neutrophil counts may be seen along with intracellular ingestion of crystals (by electron microscopy), strongly suggesting that these BCP crystals can cause primary acute inflammation. On the other hand, 30% to 60% of osteoarthritic knee synovial fluids have been found to contain BCP crystals with low neutrophil counts,

Table 147-1 Basic Calcium Phosphate Crystals

Crystal	Chemical Formula	Ca/P Ratio
Hydroxyapatite	$\text{Ca}_5(\text{PO}_4)_3\text{OH}\cdot 2\text{H}_2\text{O}$	1.67
Octacalcium phosphate	$\text{Ca}_8\text{H}_2(\text{PO}_4)_6\cdot 5\text{H}_2\text{O}$	1.33
Tricalcium phosphate (whitlockite)	$\text{Ca}_3(\text{PO}_4)_2$	1.50

suggesting that these crystals are “fellow travelers” with the chronic loss of cartilage of this disease.

Clinical Presentation

The three most common presentations of BCP arthropathy are calcific periarthritis, pseudopodagra and other acute monoarthropathies, and Milwaukee shoulder syndrome. Calcifications around the shoulder rotator cuff are very common radiographically and are almost always made up of coalesced BCP crystals. Attacks of acute pain, redness, swelling, and heat around these areas are the hallmark of symptomatic calcific periarthritis. Most patients have marked limited range of motion of the shoulder, particularly in abduction, and point tenderness just below the lateral curve of the acromion. Pseudopodagra presents as a gout-like attack of acute inflammation of the great toe metatarsophalangeal joint. Unlike gout, pseudopodagra is more common in women than in men. Acute inflammatory effusions of other joints where BCP crystals have been found are less common but do occur, involving the knee, hip, ankle, wrist, or elbow. Milwaukee shoulder is a chronic destructive cuff arthropathy in older women in which BCP crystals have been implicated as pathogenic. This entity presents with either chronic or acute rupture (sometimes with hemarthrosis) of the rotator cuff and classic physical exam signs of cuff rupture, with the patient unable to keep the arm in active abduction at 70 degrees.

Differential Diagnosis

The differential diagnosis of the BCP crystal diseases is the same as in acute gout in regard to the acute arthropathies caused by these crystals. As in gout, it is important to rule out sepsis as a cause of the arthropathy. In fact, because BCP crystals are not birefringent, patients should be treated with antibiotics until cultures return. Whether this treatment is administered intravenously with an inpatient admission or orally is dependent on clinical judgment. If the patient is febrile, has an elevated peripheral WBC count, or has any other signs of toxicity, an inpatient admission is justified.

Diagnostic Approach

Because the BCP crystals are not visible under polarized light and synovial cell counts may be normal, examination of synovial fluid may be normal. Because the involvement may be periarticular and not intra-articular, the mainstay of diagnosis is planar radiography or, in the case of Milwaukee shoulder, magnetic resonance imaging (MRI) of the rotator cuff. If calcification is seen in the area of patient complaint and correlates with the physical examination, then the diagnosis can be strongly supported. MRI evidence of complete rotator cuff tear along with cuff cal-

cification is strong evidence for the diagnosis of Milwaukee shoulder in an elderly woman.

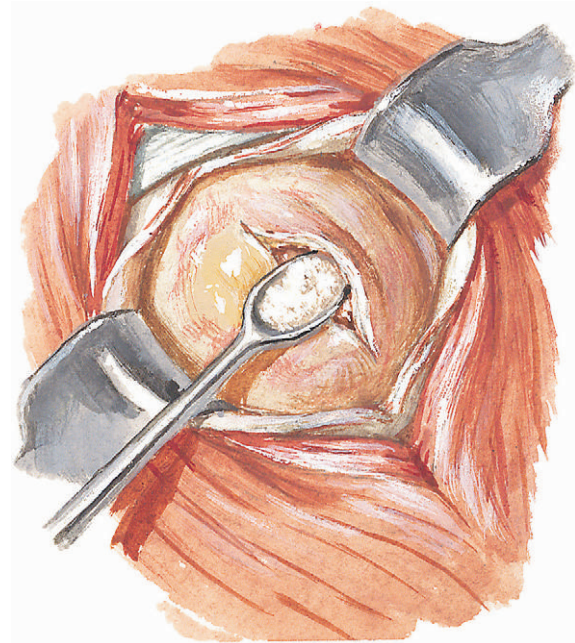

Management and Therapy

Unfortunately, other than calcific periarthritis, which responds to aspiration and corticosteroid injection, to NSAIDs, or in medically unresponsive cases, to surgical removal (Fig. 147-3), there is no effective therapy for the other entities of BCP crystal disease. Intra-articular steroids or NSAIDs should be attempted for these other forms of disease, but physician and patient expectations for pain relief should be low to moderate. Milwaukee shoulder

Figure 147-3 Calcium Crystal Diseases.

Aspiration of calcific shoulder bursitis

Surgical removal of calcium deposit in shoulder bursae

in many cases can only be treated with surgical reconstruction of the rotator cuff.

Future Directions

Similar to CPPD, the biochemical defects that result in the formation of BCP crystals are unknown, and no preventative pharmacologic agents are available for this condition. Like CPPD, the answer will lie in better understanding the physical chemistry and biologic effects of these crystals and how to prevent formation or dissolve BCP crystals.

Autoinflammatory Syndromes

Introduction

The inherited autoinflammatory syndromes are a group of rare genetic disorders characterized by recurrent bouts of systemic inflammation in the absence of autoantibodies, antigen-specific T cells, or identifiable infection. Most of these diseases fall into the category of hereditary periodic fever disorders, which include familial Mediterranean fever (FMF), tumor necrosis factor receptor-associated periodic syndrome (TRAPS), hyperimmunoglobulin D syndrome (HIDS) with periodic fever, and the cryopyrinopathies. Recently, the genetic basis of these disorders has been elucidated, resulting in improved understanding of pathophysiology, more accurate diagnosis, and newer targeted therapies.

Additional rare monogenic inflammatory disorders are often included in the category of autoinflammatory syndromes. These include a disease characterized by pyogenic arthritis with pyoderma gangrenosum and acne and a disease characterized by granulomas known as Blau syndrome. These disorders, which are not discussed in this chapter, are characterized by recurrent inflammation and are pathogenetically associated with, but not clinically related to, the periodic fevers. Other more common inflammatory diseases, including Crohn's disease and gout, have also been classified as autoinflammatory diseases, and are discussed elsewhere in this book.

Etiology and Pathogenesis

Identification of the responsible genes for the inherited autoinflammatory syndromes has begun to elucidate the etiology of these disorders. A common theme underlying the pathogenesis of these diseases is dysregulation of innate immunity. Each of the mutations results in increased cytokine-mediated inflammation at various steps of innate immune pathways (Fig. 148-1).

The innate immune system is an evolutionarily ancient part of the immune system that allows for a rapid and relatively nonspecific response to infection or danger signals, but does not require prior exposure to the inciting agent. Like the adaptive immune system, there are cellular and humoral factors that make up the innate immune response. Instead of lymphocytes, the primary cells involved are those of the myeloid lineage, including monocyte-macrophages and granulocytes. These cells migrate to the site of infection under the direction of chemokine-

chemoattractants and are able to phagocytose pathogens. Monocytes and macrophages possess extracellular and intracellular pathogen-sensing receptors called toll-like receptors and nucleotide-binding domain leucine-rich repeat (NLR) proteins that detect danger signals or pathogen-associated molecules such as lipopolysaccharide, bacterial-derived ribonucleic acid (RNA), double-stranded RNA, and peptidoglycan-derived products. Activation of these innate mediators leads to the production and release of cytokines such as interleukin-1 β (IL-1 β) and tumor necrosis factor- α (TNF- α). These humoral factors have direct and indirect effects on pathogen survival and attract additional inflammatory cells to the site of inflammation.

Although mutations in genes involved in the adaptive immune system often result in immunodeficiency, mutations in several genes that regulate the innate immune response result in increased or uncontrolled cytokine-mediated inflammation with associated fever and tissue specific symptoms. One common result of chronic

Figure 148-1 Innate Immune System Pathways Involved in the Autoinflammatory Syndromes.

J. Perkins
MS, MFA, CMI

unregulated inflammation is the development of amyloidosis, a comorbidity observed at different frequencies in each of the autoinflammatory syndromes. The mechanisms underlying the specific clinical features of each syndrome have not yet been elucidated.

Genetic and Molecular Basis

Familial Mediterranean Fever

MEFV, the gene mutated in FMF, encodes the protein pyrin. Pyrin is mainly expressed as a cytoplasmic protein in neutrophils and monocytes. Its exact role in the clinical manifestations of FMF has not been fully elucidated, but pyrin has been associated with caspase-1 regulation and therefore with IL-1 β processing. Mutations in *MEFV* have also been associated with other inflammatory diseases, such as Behçet's disease, and may also have a modifying effect on the severity of rheumatoid arthritis.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

TRAPS results from mutations in the *TNFRSF1A* gene, which encodes TNFRSF1A, the 55-kD receptor for tumor necrosis factor (TNF). In some cases, mutations cause impaired receptor shedding, leading to increased or prolonged signaling through the TNF receptor and to a reduced generation of soluble TNF-receptor (sTNFRSF1A), the natural antagonist of TNF- α . However, not all patients show defective receptor shedding, suggesting additional mechanisms behind the fever attacks in TRAPS.

Mutations with a low penetrance may lead to more general inflammatory disorders.

Hyper-Immunoglobulin D syndrome (HIDS)

Mutations in the gene that codes for mevalonate kinase (MVK) were found to be the cause of HIDS. Previously, mutations in the same gene were associated with a more severe phenotype of MVK deficiency known as mevalonic aciduria. MVK is an enzyme in the cholesterol biosynthesis pathway. It is unclear how the metabolic defect leads to the clinical manifestations of HIDS, but evidence suggests that the shortage of specific isoprenylated proteins can induce IL-1 β -mediated inflammation.

Cryopyrinopathies

Cryopyrin is coded for by the gene *NLRP3* (*CIAS1*). Cryopyrin, an intracellular NLR protein expressed in monocytes and neutrophils, shares some structural features with pyrin and has also been implicated in the regulation of cytokine production, particularly IL-1 β , by activating caspase-1. Cryopyrin and other intercellular adaptor proteins form a protein complex known as the inflammasome, which has been implicated in responses to molecules associated with pathogens and danger signals such as gout crystals. Mutations appear to gain function, resulting in increased cytokine-mediated inflammation.

Clinical Presentation

Patients with autoinflammatory syndromes present with episodes of fever alternating with disease-free periods. Systemic inflammatory symptoms involving the joints, skin,

Figure 148-2 Patient Evaluation and Clinical Presentation.

eyes, or abdomen are also characteristic of episodes. Each of these disorders has unique clinical features, which when combined with appropriate genetic testing, may aid in making the correct diagnosis and guide the choice of specific therapies (Figs. 148-2, 148-3, and 148-4).

Clinical Features of Individual Syndromes

Familial Mediterranean Fever (FMF)

FMF is the most prevalent and well known of the hereditary autoinflammatory diseases. It affects more than 10,000

patients worldwide, mostly from the Mediterranean area, including Armenians, Arabs, Turks, and Sephardic Jews. It is almost always inherited in an autosomal recessive fashion. Patients with FMF suffer from recurrent fever attacks with acute monoarthritis, abdominal pain, and serositis such as peritonitis, pleuritis, or pericarditis. Some patients have an erysipelas-like rash, and a few develop chronic erosive arthritis. Symptoms usually present in childhood, with about 80% of patients having their first attack before the age of 20 years. While the attacks usually last 1 to 3 days, patients are well between attacks, with symptom-free

Figure 148-3 Cutaneous Findings.

FMF, familial Mediterranean fever; HIDS, hyper-IgD syndrome; TRAPS, tumor necrosis factor receptor–associated periodic syndrome.

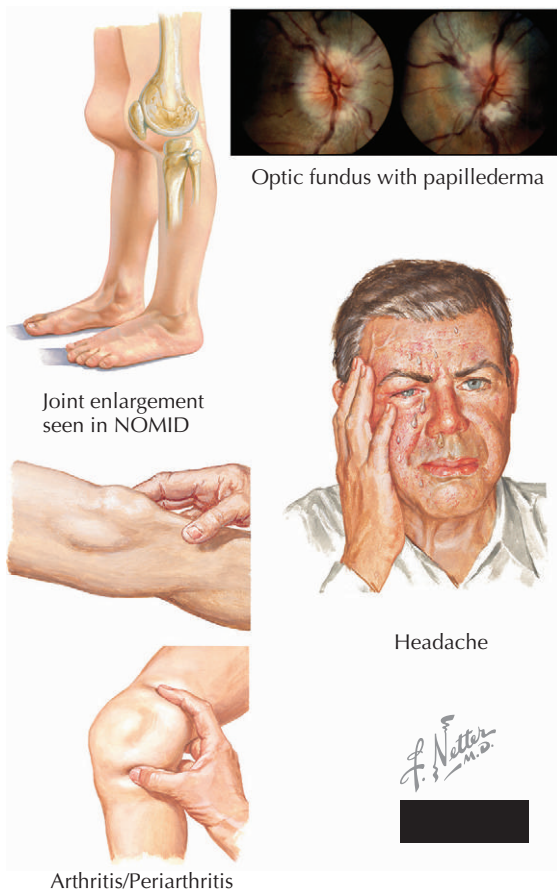

intervals sometimes lasting many months or even years. Long-term prognosis depends on the development of amyloidosis, which can result in renal failure.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome (TRAPS)

TRAPS (MIM#142680) was originally called familial Hibernian fever when it was first reported in 1982 in a large family of Irish and Scottish descent. Since then it has been described in more than 20 families from many ethnic

groups. TRAPS is transmitted in an autosomal dominant manner, and most patients have their first symptoms in childhood, but the age of onset is between a few weeks and 50 years of age. TRAPS episodes include fever, conjunctivitis, periorbital swelling, migratory rash, abdominal pain, myalgias, and monoarthritis lasting several days to weeks and recurring a few times a year. Attacks can be set off by emotional stress, minor infections, or vigorous exercise, but often are unprovoked. The main determinant for poor prognosis is the development of amyloidosis.

Figure 148-4 Joint and Central Nervous System Findings.

Hyper-Immunoglobulin D Syndrome (HIDS)

HIDS is an autosomal recessive disease affecting about 200 patients worldwide. HIDS is relatively common in the Netherlands owing to a founder effect. The recurrent fever attacks of HIDS last 3 to 5 days and usually return with some periodicity every 3 to 6 weeks. Episodes are almost always characterized by painful cervical lymphadenopathy as well as abdominal pain, vomiting, and diarrhea. Other symptoms, including skin rashes, mucosal ulcers, myalgias, arthralgias, and headaches, may also occur. Ninety percent of HIDS patients will experience their first attack within the first year of life, but the fever episodes tend to become less frequent and less severe with age. Usually, there is no obvious trigger, but episodes are occasionally provoked by infection, vaccinations, or minor trauma. Although fever may disappear after a few days, malaise and arthritis may take longer to resolve. Between attacks, patients are well.

Cryopyrinopathies

The cryopyrinopathies include familial cold auto-inflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID). These diseases were previously thought of as distinct disorders, but now they are considered a spectrum of one systemic inflammatory disease with varying severity. The exact prevalence of these rare autosomal dominant inherited diseases is unknown; however, more than 300 patients with FCAS, MWS, and NOMID have been reported worldwide.

FCAS patients present with recurrent episodes of urticaria-like rash, fever, chills, and joint pain precipitated by generalized cold exposure. Attacks are also characterized by conjunctivitis, sweating, drowsiness, headache, extreme thirst, and nausea. Symptoms usually develop 1 to 2 hours after exposure, peak about 6 to 8 hours later, and resolve in less than 24 hours. Although significant cold exposure can trigger attacks, air conditioning is a common precipitant of episodes. Many patients have daily rash and fatigue that begin in the afternoon, peak at night, and resolve by morning, regardless of cold exposure during the day. Ninety-five percent of patients experience symptoms by 6 months of age, and most present with neonatal rash.

Attacks associated with MWS are very similar to those with FCAS, except episodes often have no clear trigger. Occasionally, attacks may be precipitated by cold, heat, exercise, and stress. Acute episodes last less than 24 to 48 hours, but there are often daily symptoms of rash, fatigue, and joint pain. Disease symptoms present in early childhood, but sensorineural deafness, one characteristic feature of MWS, develops in up to two thirds of patients in later childhood and progresses through adulthood. Systemic amyloidosis develops in up to 25% of MWS patients and often leads to renal failure in adulthood.

NOMID, also known as chronic infantile neurologic cutaneous articular syndrome, is the most severe of the cryopyrin-associated phenotypes. Patients present in the neonatal period with urticaria-like rash but also develop chronic multisystem inflammatory symptoms, including persistent fever, chronic meningitis leading to neurologic impairment and complications, and progressive joint and cartilage abnormalities. One characteristic finding is cartilage overgrowth around the knee. Patients have evidence of chronic inflammation but also have intermittent acute flares. Most cases are sporadic, but autosomal dominant inheritance has been reported. Amyloidosis has been reported in older patients.

Differential Diagnosis

There are a few apparently nonhereditary conditions that also present with recurrent fever and inflammation, such as Behçet's disease and periodic fever with aphthous

stomatitis, pharyngitis, and adenitis (PFAPA). Behçet's disease is characterized by recurrent mucosal ulcers (oral and genital), uveitis and other inflammatory eye diseases, and erythema nodosum, as well as other rashes. It is prevalent in the same ethnic populations as FMF. Onset occurs usually in childhood or young adulthood, and although there is some association with human leukocyte antigen types, there is no clear genetic association. The pathophysiology of Behçet's disease is not well understood.

PFAPA is the most common cause of periodic fever in children. It is a nonhereditary autoinflammatory disease characterized by recurrent episodes of fever with one or more inflammatory symptoms including pharyngitis, cervical adenitis or adenopathy, and aphthous stomatitis. Additional symptoms are similar to those seen in many of the hereditary disorders, including headache, malaise, abdominal pain, arthralgia, and myalgia. Onset is usually between 2 and 5 years of age, and attacks last between 3 and 6 days. Episodes are often extremely predictable, occurring every 3 to 8 weeks, and are separated by completely asymptomatic periods with normal growth and development. Unlike the hereditary disorders, this condition is self-limited, and most children with PFAPA have a complete remission after 2 to 6 years of symptoms with no long-term morbidity. PFAPA symptoms are usually sensitive to systemic corticosteroid therapy.

Diagnostic Approach

Periodic fever syndromes are all characterized by recurrent inflammation. The first diagnostic step, therefore, is to examine the patient during an attack and to document fever, systemic symptoms, and acute-phase response including leukocytosis, erythrocyte sedimentation rate, C-reactive protein, or serum amyloid A protein. (This assay is unfortunately not commercially available in the United States.) A careful evaluation should be performed for occult infection. Another characteristic of the periodic fever syndromes (except NOMID) is recovery between attacks. If the patient does not fully recover, chronic or recurrent infections, autoimmune diseases, and occult malignancies must be ruled out.

In some cases, the clinical findings, such as age of onset, length of attacks, precipitating factors, associated symptoms, and family history, are adequate to distinguish a known periodic fever syndrome. In patients with clinical findings consistent with HIDS, serum immunoglobulin D and urine mevalonate may provide additional support for this diagnosis. However, in many patients, there is no straightforward diagnosis, so the combination of epidemiology, signs, symptoms, and disease course can lead to a tentative diagnosis, which may then be supported by genetic testing. Appropriate genetic testing is available at several commercial laboratories internationally, but in some cases, comprehensive testing of certain genes can only be performed in specialized research labs. Unfortu-

nately, there are some patients with classic presentation of each of the autoinflammatory syndromes who do not have identifiable mutations.

Management and Therapy

Avoiding Treatment Errors

The diagnosis of an autoinflammatory syndrome should be confirmed when possible with genetic testing. Discussion with or referral to a specialist is advisable. Adequate response to therapy includes decreased frequency or severity of episodes and decreased laboratory markers of chronic inflammation, such as C-reactive protein and serum amyloid A that may lead to amyloidosis.

Optimum Treatment

Because of the relative rarity of the disorders discussed in this chapter, there are no regulatory agency–approved therapies for most of these diseases, and knowledge of therapy comes from anecdotal case reports and case series of a few patients.

Familial Mediterranean Fever

The standard approved treatment of FMF is colchicine, which prevents inflammatory attacks in about 60% of the patients and significantly reduces the number of attacks in another 20% to 30%. Colchicine treatment has been shown to reduce the incidence of amyloidosis from more than 60% to less than 5%. Its mode of action in FMF is poorly understood but may be because of its effects on neutrophil motility. Nonsteroidal anti-inflammatory drugs (NSAIDs) are often used for pain.

Tumor Necrosis Factor Receptor–Associated Periodic Syndrome

TRAPS can be treated with NSAIDs and glucocorticoids to alleviate the symptoms associated with the flare of disease, but these drugs do not affect the frequency of attacks or the development of amyloidosis. Anecdotal experience with etanercept and recombinant interleukin-1 (IL-1) receptor antagonist has been more successful, resulting in a reduction in frequency, duration, and severity of attacks in many patients and reversal of amyloidosis in some.

Hyper-Immunoglobulin D Syndrome

HIDS is resistant to therapy. Colchicine, thalidomide, and immunosuppressive agents seem largely ineffective. Treatment with simvastatin may induce a modest improvement, and there have been case reports of successful treatment with etanercept. Recently, studies have begun with the recombinant IL-1 receptor antagonist.

Cryopyrinopathies

Treatment, until recently, has been limited to avoidance of cold exposure and NSAIDs for FCAS patients, and

high-dose steroids for more severe cryopyrinopathy patients. Recently, numerous case reports and a few controlled studies have demonstrated the effectiveness of the IL-1 targeted therapies in all three diseases, pointing to an essential role for IL-1 in these disorders.

Future Directions

In the past decade, there have been significant advances in diagnosis and treatment of the periodic fever disorders. The identification of the genes responsible for these disorders has allowed for better characterization of the clinical features, improved diagnosis, and novel treatment. Cytokine-targeted therapies hold great promise for these patients. Further study of this field will likely yield additional diseases, genes, and inflammatory pathways that may be involved in more common inflammatory diseases such as gout.

Vasculitis

Introduction

The vasculitides are a heterogeneous group of disorders characterized by leukocyte infiltration, inflammation, and destruction of blood vessel walls. The inciting events causing inflammation vary among disease groups and are largely unknown (Box 149-1). In general, infectious and immunologic abnormalities are the predominant cause postulated. A genetic predisposition to disease is likely in some forms of vasculitis. Blood vessels of all sizes are involved, from the large vessels (aorta) to the tiniest of veins (postcapillary venules). Consequently, a myriad of clinical and pathologic presentations occurs. Although specific diseases may have a predilection for certain organs (e.g., coronary vessel involvement in Kawasaki's disease), most vasculitides, especially the small vessel vasculitides, affect virtually any vascular bed. The clinical diagnosis involves careful clinical assessment, specific laboratory and radiographic tests, and tissue samples of targeted organs. The internationally accepted Chapel Hill Consensus Conference definitions of the systemic vasculitides allow for the standardized characterization of the various systemic vasculitides (Table 149-1).

The most significant recent advances in vasculitis are in the use of the immunobiologicals for treatment (i.e., rituximab and infliximab) and in the continued struggle toward minimizing toxicities of standard therapies. Basic and clinical research advances have increased our understanding of the pathogenetic mechanisms of the systemic vasculitides and subsequently given some insight into improving remission rates, alternative therapies for resistant disease, reducing the toxicities of therapy, predicting relapse, and identifying prognostic markers of long-term outcome.

Etiology and Pathogenesis

The unifying feature of all vasculitides is the activation of inflammatory mediators within vessel walls. Virtually all components of the effector arm of the immune system may be affected. For instance, T-cell-mediated inflammation has been implicated as a causative feature in giant cell arteritis and Takayasu's arteritis. In immune complex-mediated vasculitides, circulating antibody-antigen complexes deposit within the vessel wall or form within the vessel wall itself (in situ immune complex formation). Direct antibody binding to antigens integral to vessel walls occur in Goodpasture's syndrome secondary to anti-glomerular basement antibodies, and in Kawasaki's disease because of antiendothelial antibodies. Regardless of how they are deposited within the vasculature, immune complexes, complement, coagulation, and kinin systems act as

inflammatory (phlogistic) stimulants for neutrophils and monocytes. These cells then release toxic oxygen metabolites and enzymes that damage the vasculature.

Pauci-immune vasculitides are characterized by lacking either immune complexes or direct antibody binding to the vessel wall. They are closely associated with antineutrophil cytoplasmic antibodies (ANCA). Although the role of ANCA is not certain, a large body of evidence suggests that these antibodies are pathogenic agents (Fig. 149-1). In the presence of stimulatory cytokines, ANCA antigens (myeloperoxidase and proteinase 3) are translocated to the surface of neutrophils and monocytes, allowing binding of ANCA to their target antigens. Alternatively, release of these antigens from leukocytes and endothelial cells may result in damage from immune complex formation with ANCA or by the direct effect of leukocyte serine protein, causing endothelial cell death.

Table 149-1 Names and Definitions of Vasculitis Adopted by the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis

Name	Large Vessel Vasculitis*
Giant cell (temporal arteritis)	Granulomatous arteritis of the aorta and its major branches, with a predilection for the extracranial branches of the carotid artery. Often involves the temporal artery. Usually occurs in patients older than 50 years and often is associated with polymyalgia rheumatica
Takayasu's arteritis	Granulomatous inflammation of the aorta and its major branches. Usually occurs in patients younger than 50 years
	Medium-Sized Vessel Vasculitis*
Polyarteritis nodosa (classic polyarteritis nodosa)	Necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules. Kawasaki's disease arteritis involving large, medium-sized, and small arteries and associated with mucocutaneous lymph node syndrome. Coronary arteries are often involved. Aorta and veins may be involved. Usually occurs in children
	Small Vessel Vasculitis*
Wegener's granulomatosis ^{†‡}	Granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels, e.g., capillaries, venules, arterioles, and arteries. Necrotizing glomerulonephritis is common
Churg-Strauss syndrome ^{†‡}	Eosinophil-rich and granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small to medium-sized vessels and associated with asthma and blood eosinophilia
Microscopic polyangiitis (microscopic polyarteritis) ^{†‡}	Necrotizing vasculitis with few or no immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles. Necrotizing arteritis involving small and medium-sized arteries may be present. Necrotizing glomerulonephritis is very common. Pulmonary capillaritis often occurs
Henoch-Schönlein purpura [‡]	Vasculitis with immunoglobulin A–dominant immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles. Typically involves the skin, gut, and glomeruli and is associated with arthralgias or arthritis
Essential cryoglobulinemic vasculitis [‡]	Vasculitis with cryoglobulin immune deposits affecting small vessels, i.e., capillaries, venules, or arterioles, and associated with cryoglobulins in serum. Skin and glomeruli are often involved
Cutaneous leukocytoclastic angiitis	Isolated cutaneous leukocytoclastic angiitis without systemic vasculitis or glomerulonephritis

* *Large artery* refers to the aorta and the largest branches directed toward major body regions (e.g., to the extremities and the head and neck); *medium-sized artery* refers to the main visceral arteries (e.g., renal, hepatic, coronary, and mesenteric arteries); and *small artery* refers to the distal arterial radicals that connect with arterioles (e.g., renal arcuate and interlobular arteries). Note that some small and large vessel vasculitides may involve medium-sized arteries; but large and medium-sized vessel vasculitides do not involve vessels smaller than arteries.

[†] Strongly associated with antineutrophil cytoplasmic autoantibodies (ANCA).

[‡] May be accompanied by glomerulonephritis and can manifest as nephritis or pulmonary-renal vasculitic syndrome.

Adapted from Jennette JC, Falk RJ, Andrassy K, et al: *Nomenclature of systemic vasculitides. Proposal of an international consensus conference. Arthritis Rheum 37(2):187-192, 1994.*

Box 149-1 Causes of Vasculitis

- Direct infection of vessels
- Immunologic injury
 - Immune complex mediated
 - Direct antibody attack mediated
 - Antineutrophil cytoplasmic autoantibody associated and possibly antineutrophil cytoplasmic antibody mediated
 - Cell mediated
- Unknown

Clinical Presentation

Most patients present with constitutional symptoms, including fever, anorexia, fatigue, weight loss, and arthralgias. Organ-specific manifestations may be strongly suggestive of vasculitis, but these signs may lag for weeks

behind the systemic complaints. The clinical features are markedly variable and depend on the type of vasculitis, the size of involved vessels, and the organs affected.

The large vessel vasculitides typically present with ischemia of the involved tissues. The most common symptom seen with Takayasu's arteritis is claudication, particularly in the upper extremities, with absent or asymmetrical pulses and bruits. Renovascular hypertension develops in 40% of patients. Important epidemiologic features include the predominance of Takayasu's arteritis in women and in those younger than 50 years. Giant cell arteritis, on the other hand, is usually seen in patients older than 50 years, who have headache, jaw claudication, swollen and tender temporal arteries, and vision loss. About half of patients with giant cell arteritis have polymyalgia rheumatica.

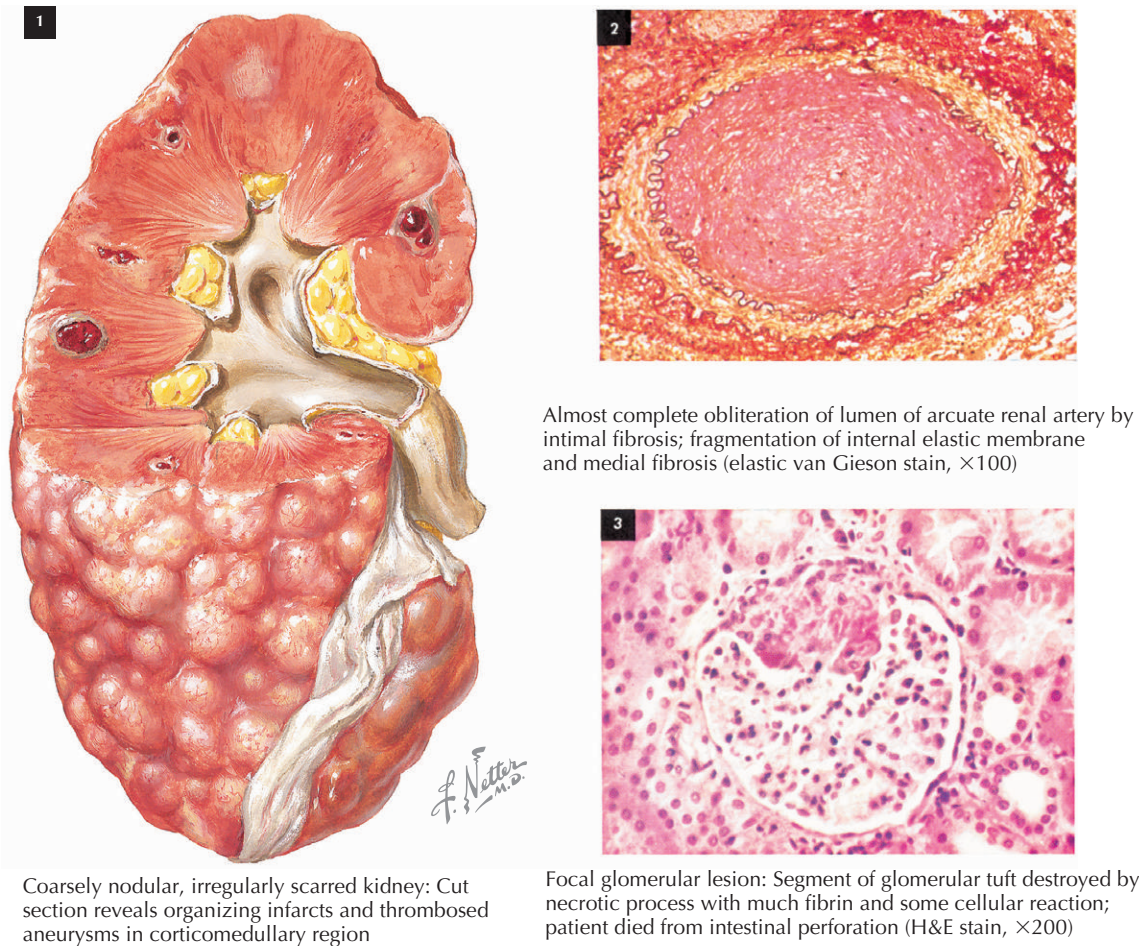

Medium vessel vasculitides often manifest with infarctions of affected organs. Polyarteritis nodosa causes

Figure 149-1 Vasculitis.

ischemia involving the vasa nervosum resulting in mono-neuropathies and polyneuropathies. Aneurysms and infarctions of the renal circulation result in renal insufficiency and hypertension, whereas disease in other vascular beds, such as the mesentery, results in symptoms of bowel ischemia (Fig. 149-2). Many cases of polyarteritis nodosa are associated with hepatitis B, and it is considered a disease of middle-aged or older adults, with a peak in the sixth decade of life. There appears to be a 1.5 : 1 male predominance for polyarteritis nodosa. Alternatively, Kawasaki's

disease occurs almost exclusively in children and is characterized by involvement of the axillary, iliac, and coronary vessels. Previously referred to as the mucocutaneous lymph node syndrome, the cardinal features include fever, conjunctivitis, adenopathy, mucosal lesions, and a desquamating rash.

Small vessel vasculitis is the most common of the vasculitides and can be classified as immune complex mediated (e.g., systemic lupus erythematosus, Henoch-Schönlein purpura [HSP]) or as pauci-immune. The pauci-immune

Coarsely nodular, irregularly scarred kidney: Cut section reveals organizing infarcts and thrombosed aneurysms in corticomedullary region

Almost complete obliteration of lumen of arcuate renal artery by intimal fibrosis; fragmentation of internal elastic membrane and medial fibrosis (elastic van Gieson stain, $\times 100$)

Focal glomerular lesion: Segment of glomerular tuft destroyed by necrotic process with much fibrin and some cellular reaction; patient died from intestinal perforation (H&E stain, $\times 200$)

Box 149-2 Signs and Symptoms of Necrotizing Small Vessel Vasculitis

- Cutaneous purpura, nodules, and ulcerations
- Peripheral neuropathy (mononeuritis multiplex)
- Abdominal pain and blood in stool
- Hematuria, proteinuria, and renal insufficiency
- Hemoptysis and pulmonary infiltrates or nodules
- Necrotizing (hemorrhagic) sinusitis
- Myalgias and arthralgias
- Muscle and pancreatic enzymes in blood
- Iritis and uveitis

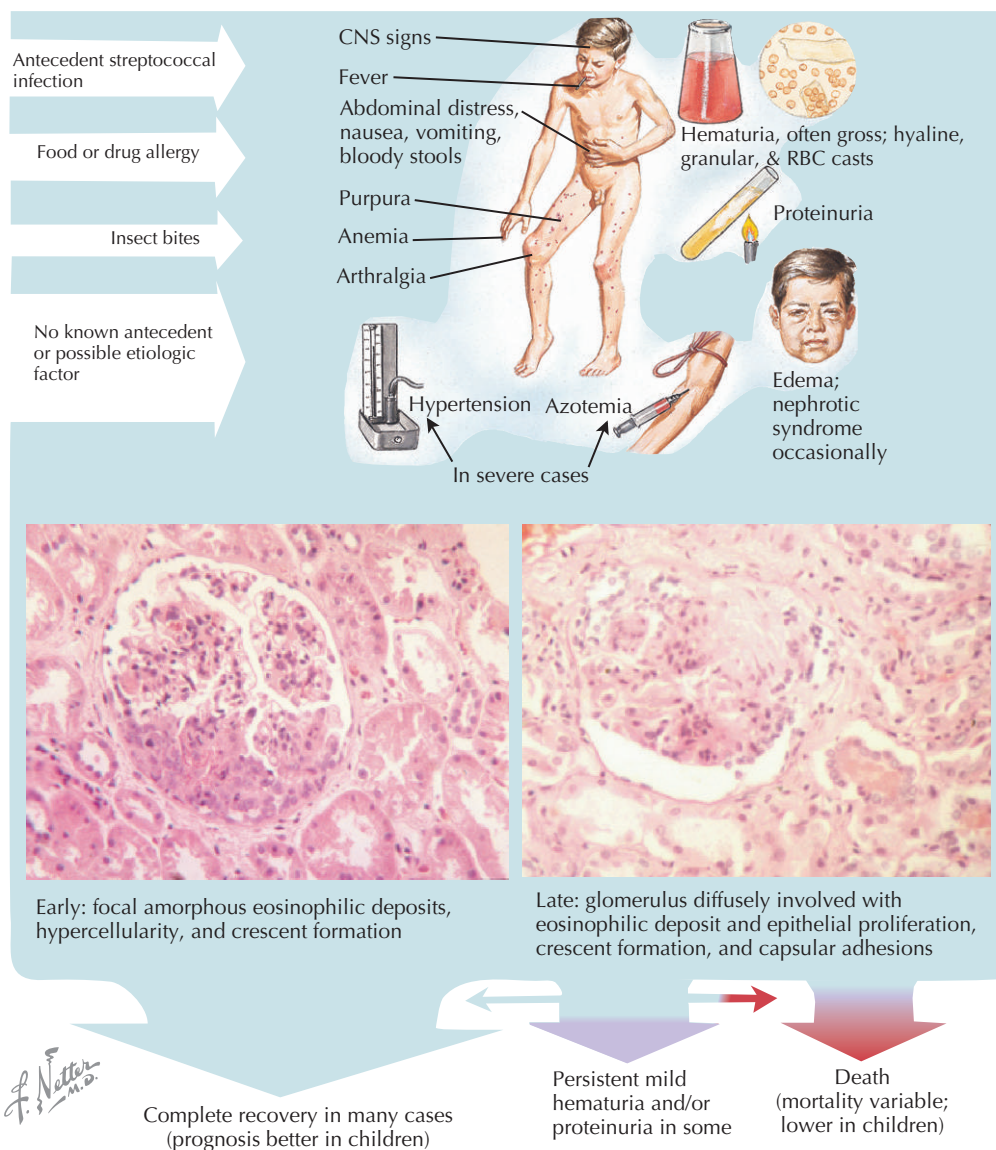

nomenclature results from the paucity or lack of immune complex deposition viewed by indirect immunofluorescence microscopy of affected tissues.

These diseases are typically associated with ANCA and include Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis. Patients can present with inflammation of single or multiple organs. Many patients present with skin disease caused by leukocytoclastic vasculitis. The cutaneous manifestations of dermal vasculitis include purpura, livido reticularis, nodules, ulcers,

and hives. Similarly, many patients present with kidney disease because of the small blood vessels that make up the glomerulus, resulting in glomerulonephritis. Glomerular inflammation results in hematuria, proteinuria, hypertension, and in some cases, rapidly progressive renal insufficiency (Box 149-2).

The most common cause of a renal-dermal vasculitic syndrome in adults is the small vessel vasculitis associated with ANCA (ANCA-SVV), especially microscopic polyangiitis. In children, the most common systemic vasculitis that causes a renal-dermal vasculitic syndrome is HSP, frequently occurring after a respiratory tract infection. HSP is characterized by cramping abdominal pain, purpura, and arthralgias (Fig. 149-3). Cryoglobulinemia, another cause of renal dermal vasculitic syndrome, has a significant association with hepatitis C.

Glomerulonephritis and pulmonary disease are found in Goodpasture's syndrome (Fig. 149-4), Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyangiitis. Respiratory symptoms range from fleeting pulmonary infiltrates to gross hemoptysis. Many patients with small vessel vasculitis have upper respiratory

Figure 149-3 Nephropathy in Anaphylactoid Purpura (Henoch-Schönlein's Disease).

symptoms, including sinus pain, epistaxis, and occasional stridor from tracheal involvement. Pulmonary involvement in Wegener's granulomatosis results in nodules and cavities. Churg-Strauss syndrome less frequently has renal involvement. Asthma is one of the disease-defining findings; allergic rhinitis is also a common finding.

Differential Diagnosis

The systemic inflammatory nature of the vasculitic process and the shared elements of the vasculitides in general often represent a diagnostic dilemma. Diseases in the differential diagnosis include systemic infections such as endocarditis, bacteremia with sepsis, and other connective tissue forms of vascular illness.

This is compounded by the fact that many of the features of the vasculitides are nonspecific. Purpura, consid-

ered a classic sign, may be seen in meningococcemia, viral illnesses, and thrombocytopenic disorders. Pulmonary abnormalities can be difficult to differentiate from respiratory infections. Glomerulonephritis can be seen with other primary renal diseases such as membranoproliferative glomerulonephritis and immunoglobulin A (IgA) nephropathy. Mononeuritis multiplex is one of the more specific findings in vasculitis, and only rarely can be mimicked by asymmetric presentations of other neuropathies such as diabetic neuropathy.

Diagnostic Approach

A clinical history and examination remain helpful diagnostic tools, but serologic tests, imaging, and often biopsy are needed for definitive diagnosis. ANCA serologies (both by immunofluorescence and enzyme-linked immunosorbent

Figure 149-4 Lung Purpura with Nephritis (Goodpasture's Syndrome).

assay) are essential for ruling in or out the pauci-immune small vessel vasculitides. Other serologic tests that may be useful include those for hepatitis B and C, antinuclear antibodies, anti-glomerular basement membrane antibodies, cryoglobulins, and evaluation of complement components C3 and C4. A urinalysis looking for hematuria is crucial.

Radiographic studies also have a valuable role in the diagnosis of vasculitides. Chest radiographs may demonstrate infiltrates or hemorrhage. Computed tomography scans are often needed for better evaluation of nodules and cavities. For large and medium vessel vasculitides, angiography may be useful; magnetic resonance angiography may allow a noninvasive diagnosis. Demonstration of aneurysms is critical in confirming the diagnosis of polyarteritis nodosa when no specific evidence of small vessel vasculitis can be found.

Biopsy of the affected organs is one of the most important tests. Biopsy specimens of purpuric skin lesions typically demonstrate leukocytoclastic vasculitis. Although this confirms the presence of vasculitis, it does not differentiate between diseases. Biopsy of the lungs or kidneys can be very helpful, especially if immunohistology is performed. Immune-mediated vasculitides will demonstrate granular deposits of immunoglobulin, such as in IgA or HSP, or linear staining, such as in Goodpasture's syndrome. ANCA-associated diseases generally demonstrate vascular necrosis without the presence of immune complexes.

Management and Therapy

Optimum Treatment

Treatment must be designed for each patient based on the severity of disease and the specific diagnosis. The natural

history of each vasculitis varies considerably. Some vasculitides are mild in nature and never cause any major end-organ damage. In contrast, the standard of care for patients with ANCA-SVV requires glucocorticoid and cytotoxic therapy to prevent morbidity or mortality.

The large vessel vasculitides, Takayasu's and giant cell arteritis, generally respond to high-dose corticosteroids. Prednisone, at 1 mg/kg daily (maximum, 60 mg), is used for the acute phase and then tapered over several months. Some patients may require maintenance low-dose prednisone. Steroid-resistant disease may be treated with methotrexate.

Henoch-Schönlein purpura (HSP) frequently requires only supportive care. Nonsteroidal anti-inflammatory drugs may be used for associated arthralgias. Steroids have shown some utility for severe abdominal pain and rapidly progressive glomerulonephritis. Unlike most vasculitides, Kawasaki's disease is not treated with steroids because they may worsen coronary artery disease. Instead, intravenous immunoglobulin and aspirin are the mainstays of therapy.

ANCA-SVV is treated with high-dose steroids and typically with a cytotoxic agent such as cyclophosphamide. Induction therapy involves pulse intravenous methylprednisolone, 7 mg/kg (maximum, 500 mg) IV every day for 3 days. In the case of pulmonary bleeding, plasmapheresis should be included as part of the induction therapy (grade A). Plasmapheresis should also be considered as part of the treatment regimen when patients present with dialysis-dependant acute renal failure. Prednisone is then given orally at 1 mg/kg daily (maximum, 60 mg) for the first month and tapered to alternate-day therapy by the end of the second month. Glucocorticoids are gradually tapered over the next 3 to 4 months. Cyclophosphamide may be given as an intravenous infusion monthly (grade A), beginning at 0.5 g/m² body surface area (BSA). The dose is increased to 1 g/m² BSA based on nadir white blood cell counts. These are drawn 2 weeks after each dose, with a goal of maintaining the white blood cell count above 3000/mm³. An alternative is oral cyclophosphamide used at 2 mg/kg per day. This regimen exposes the patient to a higher cumulative dose of cyclophosphamide, and increased side effects may result. The required duration of treatment with cyclophosphamide is somewhat variable from patient to patient, but recent evidence (grade A) suggests that azathioprine may be substituted for cyclophosphamide 3 months after induction, if the patient is in remission. Indicators of relapse that may warrant more aggressive therapy or extended length of therapy include proteinase-3 positivity, persistent high-titer ANCA at the time of placement on maintenance therapy, and the presence of upper or lower airway disease.

The use of trimethoprim-sulfamethoxazole, 1 single strength tablet each day, has been shown to reduce upper airway disease recurrence and may play a role in protecting the vasculitis patient from opportunistic infections. Goodpasture's syndrome is treated similarly to the ANCA-

associated vasculitides with plasmapheresis as part of the induction regimen.

If cryoglobulinemia is caused by hepatitis C, treatment of cryoglobulinemic vasculitis should consist of interferon- α and ribavirin, provided the patient's creatinine clearance is above 50 mL/min. High-dose corticosteroids, cytotoxic agents, and plasmapheresis have been used for severe disease. Treatment for vasculitides thought to be secondary to other systemic diseases should generally focus on optimal treatment for the underlying disease.

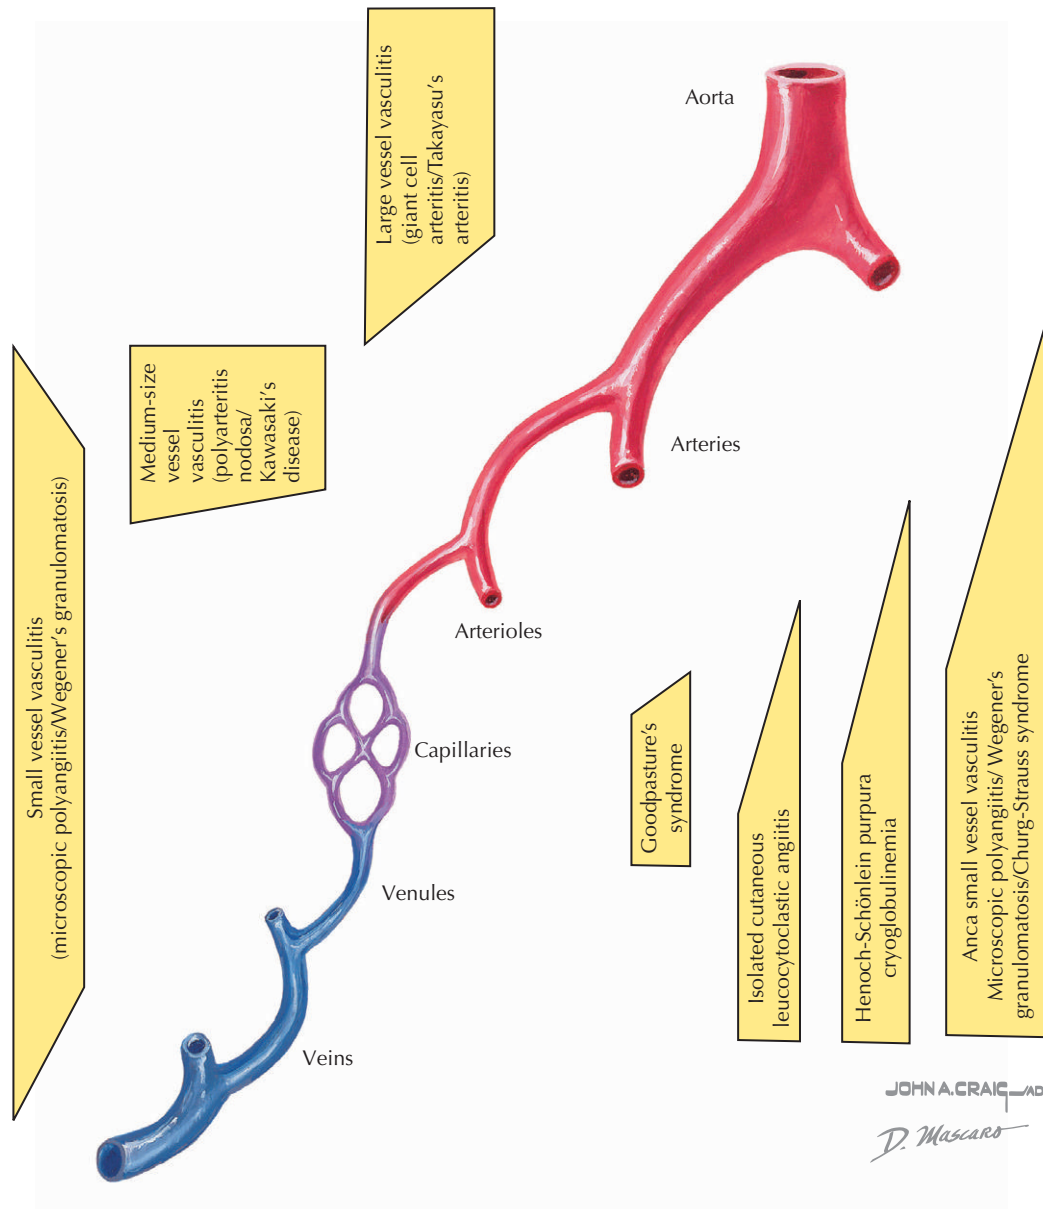

Avoiding Treatment Errors

In the case of vasculitis, the two most common treatment errors involve incorrect diagnosis and reluctance to use the toxic therapies sometimes required for an adequate therapeutic response. The diagnosis needs to be as precise as possible using laboratory and radiologic evidence and biopsies reviewed by experienced histopathologists familiar with the disease process before treatment is initiated. The diffuse nature of the vasculitides makes practitioner experience in recognizing signs and symptoms an important factor. Because the potential for relapse is often present, the physician must be constantly alert to this problem and ready to reinstitute aggressive therapy as needed at the earliest sign of recrudescence. Despite the potential for toxicity with many of the current therapies, it would be an error to be inappropriately cautious in selecting a gentler pharmacologic plan than would be ideal, or to delay treatment too long in the hope that things may improve on their own. Careful attention to dosing and close observation of the patient for side effects and beneficial effects is mandatory.

Future Directions

Studies are ongoing to determine whether alternative agents such as mycophenolate mofetil (Cellcept) may be used effectively for induction therapy. This regimen may offer less toxicity compared with cyclophosphamide. Preliminary studies using infliximab [a monoclonal antibody with tumor necrosis factor (TNF) inhibitory activity] for induction are ongoing. The recent results obtained with Rituximab (an anti-CD20 monoclonal antibody) for the treatment of resistant vasculitis patients have been encouraging. For both of these agents (infliximab and rituximab), randomized controlled trials will be necessary to document unequivocal success or equivalence of these modes of therapy.

Ideally, research should be aimed at prevention of vascular inflammation in order to avoid end-organ damage. Toward this end, basic science must continue to identify causative agents. Detecting populations at risk using genetic markers may allow for close scrutiny and earlier detection in specific individuals. Until such detection tools are available, however, early diagnosis of disease before end-organ damage occurs should be the overriding goal. Education of patients and physicians to consider the

Figure 149-5 Distribution of Specific Vasculitis Syndromes.

spectrum of vasculitis and to order the appropriate laboratory tests is vital (Fig. 149-5). Once the diagnosis is made, early treatment with drugs that specifically target pathogenetic factors without suppressing the entire immune system should be the goal. Clinical science must continue to focus on refining existing treatments such that baseline toxicities are reduced, while testing new therapies that have better toxicity profiles.

This paper reports on a multidisciplinary committee of experts' recommendations for diagnosis, treatment, and long-term management of Kawasaki's disease.

Polymyalgia Rheumatica and Giant Cell Arteritis

Introduction

Polymyalgia rheumatica (PMR) and giant cell arteritis (GCA) are linked conditions. PMR develops in up to one half of patients with GCA. On the other hand, GCA develops in only 15% of patients with PMR. Both conditions can present simultaneously or develop sequentially, with delayed onset of symptoms reported 10 years after the initial illness. PMR and GCA affect individuals older than 50 years and more often women than men. Prevalence increases with age. The incidence varies with ethnicity. High-risk populations, such as individuals of Northern European descent older than 50 years, have an incidence of PMR and GCA of 20 to 53 per 100,000 and 15 to 25 per 100,000, respectively. In contrast, African-American and Hispanic populations have an incidence of PMR of 1 to 2 per 100,000. In both conditions, markers of inflammation, such as erythrocyte sedimentation rate (ESR), are typically elevated. Elevations in interleukin-6 and association with human leukocyte antigen DR4 have also been found.

Etiology and Pathogenesis

The etiology of PMR and GCA is unknown. Several potential mechanisms, including infections, local degenerative processes, genetic susceptibility, and endocrinopathies, have been proposed as instigators of a cellular autoimmune process. Specific autoantibodies, hypergammaglobulinemia, and the presence of B cells in vascular lesions have yet to be identified. GCA is a vasculitis of medium and large vessels that often involves the cranial arterial branches originating from the aortic arch. The vasculitis is transmural with mononuclear cell infiltrate, destruction of the internal and external elastic lamina, and intimal proliferation. Multinucleated giant cells and granuloma formation may be absent.

Mortality rates of GCA are similar to those of the general population; however, there appears to be an increase in ischemic events (myocardial infarction, cerebrovascular accident) early in the disease course. There does not appear to be an increase of malignancy in patients with GCA.

Clinical Presentation

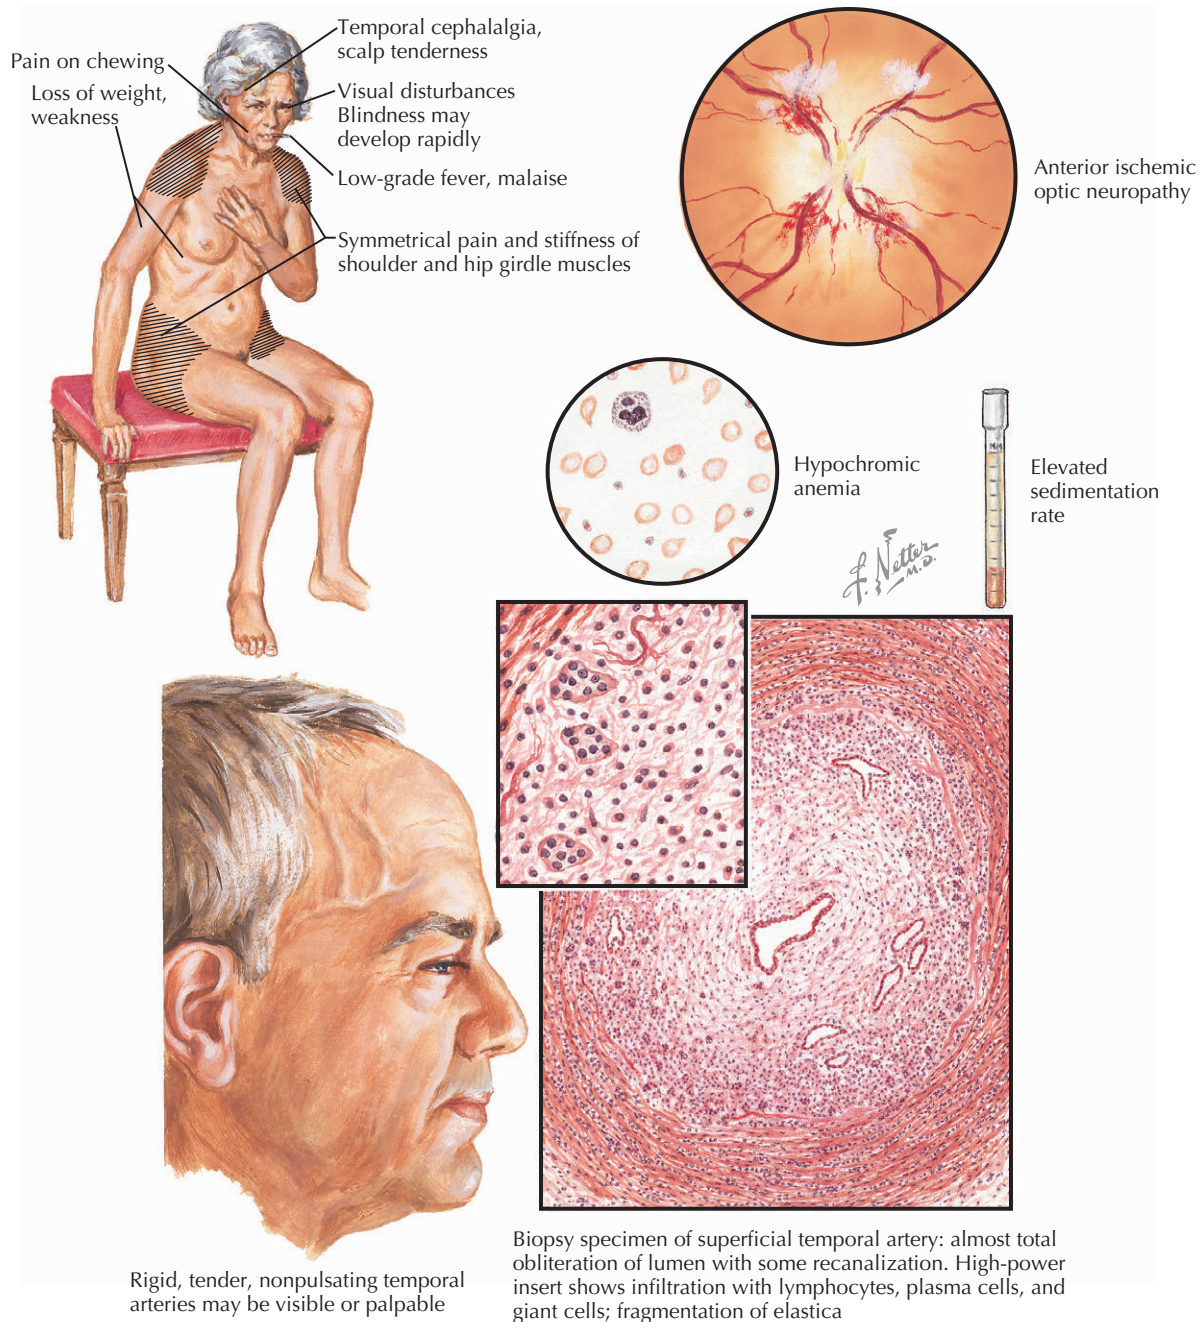

Polymyalgia Rheumatica

Symptoms consist of severe myalgia and stiffness of the neck, shoulders, and hip girdles. The pain is symmetric, often beginning in the shoulders, and may be abrupt in onset. Oligoarticular synovitis may be present. Constitutional symptoms, including weight loss, malaise, and depression, can occur; however, spiking fevers are rare. Muscle strength is normal but can appear diminished because of pain. Active rather than passive motion is limited by pain. There is often a disparity between the severity of pain and the clinical findings.

Giant Cell Arteritis

Signs and symptoms of vascular insufficiency or systemic inflammation may be the predominate complaints in subsets of GCA patients. Cranial arteritis presents with headaches of variable intensity that are localized to the

Figure 150-1 Giant Cell (Temporal) Arteritis, Polymyalgia Rheumatica.

temporal or occipital area in two thirds of patients. Temporal artery tenderness or decreased pulsation with scalp tenderness is often but not always present (Fig. 150-1). An abnormal temporal artery on exam is a clinical predictor of ischemic complications. On the other hand, anemia is a negative predictor of severe ischemic events. Jaw claudication is specific for GCA but is found in only half of patients. Patients can present with trismus rather than fatigue of the muscles of mastication. Tongue claudication and odynophagia have also been reported.

Constitutional symptoms are observed more frequently in GCA than in PMR and are present in up to 50% of patients at the onset of disease. Fever of unknown origin, with high-grade spiking temperatures, is seen in 15% of patients with GCA. Anorexia, weight loss, night sweats, chills, and depression may be presenting complaints.

Visual symptoms are diverse and include blurry vision, diplopia, eye pain, visual hallucinations, partial visual loss, and amaurosis fugax. Bilateral or unilateral blindness, often without any previous visual symptoms, occurs in 15% to

20% of patients. Unilateral eye disease, if left untreated, can progress to involve the contralateral eye. Arteritis of the posterior ciliary ophthalmic arteries results in ischemic optic neuropathy that can be visualized on funduscopic examination. An elevated ESR is associated with a reduced incidence of visual ischemic events.

Neurologic manifestations occur in up to 30% of patients and consist of transient ischemic attacks, stroke, and neuropathies. Large vessel vasculitis can present with arm claudication, pulselessness, or Raynaud's phenomenon. Thoracic aortic aneurysms are complications of longstanding disease and may be up to 17 times more common in patients with GCA. Fatalities from myocardial infarction (coronary arteritis) or ruptured aortic aneurysm, although rare, may occur.

Differential Diagnosis

Underlying infection and malignancy need to be excluded in all patients for whom the diagnosis of PMR or GCA is contemplated. Infections, such as hepatitis C, subacute bacterial endocarditis, Lyme disease, tuberculosis, and brucellosis, may cause diagnostic confusion. Multiple myeloma may present similarly; however, patients with PMR do not have a paraprotein on serum and urine electrophoresis. Amyloidosis can mimic GCA with jaw or arm claudication.

Hypothyroidism, spondyloarthropathy, polymyositis, rheumatoid arthritis (RA), and rarely amyotrophic lateral sclerosis can present in a similar pattern to PMR. Unlike PMR, polymyositis classically presents with muscle weakness and less commonly muscle pain. Early RA may initially be diagnosed as PMR and with time will clearly declare itself. Synovitis in RA is usually more pronounced and symmetrical. Complete and rapid resolution of synovitis on low-dose steroids is indicative of PMR. Erosive arthritic changes are common in RA but not PMR.

Diagnostic Approach

PMR is a clinical diagnosis supported by nonspecific laboratory findings. The diagnosis should be considered in patients older than 50 years complaining of greater than 1 month of morning stiffness (>30 minutes) and bilateral shoulder and hip girdle pain in the presence of elevated markers of inflammation. For some physicians, a rapid response to low-dose corticosteroids confirms the diagnosis of PMR.

The diagnosis of GCA should be considered in patients older than 50 years who present with symptoms of new or changing headaches, vision loss, PMR, or arterial occlusion in the extracranial vascular territory. Diagnostic confirmation of arteritis should take place with minimal delay. Temporal artery biopsy is the gold standard for the diagnosis. The temporal artery biopsy specimen is abnormal in up to 80% to 90% of GCA cases. The lesions of GCA are

patchy, and thus a larger biopsy of 3 to 5 cm is ideal. A recent study found that a 1-cm postformalin fixed arterial segment was associated with increased diagnostic yield for GCA. If the biopsy is negative, the contralateral temporal artery may be resected. The temporal artery biopsy of GCA reveals fragmentation of the elastica lamina, luminal narrowing, intimal edema, granulomas with multinucleated giant cells, and a monocellular infiltrate.

There is no single diagnostic test for PMR or GCA. ESR is usually, but not always, elevated over 40 mm/hr. Some authors suggest that up to 25% of patients with positive results on temporal artery biopsy may have a normal ESR. Other acute-phase reactants may also be elevated, such as C-reactive protein. Other findings include normochromic normocytic anemia, thrombocytosis, and abnormal liver function tests, particularly alkaline phosphatase and an elevated von Willebrand factor. Rheumatoid factor, antinuclear antibodies, and other autoantibodies such as antineutrophil cytoplasmic antibodies are negative. Complement levels are typically normal.

Magnetic resonance imaging with magnetic resonance angiography are used to assess vessel involvement, particularly large vessel involvement in GCA. Reports suggest that these changes may be present for weeks after initiation of corticosteroid therapy. Color Doppler ultrasonography (CDS) of the temporal arteries appears promising in identifying GCA. The findings of a bilateral halo have been noted to be highly specific for GCA. CDS may be a less invasive method to confirm GCA; however, results are extremely operator dependent and thus patients at this time still warrant a biopsy. 18-Fluorodeoxyglucose positron emission tomography (PET) can be helpful in the diagnosis of GCA of large arteries with an atypical presentation. PET is less accurate for smaller vessels such as the temporal artery. PET scan findings improve with corticosteroid treatment and thus may indicate a role for PET in monitoring for disease reactivation. Such scans have shown activity in the aorta in patients with PMR without clinical features of GCA. The implications of these findings are presently under study. Besides needing further validation, PET scans are limited by their availability and cost.

Management and Therapy

Optimum Therapy

Corticosteroids are the drugs of choice for the treatment of GCA and PMR. Both PMR and GCA respond dramatically and rapidly to corticosteroids. Unfortunately, steroid-sparing therapy such as methotrexate has not been uniformly effective. Pulse methylprednisolone has been evaluated to reduce overall steroid exposure.

In GCA, the initial prednisone is 1 mg/kg, usually 60 mg or less per day. There is no clear marker identifying the appropriate time to initiate tapering of steroid therapy. Often this decision is based on a combination of clinical

symptoms and normalizations of markers of inflammation. Prednisone may be decreased by 5 mg every 2 to 4 weeks until a dose of 10 mg/day and subsequently decreased by 1 mg every 2 to 4 weeks. Patients are often maintained on low-dose therapy for at least 1 to 2 years. Disease relapse or the appearance of PMR is common during the tapering of steroids. ESR and C-reactive protein do not always reflect disease activity, and recurrence of symptoms should be treated seriously.

In PMR, response to lower doses of prednisone is common. At onset of treatment, only one third of patients receive doses above 20 mg daily. Typically, patients can taper the dosage by 5-mg increments every 2 to 4 weeks. Once 10 mg/day is obtained, the dose is decreased by 1 mg every month. Although PMR is generally a self-limited process, prednisone is usually not discontinued for 1 year and may be continued in some patients for 2 years or longer. Some patients may require 1- to 2-mg doses long-term to avoid relapse. Patient symptoms, not just laboratory results, guide the steroid taper. Nonsteroidal anti-inflammatory drugs can be used in conjunction with steroids in mild PMR. This may be associated with gastrointestinal intolerance and bleeding. If a patient develops a symmetric polyarthritis, consider the diagnosis of seronegative RA. An anticitrillunated peptide antibody and hand-foot films may be helpful. Synovitis in PMR is nonerosive.

Patients with PMR should understand the importance of reporting any symptoms of GCA immediately. Along with symptoms, markers of inflammation can help determine whether a patient is having a flare. Change in treatment is not based solely on markers of inflammation. Patients should receive prophylaxis for steroid-induced osteoporosis. This should include calcium and vitamin D supplementation. A baseline bone densitometry is helpful in future decision making. Patient monitoring for steroid-associated complications of diabetes or hypertension is also important. Because patients will be on corticosteroids for over 3 months, bisphosphonate therapy warrants consideration.

Additional Therapies

The efficacy of methotrexate and azathioprine as steroid-sparing agents has not been clearly demonstrated in either PMR or GCA. Several recent trials of methotrexate in GCA reached opposite conclusions. Cyclophosphamide, an alkylating agent, has been used in large vessel vasculitis, and there are case reports of use of these drugs in severe GCA. There are encouraging case reports of therapy with antitumor necrosis factor (TNF)- α inhibitors; however, controlled trials are needed. Anti-CD20 therapy has been described as an adjunct therapy in a case report of GCA.

The use of aspirin or warfarin may have beneficial effects in GCA. A retrospective trial found a decrease in

cranial ischemic events; however, this effect was not seen in another trial.

Avoiding Treatment Errors

GCA is considered a medical emergency because of the potential risk for blindness. Corticosteroid treatment should not be delayed until after temporal artery biopsy. A biopsy performed within several days of starting steroids should not substantially lower the likelihood of obtaining a positive biopsy. Recovery of vision loss with high-dose methylprednisolone has been described; however, this approach is usually unsuccessful in preventing visual loss.

Future Directions

PMR and GCA often require at least 1 year of therapy with corticosteroids. Long-term corticosteroid use has numerous complications, and thus the search for possible steroid-sparing agents remains essential for patients unable to discontinue steroids and for those who have severe complications or who are refractory to steroid therapy. Anti-TNF agents appear promising yet need further structured randomized trials. The risk for malignancy needs further investigation with larger patient groups. Some researchers have indicated that treatment targeting interferon- γ may be useful because it is produced locally, correlating with ischemic complications. Finally, further study of the utility of aspirin therapy is needed.

EVIDENCE

1. Blockmans D, de Ceuninck L, Vanderschueren S, et al: 18F-fluorodeoxyglucose positron emission tomography in giant cell arteritis: A prospective study of 35 patients. *Arthritis Rheum* 55:131-137, 2006.

FDG uptake in the large vessels is a sensitive marker for GCA. Shoulder uptake at diagnosis correlated significantly with the presence of polymyalgia rheumatica. Results of prior PET scintigraphies do not predict relapses of GCA.

2. Jover JA, Hernandez-Garcia C, Morado IC, et al: Combined treatment of giant-cell arteritis with methotrexate and prednisone: A randomized, double-blind, placebo-controlled trial. *Ann Intern Med* 134:106-114, 2001.

The study shows the combination of methotrexate with corticosteroid therapy for giant cell arteritis therapy does not decrease a patient's steroid exposure.

3. Karahaliou M, Vaiopoulos G, Papaspyrou S, et al: Colour duplex sonography of temporal arteries before decision for biopsy: A prospective study in 55 patients with suspected giant cell arteritis. *Arthritis Res Ther* 8(4):R116, 2006.

Color duplex sonography (CDS) is an inexpensive and noninvasive method that allows a directional biopsy with an increased probability to confirm the clinical diagnosis of GCA. The authors report that biopsy is not necessary in a substantial proportion of patients in whom bilateral

halo signs can be found by CDS, although the technique is highly operator dependent.

4. Mazlumzadeh M, Hunder GG, Easley KA, et al: Treatment of giant cell arteritis using induction therapy with high-dose glucocorticoids: A double-blind, placebo-controlled, randomized prospective clinical trial. *Arthritis Rheum* 54:3310-3318, 2006.

Initial treatment of GCA with pulse intravenous methylprednisolone allows for more rapid tapering of oral prednisone and was associated with an increased proportion of patients with sustained remission of their disease.

5. Spiera RF, Mitnick HJ, Kupersmith M, et al: A prospective, double-blind, randomized, placebo controlled trial of methotrexate in the treatment of giant cell arteritis (GCA). *Clin Exp Rheumatol* 19(5):495-501, 2001.

No corticosteroid-sparing benefit could be attributed to the combination of methotrexate and corticosteroid therapy for the treatment of patients with giant cell arteritis.

6. Torrente SV, Güerri RC, Pérez-García C, et al: Amaurosis in patients with giant cell arteritis: Treatment with anti-tumour necrosis factor- α ; *Intern Med J* 37:280-281, 2007.

The authors report on a patient with blindness due to ischemic optic neuritis during a GCA flare that does not respond to high-dose corticosteroid therapy, but improves significantly with antitumor necrosis factor- α therapy.

Systemic Lupus Erythematosus

Introduction

Systemic lupus erythematosus (SLE) is a chronic inflammatory autoimmune disease that can affect multiple organ systems and is characterized by non-organ-specific autoantibodies, including antinuclear antibody (ANA), anti-double-stranded DNA (anti-dsDNA), antiphospholipid antibodies, and the marker autoantibody, anti-Smith (anti-Sm). Significant health consequences include renal failure, vasculitis, arthritis, and neuropsychiatric complications. The clinical symptoms and immunologic manifestations of SLE are diverse, and the clinical course involves periods of flares and remissions, requiring therapy that includes the extensive use of corticosteroids and other immunosuppressants. There is a striking female predominance (8 to 9 : 1), with a peak incidence during the reproductive years, but SLE can strike at any age. Concordance in monozygotic twins is 25% to 50%, reflecting a strong genetic component. African Americans have a threefold increase in incidence, tend to have onset at an earlier age, and have increased mortality when compared with whites. Those of Hispanic and Asian descent have an increased prevalence of SLE and associated nephritis. Despite investigative attention, racial differences in lupus expression remain poorly understood.

There are several forms of lupus in addition to SLE. Chronic cutaneous lupus and subacute cutaneous lupus are limited to the skin. Drug-induced lupus is self-limited and resolves when the offending drug is discontinued. Procainamide and hydralazine are commonly recognized offenders; antihistone antibodies are seen in most cases. Neonatal lupus is characterized by a transient rash or congenital heart block in the newborn and is due to maternal anti-Ro (anti-SSA [anti-Sjögren's syndrome A]) that crosses the placenta.

Etiology and Pathogenesis

The cause of SLE is unknown and is likely the result of interactions between susceptibility genes and environmental triggers. Such triggers may include endogenous factors, such as sex hormones, stress, and diet, as well as exogenous triggers, such as silica or sunlight exposure. Other triggers include infections or environmental toxins that have yet to be identified. B-cell hyperactivity, abnormal recognition of self antigens, autoantibody formation, and failure of normal tolerance are some of the reported abnormalities in immune system function. T-cell defects also occur, including excessive T-cell helper function and defects in cell-mediated immunity.

Clinical Presentation

Manifestations of SLE are protean and can affect any organ system (Fig. 151-1).

Musculoskeletal Disease

Musculoskeletal involvement is one of the earliest and most common manifestations of SLE. Arthralgias and tendonitis are more frequent than synovitis. Jaccoud's arthritis, a nonerosive but deforming arthropathy due to ligamentous laxity, can develop. Myositis is infrequent (<15%) and mild to moderate in severity. Myopathy may also develop as a result of therapy with corticosteroids or

Figure 151-1 Lupus Erythematosus of the Heart.

rarely antimalarials. Osteonecrosis or avascular necrosis develops in up to 5% to 10% of SLE patients and frequently affects the femoral heads bilaterally. This complication is often related to the duration and peak of corticosteroid exposure.

Cutaneous Disease

The mucocutaneous system is affected in 80% to 90% of patients with SLE and includes oral and nasal ulcers as well as skin manifestations. Discoid lupus is the skin finding most commonly seen, affecting 15% to 30% of patients.

The specific lupus erythematosus (LE) skin findings in SLE include acute cutaneous LE (with malar erythema or a generalized bullous or photosensitive rash). The non-specific features are protean and range from a florid cutaneous small vessel vasculitis to panniculitis or even livedo reticularis.

Cardiopulmonary Disease

Pleuritis (serositis) is the most frequently encountered cardiopulmonary complication caused by lupus. A syndrome of progressive loss of lung volume or “shrinking lung” due

to diaphragmatic dysfunction is being increasingly recognized. The symptoms of chest pain and shortness of breath have a broad differential in patients with SLE, including pulmonary embolus, myocardial ischemia, pericardial effusion, and pleural effusion. Immunosuppressive therapy increases the risk for bacterial pneumonia. Accelerated atherosclerosis accounts for the second peak of the recognized bimodal curve of lupus mortality. Interestingly, the ongoing inflammatory process appears to be an independent cardiovascular risk factor distinct from hypertension, hypercholesterolemia, corticosteroid therapy, and diabetes mellitus. Elevated serum homocysteine is another risk factor in lupus patients.

Renal Disease

Clinically, lupus nephritis can range from mild asymptomatic proteinuria to rapidly progressive glomerulonephritis associated with end-stage renal disease. Renal involvement in SLE is highly variable in histologic presentation (Fig. 151-2). Early onset of renal disease is a poor prognostic indicator. Youth, male gender, persistent azotemia, and high activity and chronicity scores on renal biopsy are other prognostic features that correlate with a poorer outcome. SLE is not a contraindication to renal transplantation because lupus patients do not differ from others in frequency of rejection or graft maintenance. The risk for recurrence of lupus nephritis in the transplanted kidney is less than 10%.

African Americans have a threefold increased incidence of SLE, more frequently develop nephritis, and have increased morbidity and mortality compared with other races. Although mortality rates from SLE have been relatively stable among whites since the 1970s, they have increased among African Americans during this time span. The progression of diffuse proliferative nephritis to end-stage renal disease is much faster in African Americans than in whites as well, even with comparable cytotoxic therapy. Progression is independent of age, duration of lupus, history of hypertension or control of hypertension, and activity or chronicity indexes on renal biopsy.

Neuropsychiatric Disease

Neuropsychiatric manifestations of lupus are protean and include both acute and chronic forms, vasculitis, and cerebritis. All levels of the central and peripheral nervous system may be involved. Headaches, seizures (focal and diffuse), and various aberrations of the psyche (affective disorders, psychoses, and organic brain disease) are the most common manifestations of central nervous system involvement. Secondary pathophysiologic mechanisms related to infection, uremia, and drugs (particularly corticosteroids) must be excluded.

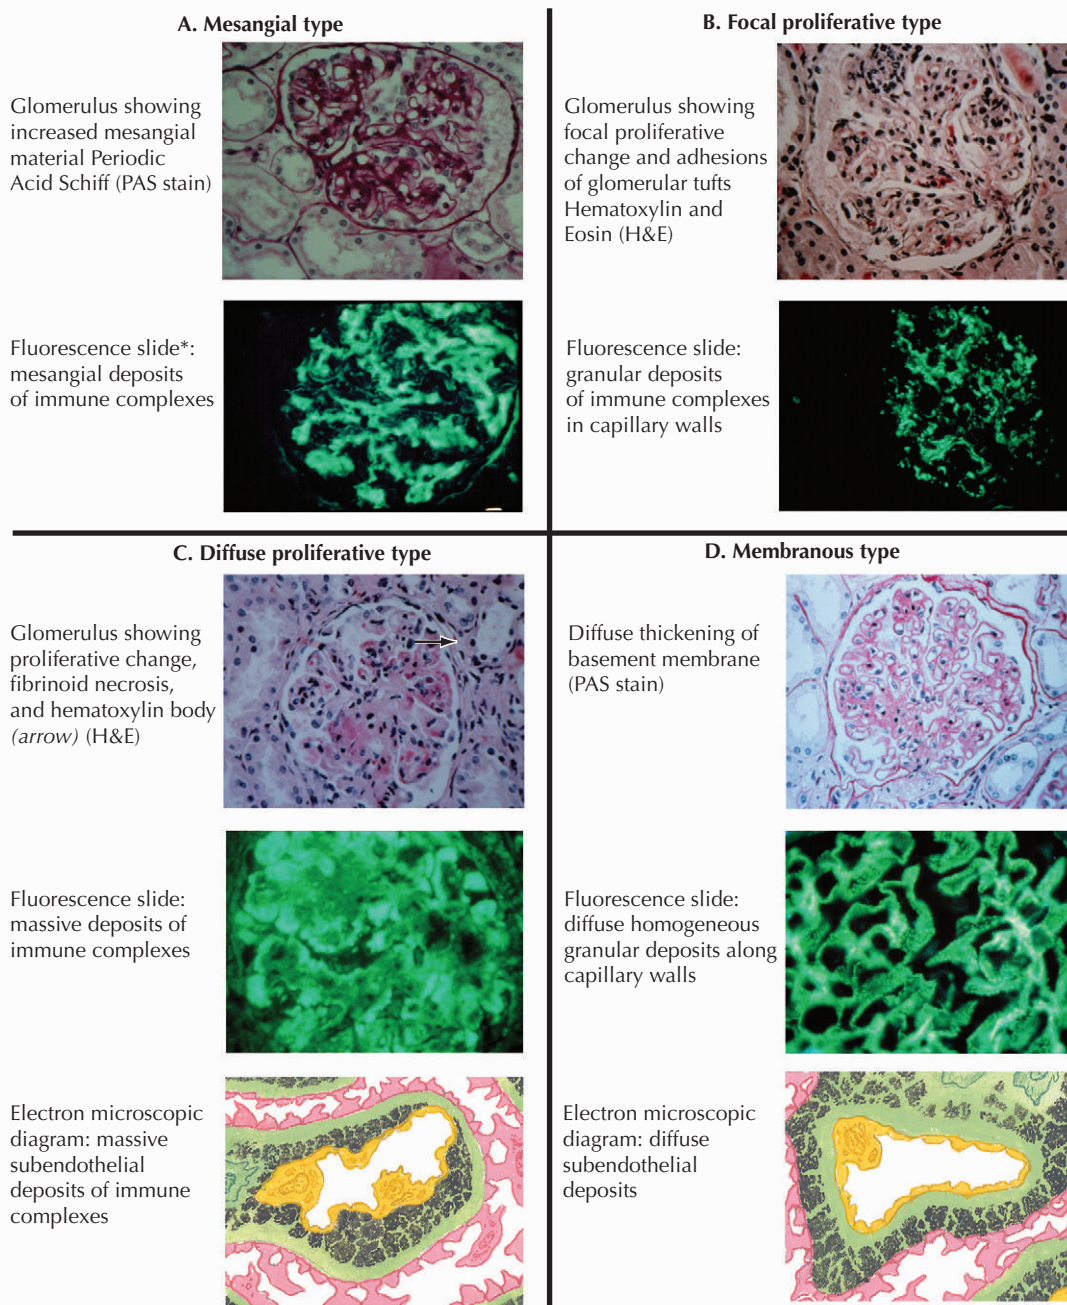

Pregnancy and Systemic Lupus Erythematosus

Surprisingly, fertility in uncomplicated SLE is normal. The frequency of lupus flares during pregnancy remains controversial because lupus exacerbations have not been found to be uniformly more frequent or severe during pregnancy. There is, however, an increased frequency of midtrimester spontaneous abortions (15%), prematurity (20%) and stillbirth (5%). Lupus activity at the time of conception is a predictor of pregnancy outcome. The neonatal lupus syndrome may present with rash, transient thrombocytopenia, and complete heart block, often irreversible. Estrogen-containing contraceptives and synthetic estrogen receptor antagonists should not be used in those with antiphospholipid antibodies due to an increased risk for thrombosis. The Safety of Estrogens in Lupus Erythematosus National Assessment (SELENA) trial, reported in 2005, noted that oral contraceptives did not increase the risk for flares in patients with stable SLE, although postmenopausal hormone replacement therapy was associated with an increased risk for mild to moderate, but not severe, flares.

Differential Diagnosis and Diagnostic Approach

The criteria for classification of SLE shown in Table 151-1 were most recently revised in 1997 by the American College of Rheumatology (ACR). It is important to remember that these criteria allow comparison of patients in clinical studies and are not meant to be used as diagnostic criteria. Patients may present with less than four features and clearly have SLE without developing other clinical or serologic features; patients with primary antiphospholipid antibody syndrome may meet four or more criteria and not have SLE. Interestingly, the ACR criteria do not include hypocomplementemia or pathology on renal biopsy, which are useful to evaluate disease activity and guide treatment. These criteria are currently under review by several groups proposing diagnostic criteria.

Antinuclear antibodies (ANA) are the most sensitive screening test; more than 95% of patients will be ANA positive when the test is performed with a substrate containing human nuclei such as HEP-2 cells. A positive test for ANA is not specific for SLE, and positive ANAs may occur in normal individuals. In fact, about 15% of those older than 65 years have a positive ANA, often low titer (i.e., 1 : 80). Positive ANAs are also associated with other autoimmune diseases that can be confused with SLE, including rheumatoid arthritis, Sjögren's syndrome, scleroderma, and isolated Raynaud's syndrome. Organ-specific autoimmune diseases such as idiopathic thrombocytopenic purpura, autoimmune thyroid disease, and hemolytic anemia can also be associated with ANA. Family members of SLE patients frequently manifest an ANA without developing clinical features of SLE. Many autoimmune

Figure 151-2 Renal Lesions in Systemic Lupus Erythematosus (SLE).

* All fluorescence slides stained with fluorescein-labeled rabbit antihuman γ -globulin

diseases may have overlapping features, which makes strict classification difficult. The presence of antibodies to the Sm (Smith) antigen is pathognomonic for a diagnosis of SLE, although found in only 30% of patients.

Drug-induced lupus is associated with a number of medications, including procainamide and hydralazine. More recently, minocycline, interferon- α , and tumor necrosis factor inhibitors have been associated with ANA and anti-dsDNA antibody formation, and with development of SLE.

Management and Therapy

Optimum Treatment

Lupus is a clinically heterogeneous disorder; some patients experience troubling skin or joint complaints, whereas others are affected by life-threatening renal or neurologic compromise. Treatment is based on each patient's individual clinical manifestations. Determination of disease activity (active versus quiescent) and severity is essential to choose appropriate therapy and to establish the potential

F. Natter
M.D.

Table 151-1 The 1997 Revised American College of Rheumatology Criteria for Systemic Lupus Erythematosus

Criterion	Definition
1. Malar rash	Fixed malar erythema, flat or raised
2. Discoid rash	Erythematous raised patches with keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
3. Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulcers, usually painless, observed by physician
5. Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	a. Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion), <i>or</i> b. Pericarditis (documented by electrocardiogram or rub or evidence of pericardial effusion)
7. Renal disorder	a. Persistent proteinuria: >0.5 g/day or >3+, <i>or</i> b. Cellular casts of any type
8. Neurologic disorder	a. Seizures (in the absence of other causes) b. Psychosis (in the absence of other causes)
9. Hematologic disorder	a. Hemolytic anemia b. Leukopenia (<4000/mm ³ on two or more occasions) c. Lymphopenia (<1500/mm ³ on two or more occasions) d. Thrombocytopenia (<100,000/mm ³ in the absence of offending drugs)
10. Immunologic disorder	a. Anti-dsDNA, <i>or</i> b. Anti-Sm, <i>or</i> c. Positive finding of antiphospholipid antibodies based on: (1) An abnormal serum level of IgG or IgM anticardiolipin antibodies, <i>or</i> (2) A positive test result for lupus anticoagulant using a standard method, <i>or</i> (3) A false-positive serologic test for syphilis known to be positive for 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of ANA by immunofluorescence or an equivalent assay at any time and in the absence of drugs known to be associated with "drug-induced lupus syndrome"

From Tan EM, Cohen AS, Fries JF, et al: The 1982 revised criteria for the classification of systemic lupus erythematosus (SLE). *Arthritis Rheum* 25:1271-1277, 1982; and Updating the American College of Rheumatology revised criteria for the classification of systemic lupus erythematosus (letter). *Arthritis Rheum* 40:1725, 1997. for involvement of vital organs. Evidence for an inflammatory process may prompt immunosuppressive therapy versus anticoagulation for thrombotic or embolic events. Patient education is a vital part of the treatment of SLE, especially in terms of long-term outcomes, recognizing clinical changes, and understanding risks.

Patients should understand the importance of avoiding excessive ultraviolet (UV) light exposure by wearing a sun-screen with a high sun protective factor (SPF; 30 or higher). Mexoril, a UVA and UVB protectant, recently received U.S. Food and Drug Administration. Fluorescent light sources should be screened for patients who experience photosensitivity. Lupus patients are at increased risk of infection even in the absence of corticosteroids; fevers should be fully assessed rather than attributed initially to SLE. Fatigue is common in SLE and can be severe. Consideration of other causes, including thyroid disease, coexisting fibromyalgia, depression, and adrenal insufficiency following steroid taper, is important. Regularly scheduled long-term follow-up is absolutely essential and should include regular urinalyses because renal involvement can be asymptomatic until well established. The increased risk

for premature cardiovascular disease secondary to underlying inflammatory disease warrants aggressive treatment of hypertension and hyperlipidemia. Patients should also receive counseling about tobacco abstinence. Lupus is associated with an increased risk for osteoporosis even without steroid therapy, and prevention or treatment of bone loss is important.

Key points in the management of SLE include the following:

1. SLE is a disease of remissions and exacerbations. Patients who are in clinical remission should not be treated.
2. Cyclophosphamide should not be employed in non-life-threatening situations because of the severity of its side effects, including gonadal ablation, alopecia, bladder hemorrhage, and malignancy.
3. Plasma exchange or plasmapheresis has not shown benefit in severe lupus nephritis, but there have been anecdotal reports of response in acute life-threatening situations such as systemic vasculitis and thrombotic thrombocytopenia (TTP) associated with SLE.

4. Sunscreen with an SPF of 30+ should be encouraged.
5. Risk factors for atherosclerosis, including hypertension, hyperlipidemia, and smoking cessation, should be addressed, as previously emphasized.

Pharmacologic Agents Available for Treatment

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs are useful for controlling joint symptoms, serositis (pleuritis and pericarditis), and headaches. The selective cyclooxygenase (COX)-2 inhibitors have not been studied specifically in SLE but are likely to show the same decreased gastrointestinal toxicity demonstrated in other patient populations. The side effects of COX-2 and nonselective COX inhibitors include adverse effects on kidney, liver, and central nervous system function that may mimic increased SLE activity.

Corticosteroids

Many of the clinical features of SLE respond to corticosteroids. Dosing is based on organ involvement, with higher doses in acute renal disease and myositis, and lower doses for arthralgias and fatigue. Numerous routes and formulations are available. Skin lesions can be injected, and intra-articular injections are often helpful in arthritis. Oral and intravenous routes are also used for delivery. The risks with long-term use include increased susceptibility to infection, cataracts, hypertension, diabetes, osteoporosis, and avascular necrosis of bone.

Antimalarial Drugs

These agents are most useful when cutaneous, joint, pleural, or pericardial features are predominant, and when patients experience severe fatigue associated with SLE. Hydroxychloroquine (Plaquenil) is the most commonly prescribed medication in this group, but chloroquine and quinacrine are sometimes used as well. Regular ophthalmology exams for monitoring possible toxicity are essential. The risk for ocular toxicity with hydroxychloroquine is low if the recommended doses are employed. Benefits include lipid-lowering and possible antithrombotic effects.

Immunosuppressive Drugs

Additional immunosuppressants are frequently used for more severe disease and for their steroid-sparing effects. Drugs in this group include azathioprine, cyclophosphamide, mycophenolate mofetil, and cyclosporine. Methotrexate has been increasingly used for severe arthritis or skin disease. Potential toxicities make close monitoring mandatory and are specific to each drug. Contraception is required during therapy because of the risk for teratogenicity associated with most of these medications.

Avoiding Treatment Errors

Given the wide range of clinical presentations in patients with SLE, there is a critical need to consider new symptoms as possible manifestations of SLE. The consideration of other medical etiologies should follow. Appropriate laboratory testing and biopsies to confirm organ involvement must always occur before the initiation of immunosuppressive therapy. SLE patients are most likely to develop new disease features within the first few years of onset; thus, close follow-up is important. Recent studies confirm the benefits of hydroxychloroquine for prevention of disease flares and for decreasing cardiovascular and thrombotic risks. The patient should continue hydroxychloroquine long term, even during periods of immunosuppressive therapy. The dose should remain no greater than 6.5 mg/kg, reduced by half in patients with renal insufficiency. Gastrointestinal intolerance may occur with generics, which are not enteric coated.

Future Directions

Previous investigators demonstrated an association between lower socioeconomic status measures and higher morbidity and mortality in SLE. This relationship is complex and a focus of long-term assessment in the Lumina cohort. Environmental risks for developing lupus have been addressed in the Carolina Lupus Study, a case-controlled population-based study of lupus patients in the southeastern United States. Exposure to silica was a strong risk in this population.

Several new agents are under investigation for SLE therapy. Mycophenolate mofetil and intermittent intravenous cyclophosphamide are being compared as initial therapy for proliferative glomerulonephritis. Shorter courses of cyclophosphamide are being evaluated in the EuroLupus Trial as well. Monoclonal antibodies to inhibit costimulatory pathways for T-cell and B-cell activation are currently in clinical trials. Several drugs approved for use in rheumatoid arthritis are also being evaluated in clinical trials for use in lupus. An oral tolerogen, JPJ 394, has shown promise in delaying initial renal flare in patients with high-titer anti-dsDNA antibodies through down-regulation of their production. Autologous hematopoietic stem cell transplantation has been performed in patients with SLE; seven patients were disease free at a median follow-up of 25 months, but the durability of response remains unknown. Immunoablative high-dose cyclophosphamide without stem cell transplantation (thus decreasing the risk for graft-versus-host disease) is being evaluated for therapy of severe refractory SLE.

This excellent comprehensive review of past and current information on causes and treatments of lupus manifestations includes a useful annotated reference list.

The Antiphospholipid Syndrome

Introduction

The antiphospholipid syndrome (APS) is the association of a group of autoantibodies having an apparent specificity for anionic phospholipids with thrombosis and pregnancy morbidity or pregnancy loss. Other clinical manifestations include thrombocytopenia, livedo reticularis, a form of valvular heart disease (Libman-Sachs endocarditis), cutaneous ulcers, and certain nonstroke neurologic problems. Antiphospholipid antibodies (aPL) are present in about one third of patients with systemic lupus erythematosus (SLE), and about one third of these patients (10% to 15% of SLE patients) have one or more clinical manifestations of APS. APS may also occur as a primary syndrome in the absence of SLE or other autoimmune diseases. Primary APS is a relatively common form of acquired thrombophilia in the general population, accounting for 15% to 20% of all cases of venous thromboembolism, up to one third of stroke in younger individuals (younger than 50 years of age), and 10% to 15% of women with recurrent pregnancy losses.

Etiology and Pathogenesis

The underlying events leading to the development of aPL are not known. It is likely that genetic factors play a role. A number of familial cases of APS have been reported; however, specific genes contributing to the development of aPL and APS have not yet been identified.

Although aPL were originally thought to be directed against anionic phospholipids, such as cardiolipin and phosphatidylserine, the major targets of these autoantibodies are now thought to be certain phospholipid-binding plasma proteins. The two most important antigens appear to be β_2 -glycoprotein I (β_2 -GPI) and prothrombin. β_2 -GPI is a normal plasma glycoprotein with an unknown physiologic function. Inherited deficiency of β_2 -GPI is not associated with a disease phenotype. β_2 -GPI may interact with certain other molecules (e.g., coagulation factor XI, oxidized low-density lipoproteins), and cells (e.g., vascular endothelial cells, monocytes, apoptotic cells). Prothrombin, of course, plays a key role in blood coagulation.

Research suggests that aPL are not merely markers of this condition but play an important role in the pathophysiology of hypercoagulability and pregnancy loss. For

example, a number of monoclonal and polyclonal antibodies to β_2 -GPI have been shown to be procoagulant or to induce pregnancy loss in animal models. Numerous mechanisms have been proposed. Certain aPL inhibit normal anticoagulant pathways, particularly the protein C pathway. Additionally, aPL may bind to and activate vascular endothelial cells or blood monocytes, leading to a procoagulant phenotype, including the expression of tissue factor and of intercellular adhesion molecules. Animal models also suggest that the pathologic effects of aPL require activation of the complement system.

It is likely that aPL are risk factors for thrombosis, that is, that they cause or contribute to a hypercoagulable state, but are not themselves the proximate trigger of a thrombotic event. In individuals with aPL, the antibodies are constantly present in the circulation, but a thrombotic event occurs only rarely, if ever, and at a particular site in the vasculature.

Clinical Presentation

The clinical presentations of APS are varied and depend on the particular clinical manifestation.

Figure 152-1 Livedo Reticularis.**Figure 152-2 Livedo Racemosa.**

Thrombosis

Thrombosis is a major clinical manifestation of APS and has been reported in nearly every location in the vasculature. The most common sites of venous thrombosis are the deep and superficial veins of the lower extremities. Pulmonary embolism occurs in up to half the cases of deep venous thrombosis. Stroke is the most common form of arterial thrombosis in APS. Thrombosis is probably the underlying pathophysiologic process in a number of other clinical manifestations of APS (e.g., placental thrombosis and infarction leading to pregnancy loss, and thrombosis of dermal blood vessels leading to cutaneous ulcers).

Pregnancy Loss and Morbidity

The type of pregnancy loss that is most strongly associated with aPL is fetal death occurring from the late first trimester onward. Earlier losses (less than 10 weeks' gestation) also occur; however, the statistical association is weaker because of the high incidence of such early losses in the general population. Various types of pregnancy morbidity are also associated with aPL. These include fetal growth impairment, oligohydramnios, preeclampsia and eclamp-

sia, fetal distress, premature delivery, and maternal thrombotic events in the postpartum period.

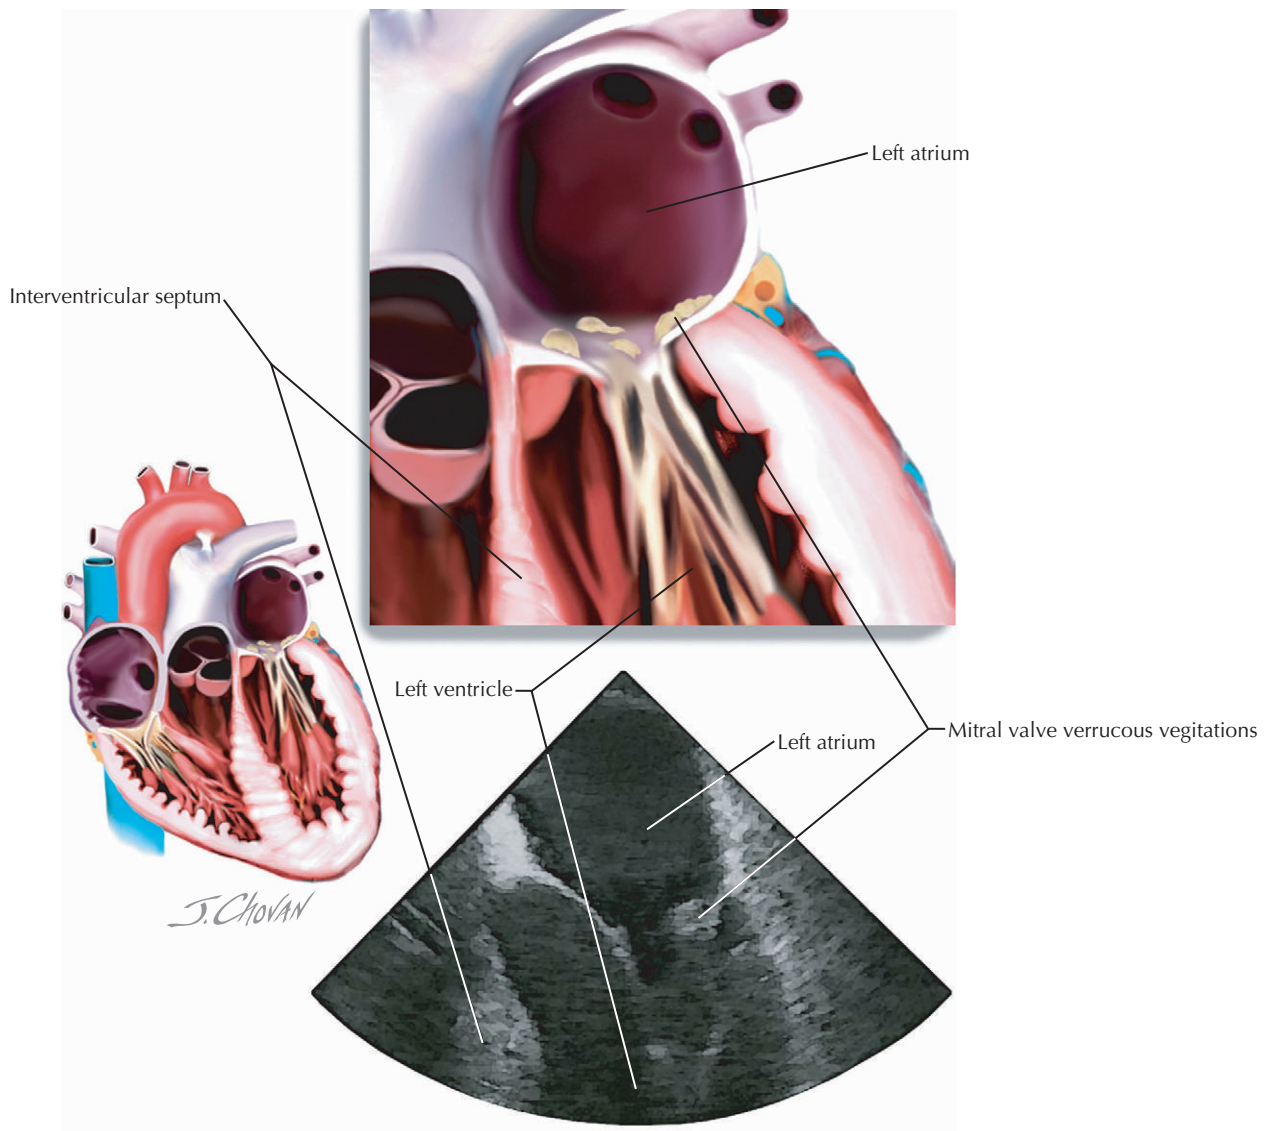

Cutaneous Manifestations

Livedo reticularis, a latticework of blue to red subcutaneous mottling, is often present in patients with aPL. Some authors make a distinction between two major patterns of livedo: livedo reticularis (Fig. 152-1) and livedo racemosa (Fig. 152-2). The latter is a more open, streak-like pattern and may have greater pathologic significance. Sneddon's syndrome, the association of livedo and stroke, is associated with aPL in many instances.

Cutaneous ulcers and skin necrosis have also been reported in association with aPL.

Thrombocytopenia

In SLE patients, thrombocytopenia is associated with aPL, occurring in about 40% of patients with aPL, as compared with only 10% of patients without aPL. aPL are also present in about one third of patients with chronic autoimmune thrombocytopenia. Thrombocytopenia in APS

Figure 152-3 Libman-Sacks Endocarditis.

is usually moderate and not associated with hemorrhage. Interestingly, low platelet counts do not appear to protect APS patients from thrombosis.

Valvular Heart Disease

Libman-Sacks endocarditis, noninfective verrucous vegetations, are associated with aPL in patients with and without SLE (Fig. 152-3). These vegetations may embolize, causing ischemic events such as stroke.

Neurologic Manifestations

As noted, stroke is the major neurologic manifestation of APS. Recurrent strokes may lead to multi-infarct dementia. Transient ischemic attacks may also occur. A number

of neurologic events that are not clearly stroke related may also be associated with aPL, although the evidence-based data are weaker than for stroke. These include transverse myelitis, multiple sclerosis-like syndromes, chorea, and cognitive dysfunction.

Catastrophic Disease

Catastrophic APS is a syndrome of multiple thromboses occurring over a relatively short period of time (days to weeks). The thromboses typically involve small vessels supplying several major organs (heart, lung, kidney, brain, liver), leading to severe organ system dysfunction or failure. Large vessel thromboses, such as deep venous thrombosis, are less common. Several hundred cases of catastrophic APS have been reported. About half the patients have a

 Hyperviscosity syndromes

history of SLE, APS, or both; in the other half, the catastrophic syndrome is the first manifestation of APS. Catastrophic APS is fatal in nearly 50% of reported cases. Major causes of death are cardiac (myocardial infarction, myocardial microthrombi, heart block) and pulmonary (acute respiratory distress syndrome, pulmonary embolism) manifestations. Apparent precipitating events (e.g., infection, surgery, trauma, or withdrawal of anticoagulant medication) are identifiable in many cases.

Differential Diagnosis

When considering the diagnosis of APS in a patient with thrombosis, it is important to consider other causes of thrombophilia (summarized in Box 152-1).

Recurrent pregnancy loss should be evaluated by a high-risk obstetrician or a reproductive endocrinology and infertility expert to exclude anatomic, hormonal, metabolic, and chromosomal causes. Inherited thrombophilic disorders (see Box 152-1) are also associated with recurrent pregnancy loss.

Catastrophic APS may mimic several conditions, including thrombotic thrombocytopenic purpura and lupus vasculitis.

Diagnostic Approach

The diagnosis of APS rests on the demonstration of persistently positive tests for one or more aPL in a patient with a history of thrombosis or recurrent pregnancy loss. The diagnosis of APS based on other clinical manifestations (in the absence of thrombosis or pregnancy loss) is more controversial. International consensus criteria for the classification of definite APS are useful for clinical trials

but have little practical use in the care of individual patients.

Laboratory Tests for aPL

Anticardiolipin Antibodies

Standard anticardiolipin antibody testing remains a key first-line test for aPL. Persistently positive tests for immunoglobulin G (IgG) or IgM anticardiolipin antibodies, at medium or high titer, are strongly associated with the clinical manifestations of APS. Transiently positive tests and low-titer antibodies are more difficult to assess. Isolated IgA anticardiolipin antibodies may also be associated with APS but are relatively rare.

Lupus Anticoagulant

Lupus anticoagulants are antibodies detected based on their ability to inhibit phospholipid-dependent coagulation reactions. Testing involves one or more screening tests. Common screening tests include an activated partial thromboplastin time optimized for the detection of lupus anticoagulants (lupus aPTT) and the dilute Russell viper venom time (dRVVT). If one of these tests is prolonged, two types of screening tests are performed. A mixing study helps to exclude a coagulation factor deficiency. Mixing patient plasma with normal plasma will correct a factor deficiency but not a lupus anticoagulant. The second type of confirmatory test is demonstration of phospholipid dependency; that is, excess phospholipid corrects prolongation of the coagulation assay.

Protein-Based Immunoassays

As discussed, most aPL are directed against β_2 -GPI and prothrombin, not negatively charged phospholipids. In patients with APS, most antibodies detected in anticardiolipin assays are specific for β_2 -GPI. Lupus anticoagulant assays detect certain anti- β_2 -GPI antibodies and antibodies to prothrombin. Anti- β_2 -GPI immunoassays are available and appear to be more specific for clinical manifestations of APS than conventional anticardiolipin tests. At present, anti- β_2 -GPI assays are considered to be second-line tests, to be utilized if initial anticardiolipin and lupus anticoagulant tests are negative or inconclusive. Antiprothrombin assays (some using a combination of prothrombin and phosphatidylserine) are being developed.

Antibodies to Other Phospholipids

Testing for antibodies to a panel of phospholipids (e.g., phosphatidylinositol, phosphatidic acid, phosphatidylcholine) is controversial. In general, these tests are poorly standardized, and their clinical significance in patients with negative anticardiolipin, lupus anticoagulant, and anti- β_2 -GPI tests has not been established.

Recommendations for aPL testing are summarized in Box 152-2.

Antibodies against other phospholipids

Management and Therapy

Optimum Treatment

Prevention of Recurrent Thrombosis

Long-term anticoagulation, rather than immunosuppression, is the mainstay of therapy. Warfarin anticoagulation at a high target international normalized ratio (INR) (3.0 to 4.0) was previously recommended. More recently, a randomized trial suggested that a target INR of 2.0 to 3.0 is adequate, and many experts in the field have adopted this recommendation. Anticoagulation with unfractionated or low-molecular-weight heparin may be used in some cases. In general, anticoagulation is for an indefinite period of time. Of course, long-term full anticoagulation carries a significant risk for bleeding complications, and the decision to institute such therapy must be individualized and take into account the patient's age, compliance, and comorbid conditions. In some patients, aPL tests may become negative after months or years. It is not known whether it is safe to discontinue anticoagulation in this situation.

Prevention of Pregnancy Loss

In women with a prior pregnancy loss related to aPL, the chance of an untreated subsequent pregnancy resulting in a live birth is only about 20%. Treatment with low-dose aspirin alone increases the live birth rate significantly, to about 40%. Treatment with heparin and low-dose aspirin is even more effective, increasing the chance of a live birth to about 80%.

Candidates for treatment are women with persistent medium or high positive tests for aPL and one or more

fetal losses (>10 weeks' gestation) or a history of thrombosis. Women with early pregnancy losses (<10 weeks' gestation) or low levels of aPL are at lower risk for subsequent pregnancy loss, and the treatment decision is more difficult.

For women with obstetric APS without a prior history of thrombosis, typical treatment regimens are minidose or low-dose unfractionated heparin (5,000 to 10,000 units every 12 hours) or prophylactic doses of low-molecular-weight heparin. Anticoagulation is held around the time of delivery but is recommended during the postpartum period (6 weeks) to prevent maternal thrombosis.

Asymptomatic aPL

Unless contraindicated, low-dose aspirin is recommended for asymptomatic individuals with aPL, including women with a history of obstetric APS who are not pregnant. This recommendation is not strongly evidence based; however, low-dose aspirin is likely to lower the risk for thrombosis, has a low incidence of adverse side effects, and is inexpensive.

Other Therapeutic Agents

In patients with SLE and aPL, hydroxychloroquine appears to lower the risk for thrombosis. The role of antiplatelet agents, such as clopidogrel, in APS is unknown. Rituximab therapy in a small number of cases of APS has produced mixed results. Intravenous immune globulin (IVIG) has been used in several cases of pregnancy loss, previously refractory to heparin and aspirin. In a small randomized trial, however, IVIG did not add benefit. HMG-CoA reductase inhibitors (statins) have a number of beneficial vascular effects in addition to lowering cholesterol. In animal models of APS, statins have shown some benefit.

Avoiding Treatment Errors

Given the considerable risks of long-term anticoagulation, it is especially important to carefully determine which patients clearly have aPL and require such treatment. Ideally, the presence of aPL, either the lupus anticoagulant or medium to high levels of anticardiolipin or anti- β_2 -GPI antibodies, should be confirmed on two or more occasions, at least 2 to 3 months apart. Care should also be taken to ensure that lupus anticoagulant testing is complete and includes the necessary confirmatory tests. A prolonged routine aPTT alone is not sufficient evidence to establish the presence of a lupus anticoagulant. Finally, panels of tests for antibodies to multiple phospholipids are not recommended and, if performed, should be interpreted with caution. As noted, most of these tests are not well standardized, and their significance, if standard antiphospholipid tests are negative, is questionable.

Future Directions

Research is rapidly shedding light on the immunology of aPL and the pathophysiology of the associated hypercoagulability. The elucidation of these mechanisms may suggest therapeutic approaches that are effective but much safer than full anticoagulation. For example, a β_2 -GPI-specific B-cell toleragen has been developed and may be able to specifically decrease levels of anti- β_2 -GPI autoantibodies.

Although the criteria themselves are of limited clinical use, this consensus statement summarizes a large body of evidence-based data on the clinical manifestations of APS.

Rheumatoid Arthritis

Introduction

Rheumatoid arthritis (RA) is a multisystem inflammatory disorder with a worldwide prevalence rate in the population of about 1%. The peak age of onset is between 40 and 50 years, with females being affected significantly more often than males; however, with increasing age, the male-to-female ratio equilibrates.

Etiology and Pathogenesis

The etiology of RA is not completely established and is likely to be multifactorial. It is clear that genetic makeup, the immune responses of the individual, and an inciting agent, possibly of bacterial or viral origin, all play a role. RA is associated with a conserved sequence in the hypervariable region of the human leukocyte antigen (HLA)-DR gene; the so-called shared epitope. The presence of the shared epitope is associated with both susceptibility to and severity of RA in some populations. A putative arthrogenic antigen has not been elucidated, although it is likely that numerous exogenous or endogenous antigens may trigger the disease.

Pathologically, synovitis is the hallmark of the disease. New blood vessel formation is prominent in early disease, and the normally thin synovial membrane becomes hypertrophic. Synovial inflammation is characterized by the influx of CD4+ cells. Release of cytokines locally helps mediate tissue destruction with cartilage degradation and, ultimately, erosion of bone.

Clinical Presentation

The diagnosis of RA is important particularly now that early treatment with disease-modifying antirheumatic drugs (DMARDs) and the newer biologic agents has been shown to improve outcomes. The diagnostic criteria of the American College of Rheumatology are shown in Box 153-1. Eventually, a symmetrical inflammatory polyarthritis with small joint involvement develops in all patients. Most patients present with an insidious onset over weeks to months, but some patients (about 10%) have an acute onset over a few days. The small joints of the hand and

wrist are most commonly involved early, but some patients may present with a monoarthritis. The diagnosis can be difficult in the early stages, and patients with chronic joint pain need to be reassessed on a regular basis.

Signs and symptoms include joint pain; joint swelling with synovitis (synovial thickening and fluid); joint stiffness, worse in the mornings; joints that are usually warm, and occasionally erythematous; limited range of motion; nodule formation on the extensor aspect of the forearm; low-grade fever in some cases; and malaise and fatigue (Fig. 153-1). Extra-articular manifestations occur in patients with more severe disease and may include Sjögren's syndrome, episcleritis or scleritis, pleurisy, pulmonary nodules, pulmonary fibrosis, pericarditis, rheumatoid vasculitis, and Felty's syndrome (Fig. 153-2).

Initial laboratory test results may be normal but can show a thrombocytosis, leukocytosis, mild anemia (normochromic, normocytic, or microcytic), elevated erythrocyte sedimentation rate, and high C-reactive protein. Immunoglobulin M rheumatoid factor is present in about 50% of cases at presentation, and in 70% to 75% of cases over time. Antibodies to cyclic citrullinated peptide (CCP) are a more sensitive marker and may be seen in early disease. Aspiration of inflammatory fluid from the joint often reveals a high white blood cell count with polymorphonuclear leukocytes predominating. Synovial fluid analysis is particularly important in early disease to rule out crystalline arthropathies, or in the case of a monoarthritis to rule out infection.

Differential Diagnosis

Box 153-2 provides the differential diagnosis of rheumatoid arthritis.

Box 153-1 Criteria for the Classification of Rheumatoid Arthritis* (Revised 1987)

1. Morning stiffness lasting greater than 1 hour
2. Arthritis in 3 or more joint areas
3. Arthritis of the hand joints
4. Symmetrical arthritis
5. Rheumatoid nodules
6. Serum rheumatoid factor
7. Radiographic changes: erosions or unequivocal periarticular osteopenia

*Patients are said to have rheumatoid arthritis if they satisfy four of the seven criteria.

Adapted from Arnett FC, Edworthy SM, Bloch DA, et al: *The American Rheumatism Association 1987 revised criteria for the classification of rheumatoid arthritis*. *Arthritis Rheum* 31:315-324, 1988. Reprinted with permission of Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

Box 153-2 Differential Diagnosis of Rheumatoid Arthritis

- Seronegative spondyloarthropathies: particularly psoriatic arthritis, but also ankylosing spondylitis, reactive arthritis, and the arthritis of inflammatory bowel disease
- Polyarticular gout or calcium pyrophosphate crystal deposition disease
- Early stages of diffuse connective tissue diseases, such as systemic lupus erythematosus, scleroderma, or polymyositis
- Hemochromatosis
- Arthritis associated with the hemoglobinopathies or hemophilia
- Infectious arthritis, particularly parvovirus B19 and other viral pathogens
- Bacterial endocarditis
- Arthritis associated with thyroid disease (hypothyroidism or hyperthyroidism)
- Osteoarthritis
- Polymyalgia rheumatica
- Rheumatic fever
- Sarcoidosis

Diagnostic Approach

Patients with recent onset of inflammatory polyarthralgia or polyarthritis should have a complete history and physical examination. Although RA is common, elements of the history or physical examination that might suggest another cause require special attention. Swollen or tender joints should be surveyed to document true synovitis and to form a baseline examination to assess progress in future visits. Radiographs are often normal in early disease. The presence of periarticular osteopenia is sometimes helpful in differentiating inflammatory from noninflammatory causes of joint pain. Radiographs of the hands (and feet if clinically indicated) can be useful to establish a baseline. The presence of erosions on the baseline radiograph is a poor

prognostic factor and indicates the need for an aggressive approach. Synovial fluid analysis is performed to document the inflammatory nature of the joint disease and rule out other causes of synovitis, including gout, calcium pyrophosphate deposition disease, and septic arthritis. Other laboratory tests include rheumatoid factor, anti-CCP, complete blood cell count, chemistry profile, and some acute-phase reactants such as the erythrocyte sedimentation rate or C-reactive protein. Serologic testing for parvovirus or other viral illnesses deserves consideration in the case of an acute presentation.

Management and Therapy**Disease-Modifying Antirheumatic Drugs**

The most commonly used DMARDs include hydroxychloroquine, sulfasalazine, methotrexate, and leflunomide. The mechanism of action of these drugs is complex, but they all inhibit inflammatory responses and suppress synovitis. Hydroxychloroquine is useful in very early and mild disease. Because it is laid down in pigment tissue, ophthalmologic assessment is recommended at baseline and annually. There is little or no risk for long-term ocular sequelae if standard dose regimens are adhered to (200 to 400 mg daily) and routine monitoring is performed. Sulfasalazine is given orally; the dosage should be increased slowly from 500 mg to 2 g daily. Some patients might require a trial of up to 4 g daily for 4 to 6 weeks if there is no response. Side effects include indigestion, abnormal liver function tests, leukopenia, anemia, and skin rashes. Required monitoring includes complete blood cell count and liver function tests on a regular basis, at least for the first 3 months of therapy, and periodically thereafter.

Methotrexate, the most commonly used member of this group, is given orally in a dose of 10 to 25 mg once a week. Side effects include indigestion, oral ulcers, hair loss, occasional blood dyscrasias, and abnormal liver function tests. The risk for hepatic fibrosis with long-term administration now appears sufficiently small to preclude routine liver biopsy, except in patients with preexisting liver disease. Treatment of patients who have a regular moderate alcohol intake, history of liver disease, diabetes, or obesity requires great care and vigilance. Patients should be screened for chronic infection with hepatitis B and C before instituting therapy with methotrexate. The drug is contraindicated in pregnancy. The addition of folic acid, 1 mg daily, is recommended to reduce toxicity. Monitoring of blood cell counts and liver function tests is recommended every 8 weeks, although less frequent monitoring can be done in patients who have been taking a long-term stable dose without a history of toxicity.

Leflunomide is given orally in a dose of 20 mg daily after a 3-day loading dose of 100 mg daily. It has been shown to slow the radiographic progression of disease. Common side effects include diarrhea, elevated transami-

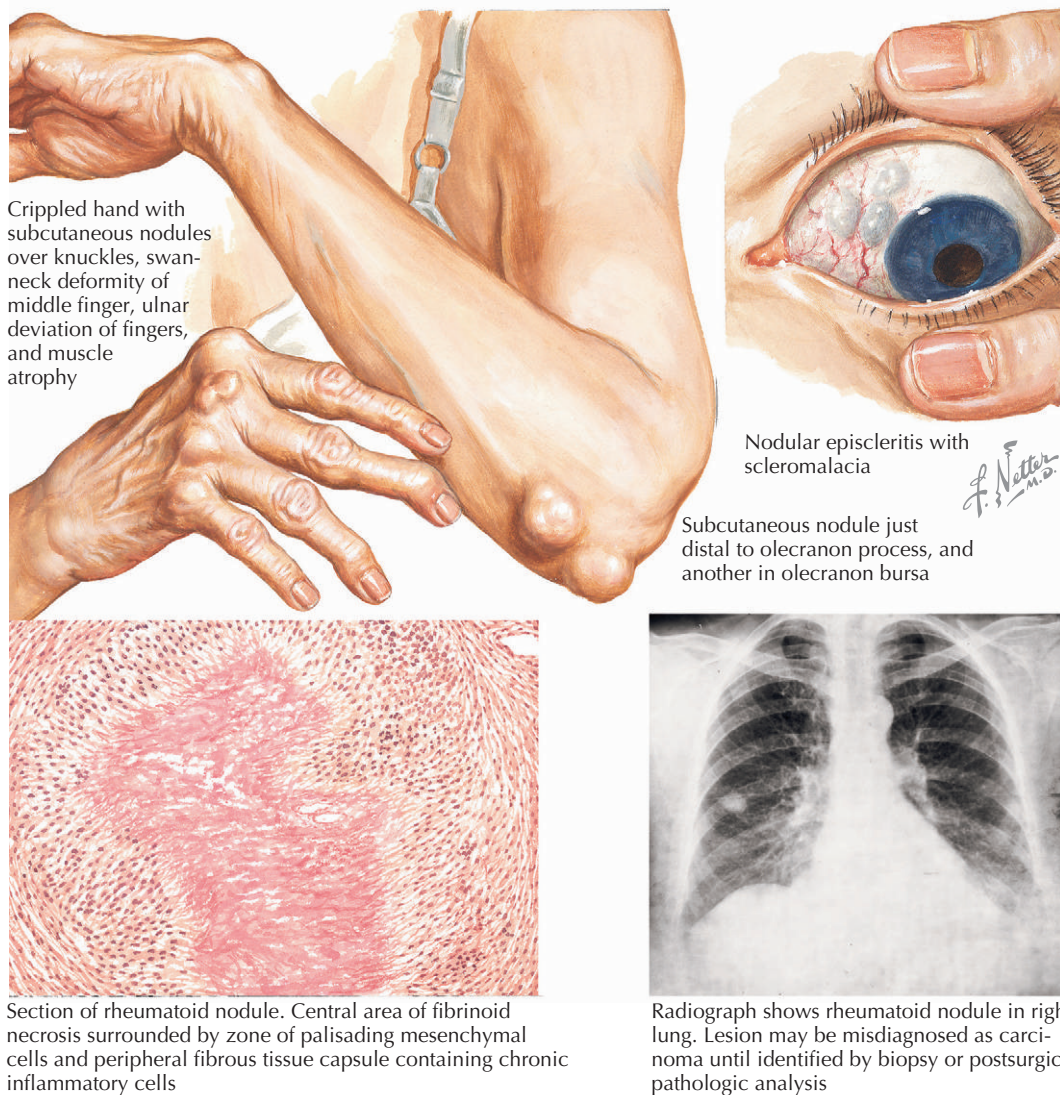

Figure 153-1 Early and Moderate Hand Involvement in Rheumatoid Arthritis.

nase levels, reversible alopecia, and rash. Leflunomide is teratogenic in animals. Women who wish to become pregnant and men who want to father a child must first discontinue the drug and take cholestyramine (8 g 3 times daily for 11 days) to eliminate the drug. Use of leflunomide in reduced dose (10 mg daily) in combination with methotrexate is an alternative, but long-term safety has not been established. Monitoring of blood cell counts and liver function tests is recommended every 8 weeks.

Biologic Agents

Etanercept is a recombinant dimeric fusion protein of the soluble human tumor necrosis factor (TNF) receptor. Etanercept, 50 mg subcutaneously weekly, has been shown to be effective in RA when there has been an inadequate response to other DMARDs. Injection-site reactions are common but rarely limit therapy. Infliximab is a monoclonal antibody that binds TNF and neutralizes its activity.

Figure 153-2 Extra-articular Manifestations of Rheumatoid Arthritis.

Section of rheumatoid nodule. Central area of fibrinoid necrosis surrounded by zone of palisading mesenchymal cells and peripheral fibrous tissue capsule containing chronic inflammatory cells

Radiograph shows rheumatoid nodule in right lung. Lesion may be misdiagnosed as carcinoma until identified by biopsy or postsurgical pathologic analysis

Like etanercept, it is indicated in RA unresponsive to traditional DMARDs. Administration is by intravenous infusion at weeks 0, 2, and 6 and then every 8 weeks. Infusion reactions may occur but are usually mild. The newest anti-TNF agent, adalimumab, is a fully humanized monoclonal antibody given subcutaneously, 40 mg every other week. Infections, some life-threatening, have been reported and warrant caution in debilitated patients. Severe infections have been reported, particularly tuberculosis. Therefore, a pretreatment purified protein derivative (PPD) tuberculin is recommended for patients starting anti-TNF therapy. The U.S. Food and Drug Administration has approved anakinra, an interleukin-1 receptor antagonist, for RA. It is given subcutaneously, 100 mg daily. Efficacy appears to be modest, but it may be an option for patients who have not responded to other, more effective therapies. Injection-site reactions can be severe but usually wane after 4 to 6 weeks of therapy.

In patients who have had an inadequate response to DMARDs or TNF- α inhibitors, two new agents with unique mechanisms may provide good clinical efficacy. Rituximab is an anti-CD20 monoclonal antibody that results in B-cell depletion. It is given by intravenous infusion, two doses separated by 2 weeks. Because of the drug's ability to effectively deplete B cells for a long period, dosing occurs no more frequently than every 6 months. Abatacept is a selective costimulation modulator with inhibitory activity on T cells. The drug is given monthly by the intravenous route.

Corticosteroids

Systemic corticosteroids are effective in the treatment of RA, but significant short- and long-term toxicity limits their use. Doses of prednisone should be kept below 10 mg

daily if possible, with the majority of the dose given in the morning. Corticosteroids should be aggressively tapered once effective DMARDs have been instituted if at all possible. At times, intra-articular injections are extremely useful in controlling inflammation in individual joints. However, they should not be given at intervals of less than 3 months and are contraindicated in the presence of local infection.

Nonsteroidal Anti-inflammatory Drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) interfere with the production of prostaglandins and therefore reduce pain and inflammation. NSAIDs produce a plethora of adverse reactions, the most common being peptic ulceration. The newer selective cyclooxygenase-2 inhibitors may have some advantage over traditional NSAIDs because the relative risk for gastrointestinal ulceration is lower. However, recent concerns regarding potential cardiovascular toxicity require careful consideration when choosing an agent. All NSAIDs have significant renal adverse effects, particularly in elderly patients, including acute renal failure and fluid retention. As a rule, NSAIDs should be used as an adjunct to DMARD therapy and never as monotherapy in patients with established RA because they do not have any disease-modifying properties.

Drug Therapy

NSAIDs are suitable first-line agents for the management of active disease. Consider low-dose prednisone (10 mg daily) in patients who are not adequately controlled on NSAIDs, at least until effective DMARD therapy can be achieved. Most patients with RA will require DMARDs, and therapy with these drugs should begin as soon as the diagnosis of RA is established. Delay will lead to irreversible joint destruction in most patients with moderate or severe disease activity. Patients may not respond to DMARD therapy for up to 3 months after a therapeutic dose is achieved. The evaluation of efficacy requires frequent monitoring of disease activity. If there is no evidence of disease suppression, then the drug should be changed. Periodic radiographic assessment is recommended even in those patients with an adequate clinical response because progression of erosive disease warrants intensification of therapy. When response to methotrexate is incomplete, the patient may benefit from combinations of methotrexate with other agents such as sulfasalazine, leflunomide, or a TNF inhibitor. If general control is achieved but individual joints continue to show active inflammation, intra-articular corticosteroid injections can be considered. These might need to be repeated on occasion, but preferably no more than 3 times per year in a single joint. A joint requiring more frequent injections may indicate the need for more aggressive systemic therapy or, in the case of a persistent monoarthritis, a surgical approach.

Surgical Treatment

The major reason for surgery is pain relief or restoration of function. Surgical options include synovectomy (of joint or tendons), arthroplasty, and arthrodesis. Synovectomy can be performed on the knees, wrists, metacarpophalangeal joints, or other joints unresponsive to medical therapies. The synovium might well grow back into the joint if disease activity continues, but patients can experience some pain relief for a number of years. Arthroplasty with joint replacement is commonly used in the hips, knees, and metacarpophalangeal and interphalangeal joints. Shoulder and elbow joint replacements are now gaining acceptance; wrist and ankle replacements are still in their infancy. Use of new prosthetic materials and cementless prostheses is likely to improve long-term morbidity. Although joint replacement should be put off as long as possible, great relief can be afforded appropriate patients. Arthrodesis remains an option for intractable wrist or ankle disease.

Avoiding Treatment Errors

The diagnosis of inflammatory joint disease should be confirmed. Whether the pain is due to active synovitis or to secondary degenerative changes should be determined. This is particularly important in those patients with chronic disease when the question of DMARD therapy is raised. It is critically important to maintain awareness of potential drug interactions and to continually reassess patients and change drugs or other treatments if there is no response to treatment. Referring patients to a rheumatologist on diagnosis is advisable, particularly for educational purposes. Also consider referral if there is deteriorating function, when the patient appears generally ill and systemic corticosteroids are contemplated, if there is persistent inflammation in a joint (this could lead to deformity), or if a surgical procedure is contemplated.

Optimum Treatment

Psychological factors are important in patients who have chronic pain and inflammatory joint disease. These need to be addressed and demand a combined approach with allied health professionals including the physiotherapist, occupational therapist, social worker, nurse, and the patient's family. Patient education and self-management skills are extremely important.

Future Directions

Research in RA has made significant strides with the understanding of the role of genetic factors in disease onset and progression, the cytokine profile in active disease, and the introduction of targeted therapies based on these discoveries. The TNF inhibitors, B-cell-targeted therapies, and co-stimulation modulation have made a large contribution to our armamentarium of antirheumatic therapies.

There is an explosion of new biologic compounds on the horizon. These include new TNF inhibitors, anti-interleukin-6 therapy, newer agents directed against interleukin-1, and many more. New targets for therapy are being sought and found. The next decade will bring further work on mechanisms of inflammation that may contribute to disease activity and the development of novel therapeutic targets.

This is an excellent review of the therapeutic principles for the treatment of RA. The article includes clear and concise algorithms and guidelines for monitoring drug therapy.

Scleroderma

Introduction

Scleroderma encompasses a heterogeneous group of chronic autoimmune disorders characterized by inflammation and fibrosis in the skin (Fig. 154-1). Systemic involvement and treatment response may correlate with the extent of skin involvement. Systemic sclerosis is classified into three major clinical subtypes: limited cutaneous scleroderma (lcSSc), diffuse cutaneous scleroderma (dcSSc), and overlap. These subtypes are distinguished from each other primarily on the basis of the extent and degree of skin involvement. Localized or limited scleroderma consists of morphea and linear scleroderma, sclerotic lesions of the skin without visceral involvement. Systemic sclerosis sans scleroderma is characterized by visceral involvement only. Diffuse scleroderma includes two syndromes: CREST (calcinosis cutis, Raynaud phenomenon [RP], esophageal dysmotility, sclerodactyly, and telangiectasias) and diffuse systemic sclerosis. In addition to the skin, systemic sclerosis involves the blood vessels, joints, skeletal muscle, and frequently internal organs such as the gastrointestinal tract, heart, kidney, and lungs. In the United States, the incidence is about 20 to 30 new cases per million people annually, with a prevalence of 105 to 138 per 1 million. The female-to-male incidence ratio is 3 : 1, and the peak age of onset is 40 to 60 years. No significant racial differences in disease onset or expression have been found.

Etiology and Pathogenesis

The etiology of scleroderma remains unknown. Monozygotic twin concordance rates are lower than those of other rheumatic diseases such as rheumatoid arthritis and lupus, suggesting an important role for environmental exposure in pathogenesis. Prior investigation suggests that scleroderma is a multigenic, complex disorder. An individual with a susceptible genetic background may encounter an inciting factor such as infection, organic solvents, drugs, or environmental agents. Implicated environmental agents include silica dust exposure, certain solvents, drugs, and chemotherapeutic agents. Several retrospective studies do not show an increased risk in women with silicone breast implants.

Clinical expression includes vascular, fibrotic, and immunologic features. Pathogenic events include endothelial cell injury and vascular obliteration, increased matrix deposition by dermal and visceral fibroblasts, and activation of cellular and humoral immune responses. Genetic factors play a role in disease susceptibility, but no single major histocompatibility complex allele is associated with an increased risk for scleroderma in all ethnic groups.

Microchimerism (the persistence of fetal cells in the maternal circulation) may contribute to immune activation in this autoimmune disorder. Complete remission in diffuse scleroderma is rare.

Clinical Presentation

Limited Cutaneous Scleroderma

There is restricted skin fibrosis affecting the distal extremities and face and occasional late development of pulmonary arterial hypertension, pulmonary fibrosis, or small bowel malabsorption. The CREST syndrome that presents with findings of calcinosis, RP, esophageal dysfunction, sclerodactyly, and telangiectasia is closely analogous to lcSSc. The 10-year survival is more than 70%.

Diffuse Cutaneous Scleroderma

Widespread skin fibrosis affects distal and proximal extremities (proximal to elbow), trunk, and face. There is a tendency to rapid progression of skin thickening and early occurrence of visceral disease affecting the gastro-

Figure 154-1 Progressive Systemic Sclerosis (Scleroderma).

Typical skin changes in scleroderma: extensive collagen deposition and some epidermal atrophy

Sclerodactyly: fingers partially fixed in semiflexed position; terminal phalanges atrophied; fingertips pointed and ulcerated

intestinal tract, lung, heart, and kidneys. Palpable tendon friction rubs and flexion contractures are frequently associated. The 10-year survival rate is usually less than 70%.

Scleroderma Sans Sclerodactyly

Some patients with scleroderma may have no detectable skin thickening and present with pulmonary fibrosis or renal, cardiac, or gastrointestinal disease. RP may be present.

Overlap

Scleroderma overlap includes either diffuse or limited skin fibrosis and typical features of one or more of the connective tissue diseases such as rheumatoid arthritis, systemic lupus erythematosus, polymyositis, dermatomyositis, or Sjögren's syndrome.

Raynaud's Phenomenon

RP, an episodic and reversible vasospasm precipitated by cold exposure or emotional stress, occurs in about 95% of scleroderma patients at some time during the disease. It is

accompanied by color changes of pallor (white), acrocyanosis (blue), and reperfusion hyperemia (red). Typically, it affects the fingers, toes, nose, and ears but can also affect the heart, lungs, and kidneys. Ischemic necrosis may occur, leading to ulceration of the fingertips in up to 15% to 25% of patients. Gangrene or superinfection may occur in these areas of tissue necrosis.

Skin

In lcSSc, skin thickening is minimal over several years and does not correlate with development of visceral disease. Calcinosis from intracutaneous or subcutaneous calcific deposition of hydroxyapatite is commonly present on the digital pads and extensor surface of the forearms, elbows, and knees. Occasionally, it is more widespread. Telangiectasias, most typical of lcSSc, are usually present on the fingers, face, lips, and anterior chest. On nail-fold capillary microscopic examination, dilated loops of capillaries are seen in both diffuse and limited subsets of scleroderma. In dcSSc, a paucity of nail-fold vessels or "drop out" may be seen.

In dcSSc, patients may complain early in the disease of puffy, edematous hands (edematous phase). This is fol-

lowed by thickening and tightening over subsequent weeks to months (indurative phase). Hypopigmentation and hyperpigmentation of the skin may occur. Over several years, the skin may revert to normal thickness or become thin (atrophic phase). Perioral involvement leads to thinning of the lips, puckering, and reduced oral aperture. In early dcSSc, skin sclerosis progresses rapidly, peaking in the first 2 years. It is closely associated with progression of visceral disease and development of joint contractures. Skin scores are employed in clinical trials to assess these changes. Notably, the natural history of the skin involvement is to decrease over time even without treatment.

Musculoskeletal

Arthralgias and joint stiffness may affect the small and large joints. Tendon friction rubs commonly palpated over the flexor or extensor tendons due to fibrinous tenosynovitis and tendinitis are specific for dcSSc. They are associated with increased skin thickness, renal involvement, and reduced survival. The patient may lose a significant degree of range of motion in the joints due to the progression of skin fibrosis or to bridging calcinosis. Erosive joint disease is also seen. Patients may also develop proximal muscle weakness that is associated with electromyographic and pathologic evidence of myositis.

Gastrointestinal Tract

Esophageal dysfunction eventually develops in about 80% of patients. The most frequent symptoms are heartburn and substernal dysphagia. Conventional barium swallow shows hypomotility of the distal portions of the esophagus. Classic manometric findings consist of an incompetent lower esophageal sphincter and low-amplitude contractions in the distal smooth muscle portion of the esophagus. Small bowel dysfunction has been reported in 20% to 60% of patients. Reduced peristalsis leads to stasis and intestinal dilation, which favors bacterial overgrowth, causing fat malabsorption and eventually malnutrition. Pseudo-obstruction is a rare complication that presents with severe postprandial bloating and cramps. Hypomotility of the small intestine results in a functional ileus with symptoms simulating a mechanical obstruction. Constipation often complicates impaired peristalsis of the colon, either alone or alternating with diarrhea. Patchy atrophy of the muscular wall leads to development of wide-mouthed diverticula on the antimesenteric border of the transverse and descending colon. The liver, biliary tract, and pancreas are rarely involved. Primary biliary cirrhosis, the liver disorder seen most frequently with limited cutaneous scleroderma, is strongly associated with the presence of the antimitochondrial antibody (AMA).

Lung

Pulmonary involvement occurs in more than 70% of patients with systemic sclerosis (diffuse cutaneous scleroderma) and is the most common cause of disease-related mortality (Fig. 154-2). Interstitial lung disease (ILD) and pulmonary vascular disease complicated by pulmonary hypertension are the main clinical manifestations. The most common symptoms of interstitial lung disease are dyspnea on exertion and dry cough. Dry, bibasilar end-inspiratory rales are usually present, and chest radiographs show reticular interstitial changes or fibrosis, most prominent in the lower lung fields. A restrictive ventilatory defect is commonly noted. High-resolution computed tomography (CT) identifies a ground-glass appearance representing active alveolitis. Bronchoalveolar lavage (BAL) is helpful to determine whether there is active inflammation (alveolitis) characterized by an overall increase in alveolar macrophages and granulocytes recovered by BAL, as well as an increased percentage of granulocytes (neutrophils >3% or eosinophils >2.2% of total cells). Interstitial alveolitis may progress to fibrosis with irreversible scarring, secondary pulmonary hypertension, and hypoxia. The factors associated with the highest risk for severe restrictive disease are black race, male gender, younger age in patients with diffuse cutaneous disease, and the presence of anti-topoisomerase I antibody.

Pulmonary hypertension characterized by rapidly progressive dyspnea and accentuation of the pulmonic component of the second heart sound occurs in about 5% of patients with lcSSc, typically 10 to 30 years after onset of RP. Occasionally, it is seen in patients who have anti-U3 ribonucleoprotein (anti-U3RNP) antibody. The diffusing capacity is severely reduced, and the electrocardiogram (ECG) shows evidence of right heart dysfunction. The prognosis is poor; a median survival of less than 2 years may be affected by intravenous or subcutaneous prostacyclin, sildenafil given three times daily, inhaled iloprostacyclin, or the endothelin receptor antagonists. Many patients receive a combination of these therapies.

Heart

Clinically symptomatic pericardial disease is infrequent (5% to 16%). The echocardiogram detects small effusions in about 41% of asymptomatic patients with scleroderma. A large pericardial effusion (>200 mL) can lead to cardiac tamponade and is a marker for poor outcome with an increased risk for subsequent renal crisis. Myocarditis is rare but occurs in patients with systemic scleroderma and concomitant skeletal myositis. Systolic or diastolic dysfunction may develop in this setting as a result of myocardial fibrosis. About 37% of patients (both diffuse and limited cutaneous) have abnormalities on resting ECG. Supraventricular and ventricular arrhythmias are found more frequently in patients with diffuse cutaneous scleroderma. Cardiac arrhythmias are strongly associated with

Figure 154-2 Progressive Systemic Sclerosis (PSS; Scleroderma); Lung Involvement.

Grossly sectioned lung. Extensive fibrosis and multitudinous small cysts. Visceral pleura thickened but not adherent to chest wall

Reticular opacification in both lungs with small radiolucencies interspersed

Microscopic section of lung. Fibrosis with formation of microcysts, many of which represent dilated bronchioles.

Esophagus, kidneys, heart, skin, and other organs as well as joints may also be affected

Rigid, pinched facies and sclerodactyly

mortality and are related to the severity of cardiopulmonary and renal involvement.

Kidney

Twenty-five percent of patients with dcSSc may develop renal crisis, in contrast to only 1% of patients with lcSSc. Scleroderma renal crisis (SRC) is defined as the new onset of accelerated hypertension and rapidly progressive oliguric renal failure. These patients have elevated plasma renin activity and may have an active urinary sediment (microscopic hematuria, proteinuria) or features consistent with ischemic renal injury (acute tubular necrosis) with muddy-brown casts or inactive urinary sediment. Microangiopathic hemolytic anemia and thrombocytopenia are

prominent hematologic features. Some patients present with congestive heart failure, ventricular arrhythmias, or large pericardial effusions. Factors helpful in identifying patients with dcSSc at risk for developing SRC are rapid progression of skin thickening, disease duration less than 4 years, anti-RNA polymerase III antibody, antecedent high-dose steroid use (>20 mg daily), and serum creatinine level higher than 3 mg/dL. All these factors are indicators of a poor prognosis.

Clinical Outcomes

Recent 5- and 10-year survival rates are 80% to 85% and 60% to 65%, respectively. Prognosis is worse for diffuse

scleroderma (10-year survival rate of 40% to 60%) than for limited scleroderma (>70%), primarily because of greater risk for early visceral involvement. Other poor prognostic indicators include later age at onset, African American or Native American race, absence of RP, and presence of tendon friction rubs. Limited scleroderma may be relatively benign at onset, but visceral involvement usually develops over time, most notably pulmonary hypertension.

Differential Diagnosis

The differential diagnosis requires consideration of several scleroderma-like disorders. These include localized scleroderma with fibrosis involving distinct areas, different levels of the skin, and sometimes the underlying soft tissue, muscle, or bone. Women and children are more commonly affected. Subtypes include isolated or generalized morphea, linear scleroderma, nodular (keloid) scleroderma, and, rarely, localized bullous lesions. Diffuse scleroderma with eosinophilia (eosinophilic fasciitis) is associated with swelling, stiffness, and restricted range of motion, but usually spares the hands and face. There is sometimes an association with preceding trauma.

Other disorders may mimic systemic scleroderma (SSc). Sclerodactyly and fibrosis of the palmar fascia occur in insulin-dependent diabetes mellitus, particularly juvenile-onset type—a condition called *diabetic chiroopathy*. A newly described disorder, nephrogenic fibrosing dermopathy, may develop in patients with renal insufficiency following exposure to gadolinium contrast administered for magnetic resonance imaging procedures. This disorder is not autoimmune but may occur in dialysis patients or in patients with renal insufficiency from any cause. The disorder may improve or resolve in some, but not all, patients if renal function improves, following medical therapy or renal transplantation. The disorder is associated with prominent and often quite rapid systemic involvement and is generally fatal because of infectious complications of skin involvement or organ dysfunction. The disease process is often very painful and rapidly produces disability due to joint contractures that may progress over days. Chronic graft-versus-host disease, particularly after bone marrow grafts, may produce many common clinical, biochemical, and histologic features of SSc. Environmental exposures (inhalation of epoxy resins, vinyl chloride, silica dusts, organic solvents and pesticides; ingestion of toxic rape seed cooking oil; or injection of paraffin or bleomycin) may produce features of SSc. Miscellaneous and rare conditions that may lead to diagnostic confusion include Sézary's syndrome, scleredema, carcinoid syndrome, Werner's syndrome, porphyria cutanea tarda, progeria, phenylketonuria, local lipodystrophies, and POEMS syndrome (plasma cell dyscrasia, polyneuropathy, organomegaly, monoclonal spikes, and scleroderma-like skin changes).

Diagnostic Approach

The diagnosis of systemic scleroderma is approached systematically by evaluating the patient for evidence of autoantibody formation and for involvement of major target organs. Features of other connective tissue disorders such as lupus or dermatomyositis require careful review.

Autoantibodies associated with diffuse cutaneous scleroderma are antitopoisomerase I (Scl 70) or anti-RNA polymerase I and III antibodies. Anticentromere antibody is found in up to 90% of patients with limited cutaneous systemic scleroderma and 5% of those with diffuse cutaneous scleroderma. Additional helpful testing includes radiographs of the hands (acral osteolysis and calcification), chest (bibasilar pulmonary fibrosis), and esophagus (barium swallow showing hypomotility). Pulmonary function testing demonstrating decreased diffusion capacity with a restrictive pattern and high-resolution chest CT showing ground-glass opacities are more sensitive indicators of early lung disease. A skin biopsy in an affected area that demonstrates a progressive increase in dermal collagen with loss of appendages can establish the diagnosis.

Management and Therapy

There is no proven therapy for scleroderma. The primary focus is preservation of end-organ function to prolong survival and to enhance quality of life. Aggressive antihypertensive therapy with ACE inhibitors has improved survival rates following onset of renal crisis to more than 2 years. Skin changes in diffuse scleroderma commonly peak in 3 to 5 years and then stabilize; musculoskeletal symptoms and well-being usually improve after this initial period. Skin changes in limited scleroderma are usually very gradual and irreversible, but may start as generalized skin patches, which then retreat to the face and hands. Localized scleroderma generally fades away in 3 to 5 years, but dark skin patches and muscle weakness may persist. After many years, the skin in diffuse scleroderma usually softens and returns to normal thickness, or thins and atrophies; hair and sweat glands always remain absent.

Skin

In the early stages, pruritus may be treated with antihistamines, topical doxepin, 1% hydrocortisone cream, or psoralen plus ultraviolet A (PUVA) therapy. Later, topical emollients help to lubricate sclerotic skin. A recent placebo-controlled study of therapeutic D-penicillamine versus low-dose D-penicillamine failed to show a difference in skin score or mortality rate. Considering the toxic side-effect profile, late onset of action, and lack of proven efficacy, enthusiasm for D-penicillamine treatment in scleroderma has greatly diminished.

Raynaud's Phenomenon

The most effective method of preventing RP is avoidance of cold exposure. Patients should wear warm protective clothing and avoid tobacco use. Long-acting calcium channel blockers (nifedipine, amlodipine, felodipine) are safe and effective vasodilators. Other vasodilators such as nitrates and prazosin are used alone or in combination with calcium channel blockers. One coated aspirin (81 mg daily) is recommended to inhibit platelet activation and occlusion. Intravenous prostaglandins (epoprostenol, iloprost), which reduce the severity of RP and may prevent digital ulceration, are effective when given acutely for critical digital ischemia. The endothelin receptor antagonist, bosentan, has also been shown to be effective as a rescue therapy. Newer more selective inhibitors are under development. Selective digital sympathectomy has been successful in cases that are not responsive to medical management. Oral antibiotics with good staphylococcal coverage are indicated if lesions become infected. Deeper soft tissue infections or osteomyelitis require treatment with intravenous antibiotics, debridement of devitalized tissue, and, if necessary, amputation.

Calcinosis

No therapies have been uniformly successful in treating this rare and often severe involvement of the affected skin. Colchicine (7- to 10-day course) may be useful in suppressing the local inflammation surrounding the areas of calcinosis. Anticoagulation with warfarin, bisphosphonates, and local drainage have been reported effective in series or pilot studies.

Gastrointestinal Disease

Esophageal dysfunction symptoms can be minimized with small, frequent meals, elevation of the head of the bed, and use of proton pump inhibitors. Patients with persistent symptoms require upper gastrointestinal endoscopy to exclude stricture and Barrett's metaplasia. Small bowel dysmotility symptoms can be managed by increasing dietary fiber, avoiding drugs that affect motility (narcotics), and administering empiric antibiotic therapy for bacterial overgrowth. Octreotide has been used as a small bowel prokinetic agent with variable results. In refractory disease, parenteral hyperalimentation may be needed to improve nutrition.

Pulmonary Hypertension

Conventional therapies such as vasodilators, diuretics, and anticoagulation are recommended. Epoprostenol (prosta-cyclin), administered by continuous intravenous or subcutaneous infusion, has been demonstrated to improve the clinical and hemodynamic measurements in patients with

scleroderma. The endothelin-1 receptor inhibitor (bosentan) and sildenafil have been approved for treatment of pulmonary hypertension.

Interstitial Lung Disease

Patients with active alveolitis had improvement or stabilization in lung function when treated with oral or monthly intravenous cyclophosphamide for 12 to 18 months. The role for bronchoalveolar lavage to diagnose alveolitis is less clear. Resting or exertional hypoxia is an indication for supplemental oxygen. Patients with scleroderma who are recipients of lung transplantation experience similar rates of survival 2 years after the procedure as patients with idiopathic pulmonary fibrosis or idiopathic pulmonary hypertension. Lung transplantation may represent a therapeutic option for patients with end-stage lung disease due to scleroderma.

Renal Disease

SRC is a medical emergency. A rapid-acting angiotensin-converting enzyme (ACE) inhibitor should be titrated to normalize blood pressure promptly. Some patients may not respond and progress to renal failure requiring dialysis. Patients requiring dialysis for 12 to 18 months for SRC may recover renal function with continued ACE inhibitor therapy.

Cardiac Disease

The dual endothelin receptor antagonist, bosentan, diminishes the vasoconstrictive and profibrotic effects of endothelin. Reports have documented that bosentan decreases vascular resistance and reduces progression of sclerosis in patients treated for pulmonary hypertension. Increased myocardial perfusion and function have been demonstrated by magnetic resonance imaging and tissue Doppler echography during bosentan therapy.

Musculoskeletal Disease

Nonsteroidal anti-inflammatory drugs may help associated arthralgias. A regular exercise program can improve joint range of motion. Active myositis is treated with methotrexate, azathioprine, or other immunosuppressive agents. Corticosteroid therapy should be avoided, or used in low dose if required, because of the increased the risk for SRC.

Avoiding Treatment Errors

The increased risk for SRC in patients given high-dose steroids cannot be overemphasized. Patient evaluation must exclude scleroderma or scleroderma overlap before committing to prednisone dosing. When it is essential to

treat with steroids, particularly during the edematous phase, the lowest dose that effectively controls symptoms, preferably less than 20 mg of prednisone daily, is prescribed. To reduce the risk for SRC, treatment with ACE inhibitors is essential provided the patient can tolerate these agents.

Future Directions

There are no proven effective therapies for systemic sclerosis. There have been few randomized controlled trials (RCTs) in pulmonary fibrosis in SSc. A recently published RCT investigated the effects of intravenous cyclophosphamide followed by azathioprine treatment in pulmonary fibrosis in SSc. Primary outcome measures were change in percentage of predicted forced vital capacity and change in single-breath diffusing capacity for carbon monoxide. Secondary outcome measures included changes in appearance on high-resolution computed tomography and dyspnea scores. The trial did not demonstrate significant improvement in the primary or secondary end points. Recent trials of methotrexate and cyclosporine have not shown convincing efficacy. A large multicenter trial of relaxin (an insulin-like protein secreted by the corpus luteum during pregnancy that decreases collagen synthesis by fibroblasts) did not demonstrate improvement in skin score. New therapies under investigation include an oral endothelin-1 inhibitor (bosentan), subcutaneous infusion of prostacyclin, and intravenous interferon- γ infusion. Distinctive fibrotic features and data from translational research consistently place transforming growth factor- β (TGF- β) as a central mediator in SSc. A pilot study of a systemic anti-TGF- β 1 drug, CAT-192, showed no evidence of efficacy. Interleukin-4 and interleukin-13 are other fibrotic mediators produced during immune activation that might be targeted for SSc therapy, and therapeutics targeting these interleukins are also being developed. Immune dysregulation, leading to overproduction of these or other fibrotic mediators, might respond to currently available immunosuppressive

agents, including mycophenolate mofetil, cyclosporine, tacrolimus, or sirolimus, alone or in combination.

Spondyloarthropathies

Introduction

The spondyloarthropathies are a group of systemic inflammatory disorders with similar musculoskeletal findings, extra-articular manifestations, and immunogenetic associations. The major conditions and syndromes are ankylosing spondylitis (AS), reactive arthritis (formerly Reiter's syndrome), enteropathic arthritis, psoriatic arthritis, and juvenile spondyloarthropathy. Although these diagnostic entities are useful and important, it may be more useful to regard the spondyloarthropathies not so much as a group of four or five distinct entities, but as arthropathies characterized by combinations of findings, including sacroiliitis, with or without spondylitis; peripheral inflammatory arthritis, which is often asymmetrical and affects the lower limbs predominantly; enthesopathy, especially at the heels and around the pelvis; certain extra-articular features, including iritis, and some mucocutaneous lesions; absence of rheumatoid factor; and familial aggregation and increased prevalence of human leukocyte antigen (HLA)-B27.

Etiology and Pathogenesis

Most of the spondyloarthropathies are associated with inheritance of the HLA-B27 histocompatibility antigen (Table 155-1). HLA-B27 is particularly associated with spondylitis, sacroiliitis, and eye involvement. Epidemiologic data and transgenic animal models support the role of HLA-B27 in disease pathogenesis. HLA-B27 diseases are closely associated with intestinal bacteria or inflammation. Reactive arthritis is associated with *Yersinia*, *Salmonella*, *Shigella*, and *Campylobacter* species gastrointestinal infections, as well as with *Chlamydia* species genitourinary infection. Although intact organisms are not present in inflamed joints, bacterial antigens have been identified in affected synovium. In inflammatory bowel disease, increased intestinal permeability and exposure to normal intestinal flora may play a role in the development of enteropathic arthritis. Microscopic, and usually asymptomatic, gastrointestinal inflammation is present in patients with AS and infection-associated reactive arthritis.

Clinical Presentation

The musculoskeletal features that characterize the spondyloarthropathies as a group include inflammatory back pain, axial arthritis, and enthesopathy.

Inflammatory back pain and axial arthritis are characterized by an insidious onset, radiation of pain to the buttocks and thighs that sometimes alternates from side to side, prominent stiffness, and relief with activity rather than rest. Initially, pain is worse in the low back, but later it may involve the thoracic and cervical areas, sometimes with pain around the thoracic cage. In established disease, there may be loss of normal lumbar lordosis, restriction of lumbar movements in all directions, restriction of chest expansion, and sacroiliac joint and sternal tenderness.

Enthesopathy is inflammation at the site of ligamentous attachments to bone (the enthesis). In spondyloarthropathy, enthesopathy commonly causes plantar fasciitis, Achilles tendonitis, and pain at other sites, including the attachment of the thigh adductors at the pelvis, intercostal muscle insertions, ischial tuberosities, and pelvic brim.

Ankylosing Spondylitis

AS usually presents with inflammatory back pain and stiffness in a young adult, although 20% of patients present with peripheral joint involvement, and more than 50% have joints other than the spine affected at some stage. The disease is 3 times more common in males than females (Figs. 155-1 and 155-2). Enthesopathy is a common association, as previously described.

Table 155-1 HLA-B27 Frequency in Spondyloarthropathies

Disorder	HLA-B27 frequency
Ankylosing spondylitis	90%
With uveitis or aortitis	Nearly 100%
Reactive arthritis	50%-80%
With sacroiliitis or uveitis	90%
Juvenile spondyloarthropathy	80%
Inflammatory bowel disease	Not increased
With peripheral arthritis	Not increased
With spondylitis	50%
Psoriasis	Not increased
With peripheral arthritis	Not increased
With spondylitis	50%
Unaffected whites	6%-8%

Iritis (uveitis) occurs in 25% to 30% and may present with severe throbbing pain, usually unilateral, associated with lacrimation, photophobia, and blurring of vision (see Fig. 155-2). Cardiac involvement occurs in 1% to 4% and includes aortic insufficiency, conduction defects, and pericarditis (see Fig. 155-2). HLA-B27 is present in 90% of patients (nearly 100% of patients with uveitis or aortitis).

Reactive Arthritis

Nonseptic arthritis and often sacroiliitis develop after an acute infection with certain venereal or dysenteric organisms (Fig. 155-3). HLA-B27 is positive in 60% to 80% of cases. Onset is usually abrupt, with urethritis or diarrhea, and conjunctivitis, followed 1 to 3 weeks later by arthritis. The knees and ankles are usually affected, but radiologic sacroiliitis occurs in about 20% to 40% of cases, and a small subset of patients develop a condition indistinguishable from AS.

Mucocutaneous lesions, including keratoderma blennorrhagicum and circinate balanitis, may occur. Cardiac disease develops in 5% to 10% of cases.

Psoriatic Arthritis

Some form of psoriatic arthropathy develops in about 5% of patients with psoriasis. There are several patterns of arthritis.

Monoarticular or oligoarticular disease is the most common (70% to 80%). The distribution is asymmetrical, affecting a large joint, such as the knees, and a few scattered distal interphalangeal joints, proximal interphalangeal joints, and metacarpophalangeal joints. There may be diffuse swelling of one or more involved fingers and toes (sausage digits).

Some patients present with a symmetrical polyarthritis that may resemble rheumatoid arthritis. Arthritis mutilans, a particularly aggressive form of the disease with osteolysis of affected joints, occurs in about 5% of patients with psoriatic arthritis.

Spondyloarthropathy occurs in about 10% of patients. Sacroiliitis may be less symmetrical than AS, and unilateral spinal changes may be seen. HLA-B27 is present in about 60% of patients with spondylitis. It is not associated with psoriasis or with peripheral psoriatic arthritis (Fig. 155-4).

Enteropathic Arthritis

Both peripheral and axial involvement can occur in patients with inflammatory bowel disease (ulcerative colitis and Crohn's disease). Peripheral arthritis occurs in 10% to 20% of patients. Joint disease may precede the onset of bowel symptoms and the diagnosis of inflammatory bowel disease, particularly in Crohn's disease. Arthritis may be acute and migratory. Knees, ankles, and feet are most frequently affected.

Spondylitis and sacroiliitis occur in about 10% of patients with inflammatory bowel disease. They may resemble AS and are occasionally asymptomatic.

HLA-B27 is present in 50% of inflammatory bowel disease patients with axial joint disease, but not frequently in patients with peripheral joint disease.

Juvenile Spondyloarthropathy

A subgroup of patients with juvenile-onset arthritis present with pauciarticular onset, often later than other forms. The age of onset is in the early teens, affecting boys more than girls. Hips, knees, and ankles are affected. Acute iritis is common, and HLA-B27 is usually positive. An arthropathy indistinguishable from AS develops in about half of these patients in young adult life.

Differential Diagnosis

Spondylitis and Sacroiliitis

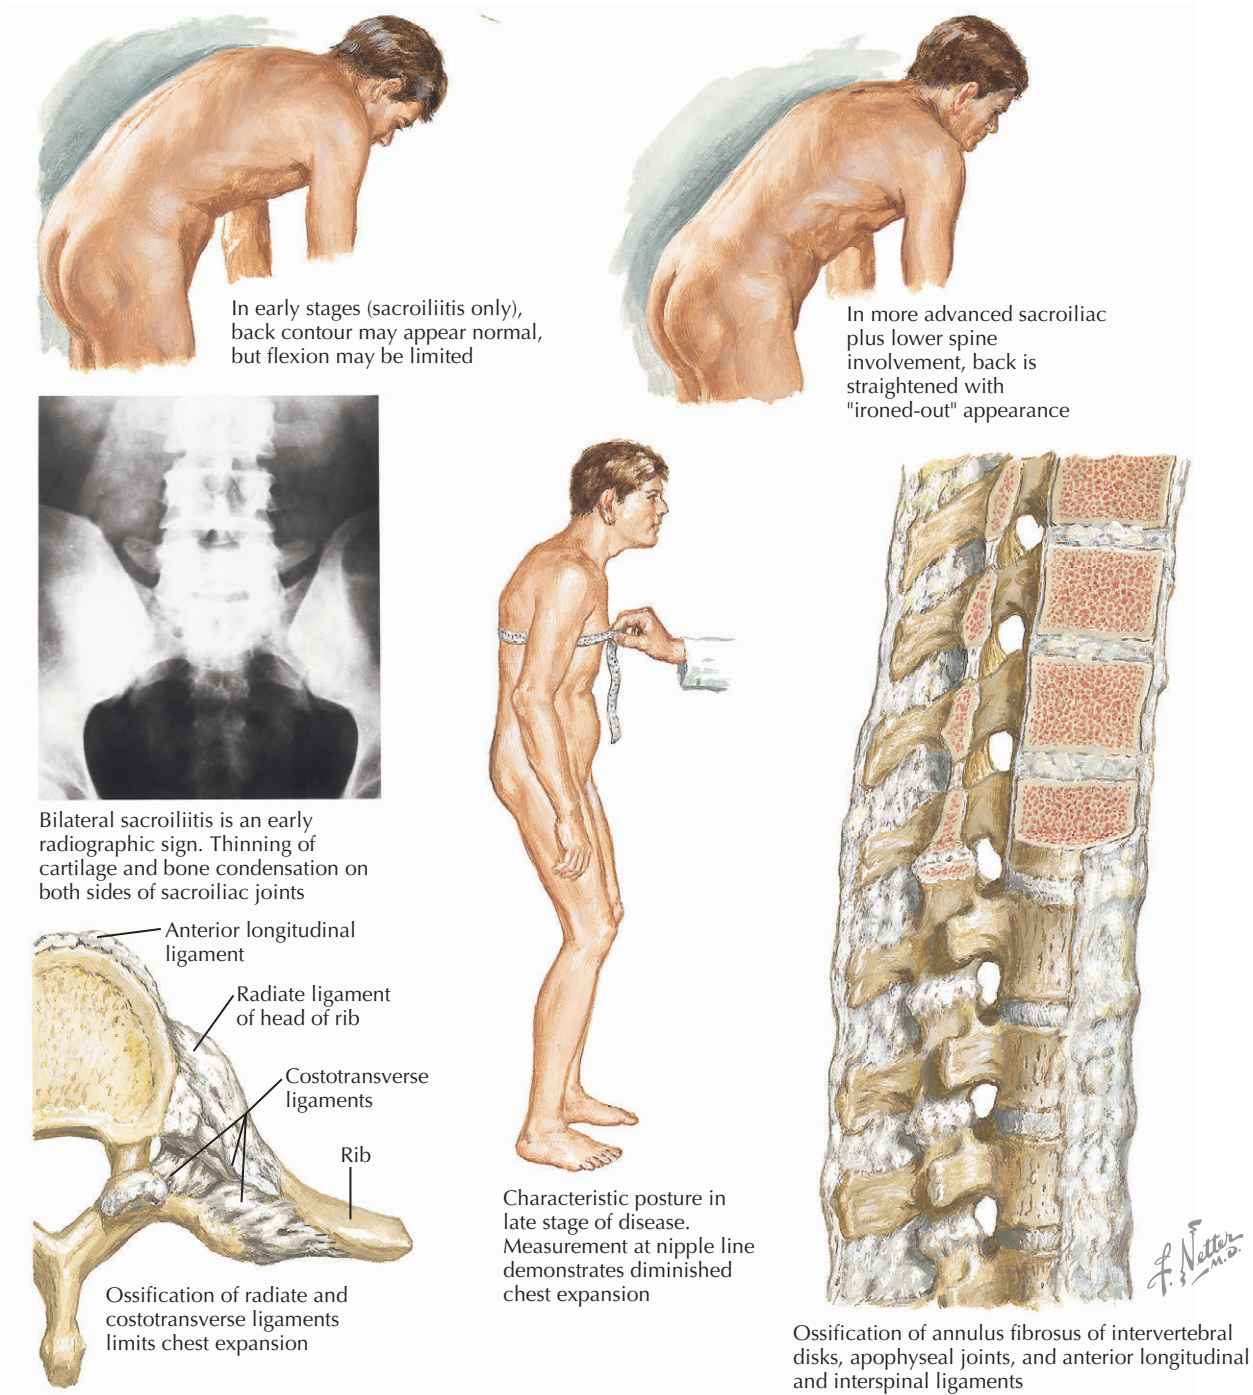

Mechanical low back pain may be difficult to differentiate. Features suggestive of inflammatory back pain and the spondyloarthropathies include an insidious onset, younger age, pain lasting longer than 3 months, and improvement with exercise. Lumbosacral disk disease may have similar clinical characteristics; however, neurologic signs of nerve root compression are uncommon in the spondyloarthropathies. Osteoarthritis occurs in older patients and can usually be differentiated radiographically.

Diffuse idiopathic skeletal hyperostosis occurs in older patients and may involve all levels of the spine. This disease is characterized by large spurs and ossification along the anterolateral aspect of multiple contiguous vertebrae.

Peripheral Arthritis

Acute monoarthritis should be differentiated from septic arthritis, gout, or pseudogout by synovial fluid examina-

Figure 155-1 Ankylosing Spondylitis.

In early stages (sacroiliitis only), back contour may appear normal, but flexion may be limited

In more advanced sacroiliac plus lower spine involvement, back is straightened with "ironed-out" appearance

Bilateral sacroiliitis is an early radiographic sign. Thinning of cartilage and bone condensation on both sides of sacroiliac joints

Characteristic posture in late stage of disease. Measurement at nipple line demonstrates diminished chest expansion

Ossification of radiate and costovertebral ligaments limits chest expansion

Ossification of annulus fibrosus of intervertebral disks, apophyseal joints, and anterior longitudinal and interspinous ligaments

tion. Psoriatic arthritis resembling rheumatoid arthritis may be differentiated by distal and asymmetrical interphalangeal joint involvement, the absence of rheumatoid factor, and the presence of psoriatic skin and nail lesions.

Distinguishing between different types of spondyloarthropathy may be difficult, especially early in the course of the disease. For example, spondylitis preceding the development of inflammatory bowel disease may be indistinguishable from AS. Cutaneous lesions of reactive arthri-

tis may be indistinguishable from pustular psoriasis. The presence of other extra-articular manifestations of reactive arthritis is helpful.

Diagnostic Approach

The diagnosis of the spondyloarthropathies is largely based on the history, physical examination, and radiography. Laboratory tests rarely confirm or refute the diagnosis.

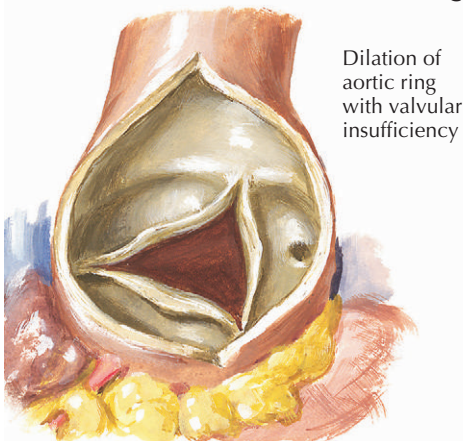

Figure 155-2 Ankylosing Spondylitis.

Radiograph shows complete bony ankylosis of both sacroiliac joints in late stage of disease

"Bamboo spine." Bony ankylosis of joints of lumbar spine. Ossification exaggerates bulges of intervertebral disks

Complications

Dilation of aortic ring with valvular insufficiency

Iridocyclitis with irregular pupil due to synechiae

The patient's history is critical. Characteristic features include inflammatory back pain in younger patients, asymmetrical peripheral arthritis, pain at one or more entheses, extra-articular features or precipitation of the arthritis by enteric or sexually acquired infection, and a positive family history.

The physical examination may not demonstrate obvious physical signs of spondylitis in early or mild disease. Forward flexion can be measured by the Schober test, in which the examiner marks 2 points on the patient's back, one at the lumbosacral junction (sacral dimples) and one 10 cm above. Forward flexion in normal individuals increases the distance between the 2 points by at least 5 cm. Any loss of lumbar lordosis should be noted. Costovertebral involvement is manifested by decreased chest expansion (<5 cm chest expansion on inspiration, measured

at the nipple line). However, these signs frequently do not become positive until there has been significant damage. Tenderness over the sacroiliac joints and other signs of sacroiliitis such as pelvic compression and the Gaenslen sign (pain on involved side hip hyperextension with the opposite hip in flexion) may be helpful, but are not uniformly reliable. Enthesitis at one or more sites (e.g., plantar fasciitis, Achilles tendonitis, epicondylitis) may be present. A thorough search for extra-articular manifestations is especially important, including examination of the skin, nails, genitalia, heart, and eyes.

Radiographic studies may demonstrate syndesmophytes as evidence of sacroiliitis or spondylitis. Periostitis and new bone formation may occur at sites of enthesitis or around affected joints. Radiographic features of psoriatic arthritis include asymmetrical erosions of interphalangeal joints,

Figure 155-3 Reactive Arthritis.

including the distal interphalangeal joints, and pencil-in-cup appearance of the distal interphalangeal joints (see Fig. 155-4). Synovial fluid analysis is nonspecific but useful in excluding infection and crystal-induced arthritis. Tests for rheumatoid factor and antinuclear antibodies are characteristically negative. HLA-B27 testing is generally not necessary, but in selected cases, it may be useful in decreasing the uncertainty of the diagnosis. The test does not help distinguish between AS and other spondyloarthropathies. In reactive arthritis, identification of persistent pathogens by urethral and stool culture or polymerase chain reaction (e.g., *Chlamydia*) is recommended.

Management and Therapy

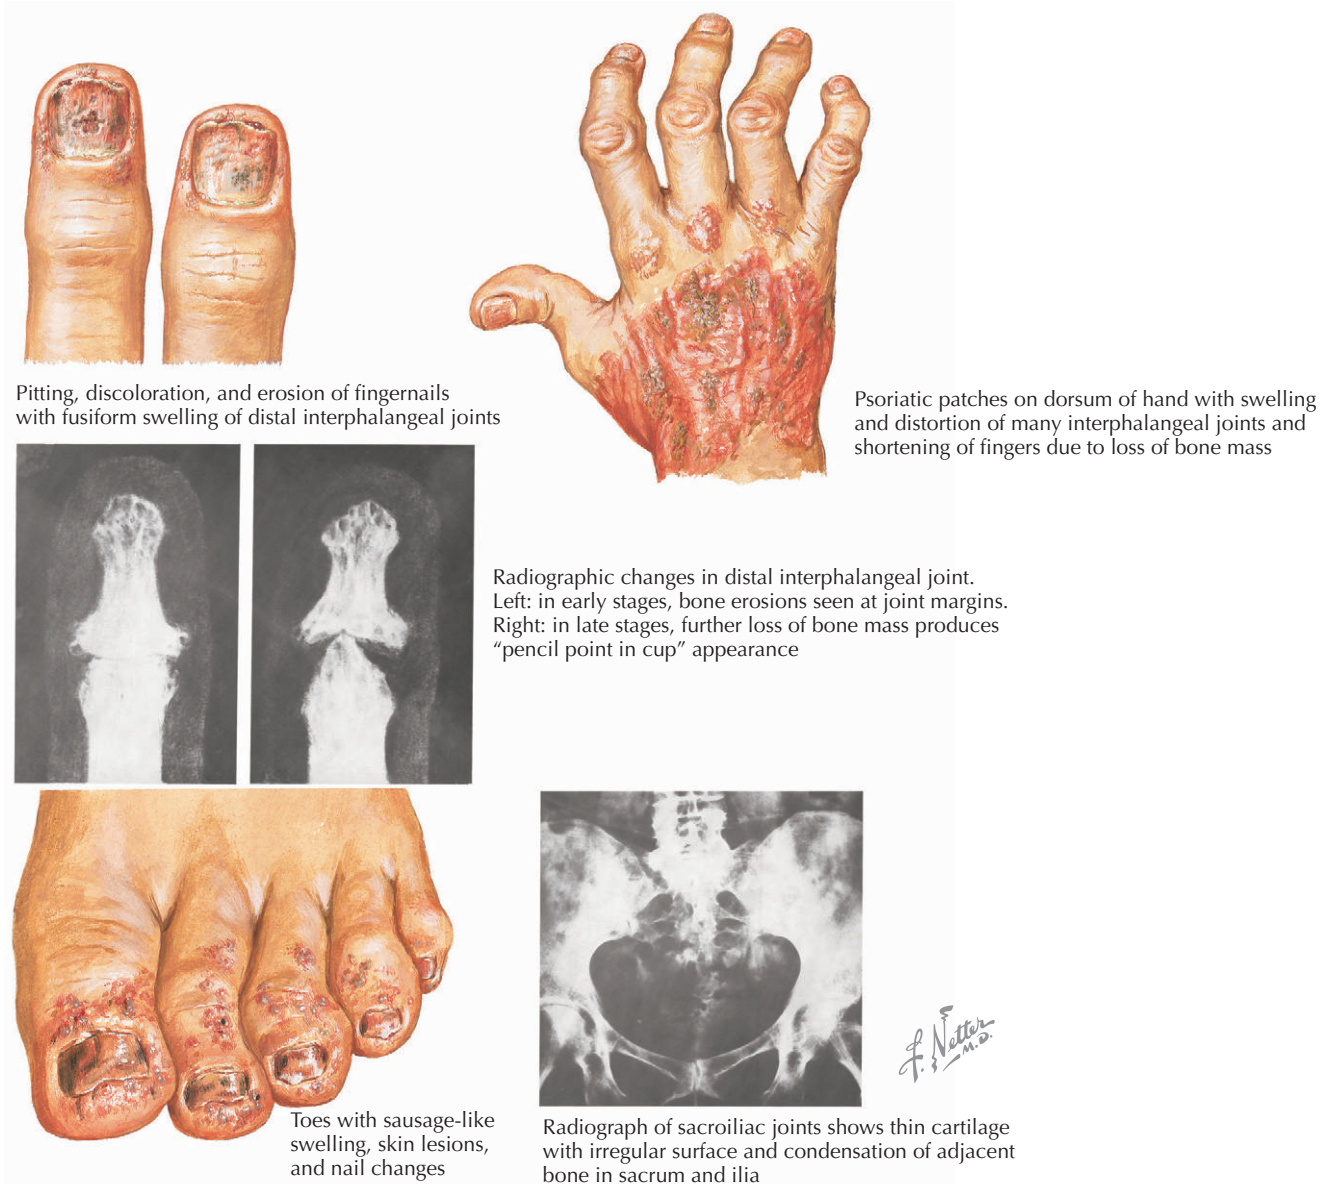

Optimum Treatment

It is important to identify the active elements in the disease (spondylitis, peripheral arthritis, enthesopathy) because

their relative activity and severity affect both the treatment and prognosis. The management of the spondyloarthropathies has advanced considerably over the past decade. The primary goals of therapy are to limit joint damage and to maintain functional status. Management has two main components: drugs to control pain and stiffness and to limit joint damage and physical therapy to prevent range-of-motion limitation and to maintain muscle power.

The diagnosis and prognosis should be discussed with the patient, stressing the importance of early and appropriately aggressive therapy. For most patients, there is effective, but noncurative, treatment, but the long-term prognosis is generally fairly good.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are important in controlling symptoms of spondylitis and peripheral arthritis. Indomethacin (25 to 50 mg 3 to 4 times daily) is usually effective. The extended-release

Figure 155-4 Psoriatic Arthritis.

Radiograph of sacroiliac joints shows thin cartilage with irregular surface and condensation of adjacent bone in sacrum and ilia

capsule or a nighttime suppository may be given to counter early morning stiffness. Several agents may be tried to find the best tolerated drug.

Sulfasalazine is effective in treatment of the peripheral arthritis of spondyloarthropathy. Side effects include nausea, rash, reversible reduction in sperm count, and rarely, agranulocytosis. Regular hematologic monitoring is required, at least in the early stages. Despite side effects, if NSAIDs have failed, sulfasalazine is a useful drug (2 to 3 g daily in divided doses). Intra-articular corticosteroid injections are useful for selected peripheral joints. Systemic corticosteroids are not indicated.

Methotrexate is an effective treatment for the skin and joint manifestations of psoriasis. Typically, therapy is initiated with a single weekly oral dosage of 10 mg. The weekly dosage may be gradually increased in 2.5- or 5.0-mg incre-

ments to 25 mg per week. Methotrexate may also be useful in other forms of spondyloarthropathy when peripheral joint disease predominates. The axial joint disease is usually not responsive to methotrexate.

Antibiotics should be given to patients with proven *Chlamydia* urethritis. A number of studies also suggest that antibiotics may decrease the duration of disease in patients with *Chlamydia*-induced reactive arthritis. The use of antibiotics in postdysenteric reactive arthritis is controversial.

Inhibition of tumor necrosis factor- α (TNF- α) is useful in patients not responsive to other agents. All three TNF- α inhibitors (etanercept, infliximab, and adalimumab) have demonstrated effectiveness in controlling symptoms of disease activity in AS and psoriatic arthritis. In addition, the TNF inhibitors slow the progression of joint damage in psoriatic disease.

In axial disease, the major aims of early therapy are to relieve pain and stiffness and to maintain normal posture and mobility. The inflamed painful spine may feel more comfortable in the flexed position, but fusion in this position can be functionally disastrous. Physical therapy aims to reduce rigidity and ensure that, if ankylosis does occur, the spine is in a nonflexed position. Regular supervision is usually required, and participation in classes may be helpful. Various modalities, including ultrasound, may be helpful in relieving pain due to enthesopathy.

Appropriate orthotic devices may be helpful (e.g., insoles for plantar fasciitis). Uveitis, cardiac, pulmonary, and severe cutaneous involvement should be assessed by appropriate specialists.

Avoiding Treatment Errors

The diagnosis of an active seronegative spondyloarthropathy should be confirmed. If the diagnosis is in question, or if biologic therapy is considered, a consultation with a rheumatologist should be sought. Careful workup to assess the activity of the disease before instituting disease-modifying antirheumatic drug (DMARD) therapy is essential. Periodic evaluation of the patient to determine efficacy and to assess for drug toxicity is also important. Early involvement of other health care providers such as physical therapists, occupational therapists, and psychologists can help the patient manage chronic illness and decrease long-term morbidity.

Future Directions

Ongoing investigations in the seronegative spondyloarthropathies include studies of the pathophysiology of the

diseases, specifically with respect to the role of pathogenic bacteria; the immunogenetics of the diseases; and the role of the new biologic response modifiers in the treatment of severe disease.

Polymyositis and Dermatomyositis

Introduction

Polymyositis (PM) and dermatomyositis (DM) are idiopathic inflammatory myopathies. Both diseases may present with an insidious onset of proximal symmetric muscle weakness. Extramuscular disease may manifest as cardiac, gastrointestinal, pulmonary, cutaneous, or arthritic symptoms. PM and DM can occur in association with other autoimmune diseases and malignancies.

The true incidence of these diseases is difficult to ascertain because of their rarity. The estimated annual incidence is 2.18 to 7.7 cases per million per year with a bimodal age distribution. The onset in children occurs between 10 and 15 years of age and in adults between 45 and 60 years of age. DM is more common than PM, particularly in children. As with most autoimmune diseases, women are affected disproportionately (2 : 1 female-to-male ratio), and there appears to be an increased incidence in African Americans compared with whites. An overall increase in incidence has been suggested; however, improved diagnostic criteria and elevated awareness may account for this trend.

Etiology and Pathogenesis

The etiology and pathogenesis of PM and DM remain unclear. Reports of idiopathic inflammatory muscle disease in multiple members of a single family and in monozygotic twins implicate a possible genetic predisposition. Correlations have been observed with human leukocyte antigen (HLA)-DRB1*0301 in whites with PM and with HLA-DQA1*0501 in juvenile DM. Myositis-specific antibodies unique to these diseases have been identified; however, whether these antibodies play a pathogenic role remains unclear. Three groups of myositis-specific antibodies have been well studied, and clinical profiles have been described for each group (Table 156-1).

Although PM and DM have similar presentations, the immunologic process of the underlying disease pathogenesis appears quite different. DM results in microangiopathy, destruction of endomysial capillaries, and muscle ischemia from humoral-mediated injury. B cells predominate in the inflammatory perivascular infiltrate, and immunoglobulins and complement split products are deposited in the blood vessels. In contrast, the inflammation of PM occurs through a cell-mediated mechanism. Muscles

expressing major histocompatibility complex (MHC) class I are infiltrated with CD8+ cytotoxic cells.

Inflammatory myopathies can occur as a part of a heterogeneous connective tissue diseases complex with overlapping features of scleroderma, systemic lupus erythematosus (SLE), mixed connective tissue disease, or Sjögren's syndrome. Less commonly, PM and DM are seen in association with rheumatoid arthritis, adult-onset Still's disease, or Wegener's granulomatosis. Muscle weakness is often a prominent symptom in these overlap syndromes.

The risk for malignancy is increased in both PM and DM, but DM has a greater relative risk. Prototypic malignancies associated with these inflammatory myopathies are ovarian, breast, stomach, colon, and non-Hodgkin's lymphoma, although any neoplasm is possible. The risk for malignancy is highest within the first year of the diagnosis and then decreases but never reaches that of the normal population.

Clinical Presentation

PM and DM are defined by the insidious onset of symmetrical proximal muscle weakness over weeks to months,

Table 156-1 Myositis Specific Antibodies

Autoantibody	Clinical Manifestations	Treatment Outcomes
Anti-aminoacyl tRNA synthetase (Anti-Jo-1 most common)	Increased risk for interstitial lung disease. <i>Antisynthetase syndrome</i> : fever, arthritis, interstitial lung diseases, Raynaud's phenomenon, and mechanic hands	Variable
Anti-Mi-2	Acute onset of dermatomyositis often with shawl sign	Good
Anti-signal recognition particle (SRP)	Polymyositis Acute severe illness Possible association with necrotizing myositis	Poor

Table 156-2 Cutaneous Manifestations of Dermatomyositis

Cutaneous Manifestation	Description
Gottron's papules	Pathognomonic for DM. Flat or raised, violaceous to dusky red papules on dorsal aspect of MCP, PIP joints. Can occur over wrist, elbows, knees, and malleoli. SLE differs in that the rash occurs between MCP and PIP joints (see Fig. 156-2)
Heliotope rash	Highly characteristic of DM. Lilac/purple colored rash often periorbital with edema. Can involve chin, forehead and malar region. Unlike SLE does not spare nasolabial folds (see Fig. 156-2)
V sign	Less specific. Violaceous, erythematous, and confluent macular lesions of the neck and anterior chest
Shawl sign	Less specific. Violaceous, erythematous macular lesions involving the nape of the neck, upper back, and posterior shoulders
Holster sign	Less specific. Violaceous, erythematous macular lesions over the lateral aspects of the thighs
Mechanic hands	Hyperkeratosis, scaling and fissuring of the lateral portion of the fingers and palms. This can be associated with antisynthetase syndrome
Calcifications	Subcutaneous, fascial, and intramuscular. Predominately seen in juvenile DM. Can be extensive, debilitating, and independent of inflammatory muscle involvement
Nail-fold telangiectasias, periungual erythema, and cuticular overgrowth	Nonspecific findings seen in both DM and PM, as well as other connective tissue disorders

DIP, distal interphalangeal; DM, dermatomyositis; MCP, metacarpophalangeal; PIP, proximal interphalangeal; PM, polymyositis; SLE, systemic lupus erythematosus.

which often delays patients from seeking medical attention and thus a definitive diagnosis. Classically, painless muscle weakness is the hallmark of disease; however, myalgia accompanies weakness in up to 30% of cases.

Patients may complain of difficulty getting up from a chair or toilet on their own or without the use of their hands (Fig. 156-1). Proximal lower extremity weakness results in an unsteady, waddling gait. Stairs and steps become a challenge, especially if there is no handrail available. Involvement of the shoulder girdle causes weakness that manifests as complaints of trouble shampooing and combing hair (see Fig. 156-1). The central muscles of the trunk and neck can be involved, making it difficult to rise from a supine position or raise the head from the pillow. Over time, patients may develop distal muscle weakness, but facial and ocular involvement is extremely rare.

As the name implies, the differentiating clinical feature of DM from PM is cutaneous involvement (Table 156-2; Fig. 156-2), which can precede, develop simultaneously, or occur after muscle manifestations. The rashes are often photosensitive. A minority of patients develop classic skin

findings without muscle involvement, referred to as *amyopathic dermatomyositis* or *dermatomyositis sine myositis*.

PM and DM are systemic diseases and can involve multiple organ systems. The prevalence rate of interstitial lung disease varies widely from 5% to 65% and can occur at any time in the course of the disease. Symptoms range from asymptomatic (27%) or dry cough to frank dyspnea. Having anti-histidyl-tRNA synthetase antibodies (anti-Jo-1) is associated with an increased risk for interstitial lung disease. However, dyspnea in inflammatory muscle disease may not always be interstitial lung disease and can result from weakness of the thoracic muscles or chronic aspiration from esophageal dysfunction.

Cardiac involvement typically manifests as asymptomatic electrocardiogram changes in up to 50% of cases. Significant arrhythmias, myocarditis, and congestive heart failure are rare.

Dysphagia occurs in up to one third of cases. This is either from weakness of the oropharyngeal muscles or from involvement of the striated muscles of the upper one third of the esophagus. Aspiration pneumonia, nasal regur-

Figure 156-1 Signs of Inflammatory Myopathies.

gitation, and dysphonia can result from oropharyngeal or esophageal muscle weakness. Although rare in adults, gastrointestinal bleeding can occur in juvenile dermatomyositis secondary to vasculitic lesions.

A non-deforming, rheumatoid-like arthritis may occur, which is typically mild. In contrast, anti-Jo-1-positive patients and those with antisynthetase syndrome may have a destructive arthritis involving the hands. The term *floppy thumb* describes the destruction of the first interphalangeal joint in these patients.

Differential Diagnosis

Patients presenting with muscle weakness require a complete history and physical examination. PM and DM are rare diseases, and thus one must look for findings indica-

Figure 156-2 Classic Cutaneous Findings of Dermatomyositis.

tive of other etiologies (Box 156-1). Differentiating PM from inclusion body myositis clinically may be difficult (Table 156-3), which is why muscle biopsy is usually recommended for a definitive diagnosis.

Diagnostic Approach

PM and DM can overlap with other connective tissue diseases, especially scleroderma and SLE, so an extensive review of systems is essential. All medications need to be examined as potential causes of weakness (see Box 156-1). Documentation of activities that cannot be performed is useful. For instance, testing proximal lower extremity strength by having a patient rise from a seated position without the use of the arms or having the patient squat and

stand will clearly define the patient's strength and provides an easy way of measuring response to treatment.

Initial laboratory work should consist of a complete blood count with differential, chemistries and electrolytes, liver function tests, creatine kinase (CK), aldolase, erythrocyte sedimentation rate (ESR), thyroid-stimulating hormone, antinuclear antibody (ANA), and serum protein electrophoresis. The most sensitive muscle enzyme is CK, which is elevated before detectable weakness and should normalize before a discernable response to therapy. Elevations of aldolase, aspartate, and alanine aminotransferases can also be observed, and these typically are markers of muscle breakdown. Commonly, but not always, there are increases in markers of inflammation (ESR, C-reactive protein). ANA can be found in up to 80% of patients.

Electromyography (EMG) is a sensitive, yet nonspecific, test for inflammatory muscle disease. Infections and metabolic disorders can have similar EMG findings as DM and PM. Because not all muscles are necessarily involved, several sites should be evaluated, particularly because EMG is useful for guiding the location for biopsy. Typical findings on EMG are spontaneous fibrillations, needle insertion irritability, low-amplitude polyphasic motor units of short duration, and early recruitment. EMG is also useful during the interval management of these patients because it can differentiate between steroid myopathy (chronic steroids are used in the treatment of DM and PM) and persistently active inflammatory disease.

Because muscle enzymes and EMG findings can be abnormal in a variety of muscular disorders (see Table 156-3), a muscle biopsy is the gold standard for the diagnosis of both PM and DM. Traditionally, this has been

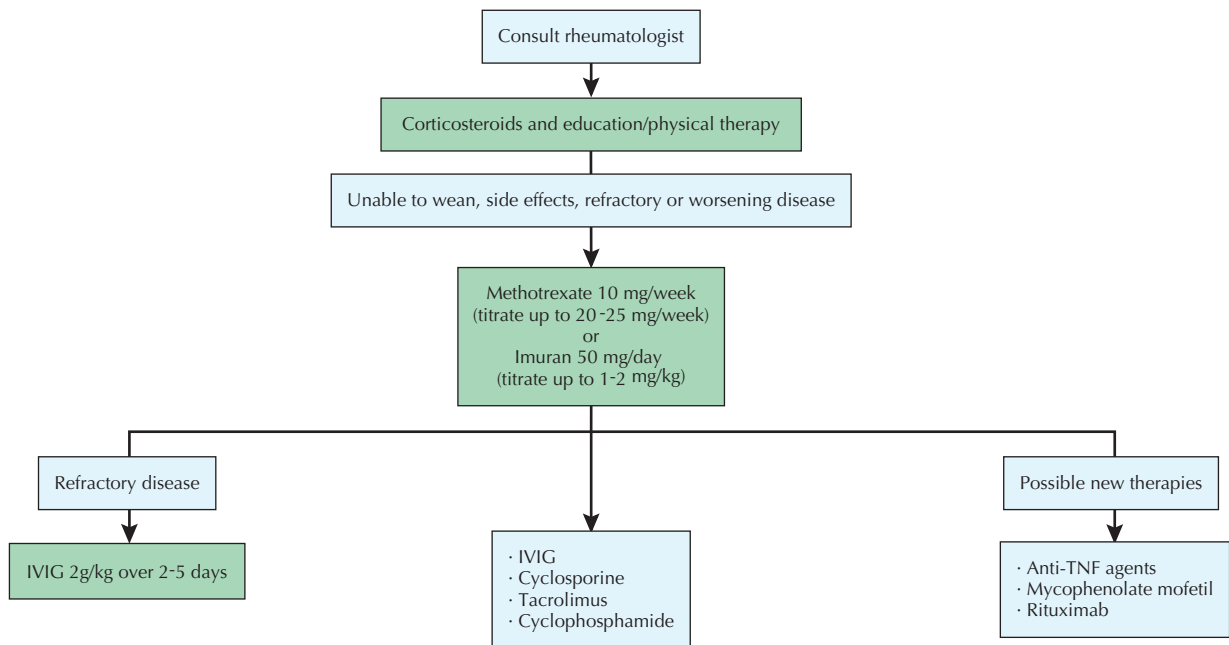

Table 156-3 Differentiating Characteristics of Polymyositis, Dermatomyositis, and Inclusion Body Myositis

	Polymyositis	Dermatomyositis	Inclusion Body Myositis
Age	>2nd decade	Any age (bimodal)	>50 years of age
Sex	Female-to-male ratio of 2 : 1	Female > male	Male > female
Muscle weakness	Symmetrical and proximal	Symmetrical and proximal	Asymmetrical, proximal, and distal. Muscle atrophy of quadriceps and finger flexors
ANA	Common	Common	Uncommon
Cutaneous	No	Yes	No
CK	≤50 times normal	≤50 times normal	Often ≤5 times normal
Anti-Jo-1 antibody	Up to 20%	Yes	No
Muscle biopsy	Cell mediated, CD8+, endomysial infiltrate	Humoral-mediated, CD4+ infiltrate, perivascular, and interfascicular	CD8+ infiltrate, vacuolated muscle fibers, intracellular amyloid deposits
Multiple organ system involvement?	Yes	Yes	No
Treatment	Responsive	Responsive	Often refractory

IVIG, intravenous immunoglobulin; TNF, tumor necrosis factor.

done as an open biopsy; however, percutaneous needle biopsies are now being performed because they are less invasive and multiple samples can be obtained to increase the sensitivity of the diagnosis. To rule out muscular dystrophies, glycogen and lipid storage diseases, the muscle biopsy requires immunohistochemical, biochemical, and genetic evaluation.

The muscle biopsy of PM will demonstrate scattered necrotic, regenerating fibers. Inflammation will be localized around individual muscle fibers, with a predominance of CD8+ cells. Class I major histocompatibility complex is not normally expressed on muscles. Further immunocytochemical staining and genetic testing are important because the pathology described in PM can be seen in muscular dystrophies and inclusion body myositis. DM, which is a humorally mediated process, will have perivascular and interfascicular inflammation with associated microinfarctions and perifascicular atrophy.

After a diagnosis of either DM or PM is made, it is important to evaluate for extramuscular involvement. A baseline chest radiographic examination and spirometry with diffusion capacity is a part of the initial workup for pulmonary involvement. High-resolution chest computed tomography or bronchoalveolar lavage may be indicated if symptoms or screening abnormalities suggest interstitial lung disease. Screening for anti-Jo-1 antibodies can predict the risk for developing interstitial lung disease because up to 70% of anti-Jo-1-positive patients develop this complication. Esophageal dysmotility is common, and thus one should have a low threshold for obtaining a barium swallow in the workup of dysphagia and dyspnea. Age-appropriate

cancer screening should be performed given the association with malignancy.

Management and Therapy

Optimum Treatment

Corticosteroids are first-line therapy (Fig. 156-3). For severe disease, pulse intravenous steroids are given for 3 days at 1 g/day and then switched to oral steroids at 1 mg/kg/day. More commonly, oral steroids are initiated at 1 mg/kg/day. Titration of corticosteroids begins once the muscle exam and enzymes normalize, which may take several months. Currently, there are no clinical trials to guide the titration of corticosteroids, but consensus opinion recommends a taper of 20% every 3 to 4 weeks. Once the patient is weaned to 10 mg/day, this dose is continued for about 1 year. The American College of Rheumatology recommends the initiation of bisphosphonates for patients who will require corticosteroids for more than 3 months. When a patient has esophageal dysmotility, intravenous pamidronate is the bisphosphonate of choice. Early incorporation of physical therapy into the treatment regimen of patients with inflammatory myositis is essential.

A steroid-sparing agent can be added to the treatment regimen when corticosteroids are unable to be decreased or are incompletely effective. These agents are typically added early in disease to minimize the exposure and complications from high-dose corticosteroids. Azathioprine or methotrexate is most commonly used during active treatment or maintenance of remission. A prospective placebo-

controlled trial of the combination of azathioprine and corticosteroids found improved functional outcomes and ability to wean corticosteroids compared to placebo. A retrospective series found that 71% to 88% of patients with DM and PM improved with the addition of methotrexate to prednisone therapy. However, because of the idiosyncratic side effect of pulmonary involvement with methotrexate, azathioprine is preferred in patients with interstitial lung disease and in anti-Jo-1-positive patients.

Intravenous immunoglobulin (IVIG) is used in the setting of critically ill patients with pulmonary or cardiac disease. IVIG is also used as a second-line agent for patients refractory to prednisone, azathioprine, or methotrexate. In DM, a double-blind, placebo-controlled trial found improved muscle strength and functional status using IVIG compared with placebo.

Other immunosuppressive agents used in inflammatory muscle disease include cyclosporine, tacrolimus, and cyclophosphamide. The use of these medications is driven by failure to respond to the aforementioned medications, by the severity of disease, or by extramuscular involvement. Cyclosporine and tacrolimus have been shown to improve muscle strength and functional status. Both medications, in case series, appear beneficial for inflammatory myositis, associated interstitial lung disease, and antisynthetase syndrome. More recently, there are case series showing benefits of mycophenolate mofetil, tumor necrosis factor- α antagonists, rituximab, and leflunomide, but further controlled studies are needed to assess the efficacy of these medications.

Avoiding Treatment Errors

As with any disease, the diagnosis should be confirmed before initiating a treatment regimen. After treatment is started, monitoring for toxicity is essential. Most medications used in DM and PM result in significant immunosuppression and increase the risk for infection. Consequently, worsening symptoms such as weakness and dyspnea do not necessarily reflect disease activity. Specifically, prolonged steroid therapy can result in weakness secondary to a steroid myopathy. If this is not recognized, it may lead to an unnecessary exposure to further immunosuppression and toxicity. In another example, increased dyspnea could result from the known pulmonary manifestations of DM and PM but could also reflect secondary pulmonary infections or hypersensitivity pneumonitis from therapy (i.e., methotrexate).

Creatine kinase and aldolase, markers of muscle breakdown, are often used to monitor for disease activity in a stable patient. Often, there is a delay between the initial rise in these markers and the detectable onset of weakness. Although treatment should not be changed based on laboratory values alone, an increased vigilance by the patient and physician is indicated if this is observed.

Future Directions

In 2000, the International Myositis Outcome Assessment Collaboration Study (IMACS) group was created to help standardize trial design and outcome assessment. The group has defined measurements of disease activity for outcomes assessment, proposed a definition for clinical improvement, and proposed consensus guidelines for clinical trials in myositis. Several initiatives to determine the utility of newer medications are either enrolling or awaiting approval. These studies evaluate B-cell therapy in idiopathic myopathy, etanercept in adult DM, infliximab in DM and PM, methotrexate in PM and DM, and interleukin-1 receptor antagonists in chronic inflammatory myopathy. The results of these trials may broaden the treatment options significantly.

Myopia and Common Refractive Disorders

Introduction

Ocular refractive disorders, or ametropias, are defined as aberrant focusing of entering light rays away from the optimal plane of the retinal macula. Ametropias include myopia, hyperopia, astigmatism, and presbyopia. These conditions represent a significant public health issue in the United States. A 1980 survey of vision correction in the United States estimates that more than half of the population older than 3 years have refractive errors corrected with spectacles or contact lenses. Myopia alone afflicts about 70 million Americans, with associated costs of up to \$4.6 billion per year.

Etiology and Pathogenesis

In basic optical terms, the human visual system is made up of the cornea, crystalline lens, and ocular axial length. Each of these anatomic components must develop in precise balance to produce sharp optical focus on the retina.

Emmetropia (Fig. 157-1) is vision devoid of optical defects, and emmetropization is the developmental process of growth and integration of ocular components, which optimally leads to normal vision. Until age 3 years, cornea and lens curvatures (refractive powers) are adjusted through a poorly understood mechanism to correlate with changes in axial length. The result is that greater than 95% of eyes end up with a refraction close to emmetropia (between +4 and -4 diopters of refractive error).

Myopia (nearsightedness) (see Fig. 157-1) is the most common refractive error, with a prevalence of 80% of ametropias. In simple terms, myopia occurs when light from distant objects is focused anterior to the retina. The refractive power of the eye is too strong for its axial length. Myopia can be classified as simple juvenile onset, adult onset, and degenerative.

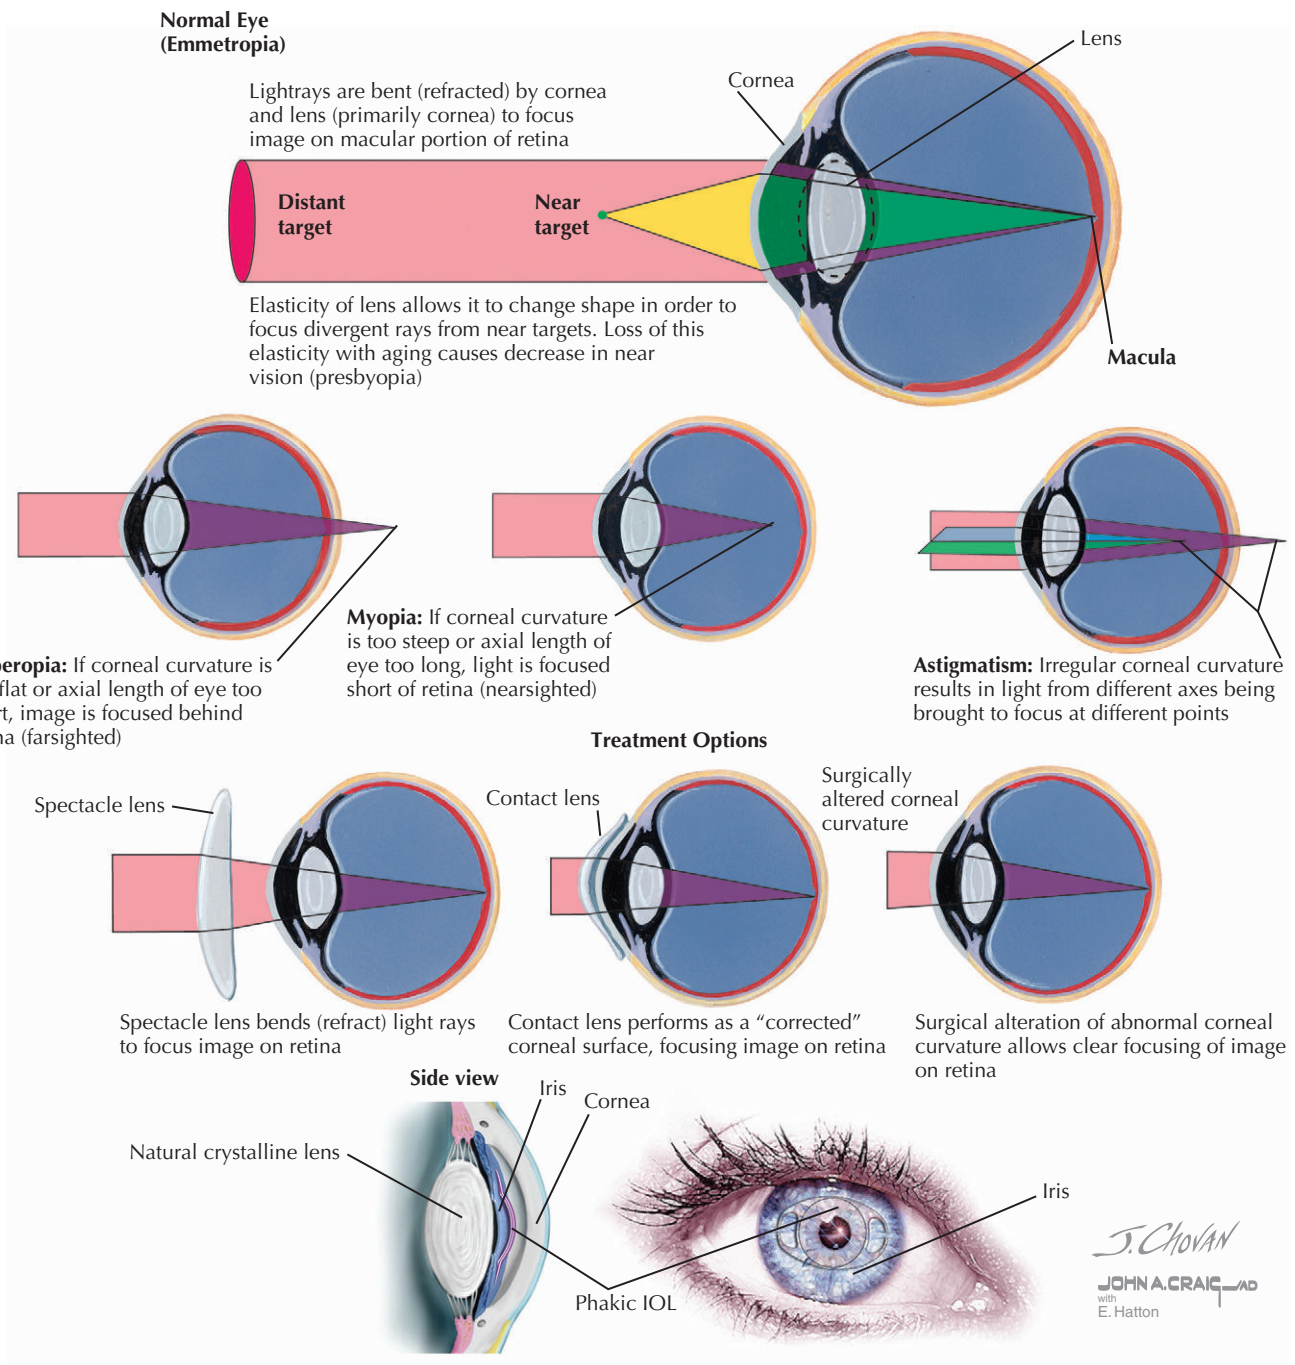

Simple myopia accounts for more than 85% of all myopia. It is estimated that 15% to 25% of the U.S. population has or will have juvenile-onset myopia. Typically, it begins after age 5 years with gradual increases in severity until around age 16 years, when 75% stabilize in prescrip-

tion. Others may experience an increase in severity into their 20s and 30s. Increases of -0.25 to -0.75 per year are common, but higher rates are not unusual.

Generally, earlier onset of myopia leads to higher refractive error at maturity. There is evidence of gender difference; females tend to begin progression of myopia and stabilize 1 or 2 years before males. Controversy exists regarding the exact etiology of myopia (heredity versus use-abuse), but recent research has reinforced the theory that positive family history is the primary risk factor for developing myopia. Studies indicate that children of parents who both have myopia have a 30% to 40% prevalence of myopia, and when only one is afflicted, a 20% to 25% prevalence. If neither parent has myopia, there is a less than 10% chance of developing myopia. Research involving prediction of myopia indicates that at third-grade age, 60% of individuals with a cycloplegic refraction of $+0.5$ (hyperopia) or less will become myopic by eighth grade.

Adult-onset myopia affects individuals in high near-point stress environments, such as graduate students, and usually begins around 20 years of age. The disorder has an unpredictable end point in terms of time and severity but usually ends in low to moderate myopia. It is possible for previously stable myopic individuals to experience an increase in myopia years later in times of increased near-point activity. It has been hypothesized that a new process

Figure 157-1 Myopia and Other Refractive Errors.
IOL, intraocular lens.

of emmetropization occurs, developing an optical focus for near, which induces myopic progression.

Degenerative myopia is rare (1% to 2% of all myopia) and is a far more serious form in which the eye elongates at a rapid, pathologic rate. As the eye elongates, the retina thins, increasing the incidence of retinal degeneration and detachment. Tears in the retina can occur at the level of Bruch's membrane, with secondary hemorrhages and scarring at the macula leading to permanent

visual distortion and blindness. Degenerative myopia is developmental in origin and progresses most rapidly at puberty.

Other causes of temporary myopic shifts are variations in blood sugar levels, nuclear sclerotic cataract progression, or introduction of various pharmaceutical agents (pilocarpine, tetracycline, adrenergic agents, phenothiazines, corticosteroids, oral contraceptives). These myopic tendencies are usually reversible.

Hyperopia (farsightedness) (see Fig. 157-1) is characterized by a weaker than normal refractive power or a shorter axial length, both of which cause light to focus posterior to the retina in the unaccommodated eye. Its incidence is directly related to age. Most full-term infants begin life with low hyperopia, but the condition diminishes rapidly with the emmetropization process of flattening of lens and cornea in conjunction with growth-related elongation of the eye. The amount of hyperopia in individuals younger than 30 years is often difficult to measure because of the ability of the accommodative system to produce positive refractive power, in essence correcting hyperopia. This aberrant use of the accommodative system can cause symptoms of headache and eyestrain as well as other binocular integration and general eye disorders. There is a strong association between moderate to high hyperopia in childhood and development of esotropia and amblyopia.

Astigmatism (see Fig. 157-1) is a refractive disorder in which the cornea has a nonspherical shape, with different powers at individual meridians or axes. This causes entering light rays to focus at multiple locations instead of a single point. Lenticular astigmatism is an unusual variant caused by abnormal tilting of the crystalline lens. Astigmatism follows a course similar to myopia, manifesting at about 8 years of age and stabilizing in the middle teen years. There is no gender difference, and both distance and near vision are affected. Astigmatism affects about 25% to 40% of the population and is commonly found in conjunction with myopia or hyperopia.

Presbyopia involves the progressive loss of accommodative ability in middle age leading to difficulty focusing on near objects. Accommodation, the ability to change shape and power of the crystalline lens by contraction of the ciliary body, develops maximum amplitude early in childhood. With advancing age, hardening of the crystalline lens reduces flexibility and decreases accommodative amplitude. Although hyperopia is often confused with presbyopia, hyperopia is relatively uncommon, whereas presbyopia will cause noticeable effects in everyone by age 45 years. Other eye disorders such as accommodative insufficiency may cause identical symptoms at an earlier age.

Clinical Presentation

The clinical presentation of all ametropias involves blurred vision at one or more viewing distances. In myopia, distance vision is affected, whereas near vision remains intact. Frequently, an individual will seek eye care when having difficulty driving at night or watching television. Unfortunately, children often tolerate very poor vision without complaint, so attention should be given to apparent difficulty seeing the classroom blackboard or while playing sports. Frequently, individuals with myopia report that squinting (creating a pinhole effect) improves vision.

Hyperopia is less straightforward in presentation. Theoretically, it is the opposite of myopia, leading to the assumption of blurred near and intact distance vision, but that is rarely the case. The accommodative system is able to provide optical correction for low amounts of hyperopia without much difficulty until ages 30 to 40 years. Individuals under this age are rarely aware of their refractive error and are resistant to the notion of refractive correction. Eventually, the accommodative system wanes, and the farsighted person has difficulty seeing all distances and must resort to wearing spectacles or contact lenses.

Astigmatism is usually less visually disturbing unless it develops concurrently with another refractive error. Those afflicted can function well for years without correction, and as with myopia, squinting improves vision. Common complaints include visual halo distortions while driving at night, or monocular diplopia.

Presbyopia is easily recognized in individuals 40 years and older. It manifests as gradual and progressive loss of near focusing ability, usually worse at the end of the day. As the accommodative demand for near work exceeds the accommodative reserve, blurred vision, headaches, fatigue, and eyestrain occur. Hyperopes typically have an earlier onset than myopes, and astigmatism can exacerbate symptoms.

Diagnostic Approach

Diagnosing refractive error is relatively straightforward and can be accomplished using Snellen or other visual acuity charts for near and far. The Snellen equivalent optotype system is based on a standard normal acuity measurement of 20/20, which equates to a letter height of 8.7 mm measured at 20 feet. All other sizes of letters for different acuity levels are extrapolated from this standard. The numerator in the acuity fraction corresponds to the distance a standard letter can be seen by a tested individual (usually 20 feet), and the denominator corresponds to the distance the same letter can be seen by a normal observer. An acuity level of less than 20/20 at distance with normal acuity at near indicates some level of myopia. Normal acuity at distance with difficulty focusing at near indicates hyperopia. Astigmatism causes a generalized reduction of acuity at near and far, and presbyopia is similar to hyperopia in middle-aged or older individuals.

The most accurate method of measuring refractive error is to perform cycloplegic refraction to best-corrected acuity. This procedure requires instillation of pharmaceutical agents (e.g., cyclopentolate) for paralysis of the ciliary body and the accommodative system. Cycloplegia is especially important when assessing refractive error in children because of their high accommodative amplitude and its effortless use. In-office use of specialty ophthalmic equipment such as phoropter and automated refractor enable quick and efficient measurement of refractive error and simulates spectacle-corrected vision.

Management and Therapy

There are many treatments (see Fig. 157-1) available for the correction of ametropias, running the gamut from very basic to extremely high-tech. Corrective options are generally classified as nonsurgical or surgical.

Optimum Treatment

Nonsurgical Methods

Nonsurgical corrective options, including spectacles and contact lenses, are most widely used and are reversible. Spectacles, the most common option, provide economical, safe, and exacting correction of all ametropias. Limitations include facial discomfort, lack of peripheral vision, and cosmesis issues. Nonetheless, with the advent of high-index materials, improved progressive bifocal designs, and newer frame designs, spectacle use has increased in popularity. Plastic polymers are the most widely used materials in the fabrication of ophthalmic lenses because they are lighter weight and safer than glass. Recent estimates of contact lens use in the United States are as high as 10% to 15%. Soft hydrogel contact lens wearers make up 85% of the population wearing contact lenses with the remainder using rigid gas permeable or polymethyl methacrylate (PMMA). With current technology, contact lenses can be used to correct virtually any refractive condition. Advantages include improved cosmesis, intact peripheral vision, and correction of irregular corneal disorders not correctable with spectacles (e.g., keratoconus). Disadvantages include expense, risk for infection or other pathology, and required diligence in care.

Surgical Methods

Current surgical corrective options include laser procedures and intraocular lens (IOL) implantation. Of these, laser procedures are most widely used. They offer an ever-expanding level of precision sculpting of corneal tissues to provide refractive correction.

Photorefractive keratectomy (PRK) uses a computer-guided excimer laser (193 nm wavelength) to reshape the corneal stroma to a desired curvature for refractive correction. PRK requires removal of stromal tissue, so unusually thin corneas can limit the amount of correction. Because epithelial tissue must be disrupted for laser access to the stroma, a bandage contact lens is applied directly after surgery to decrease pain and protect healing epithelium. Mild to moderate discomfort may be reported for 2 to 3 days as re-epithelialization occurs. PRK usually takes only 1 to 2 minutes to perform and can currently be used to correct 1 to 12 diopters of myopia, 1 to 6 diopters of hyperopia, and up to 4 diopters of astigmatism. Approved by the U.S. Food and Drug Administration in 1995, PRK has proved most accurate in correction of low to moderate myopia (up to -6 diopters) with a postoperative acuity of 20/40 or better in 90% to 95% of procedures. Major complications, aside

from undercorrection or overcorrection, include a transient visual disturbance described as foggy or hazy vision that is most noticeable at night and dry-eye symptoms.

Laser-assisted in situ keratomileusis (LASIK) is a refractive procedure that combines PRK with the surgical creation of a corneal flap by an instrument called a microkeratome. This precise instrument cuts a thin, circular flap in the stromal and epithelial layers of the cornea, leaving a hinge on one side. Once the flap is folded away, PRK is performed on the exposed stroma. The flap is then carefully placed back in its original position, completing the procedure. Like PRK, LASIK can be used to treat myopia, hyperopia, and astigmatism. The accuracy of postoperative correction has been greatly enhanced by employing wavefront-guided laser paradigms that can compensate for higher-order optical aberrations, yielding extremely acute vision.

The advantages of LASIK over PRK are faster vision rehabilitation and less discomfort. Complications of LASIK include surgical flap creation errors, loss of best-corrected acuity, and reduced corneal sensitivity, which can lead to a chronic irritation similar to dry-eye syndrome. Both PRK and LASIK can be performed several times on the same eye (enhancements) for refinement of surgical correction or naturally occurring refractive changes.

Phakic IOLs are surgically implanted anterior to the natural crystalline lens and are available for medium to extremely high amounts of myopic correction (-5 to -20 D). Postoperative acuity has been excellent, especially in higher myopic corrections. Potential complications include glaucoma, cataracts, and infection.

Avoiding Treatment Errors

The process of identifying appropriate candidates for refractive surgery has evolved and improved significantly as the surgical techniques have become more precise. Mandatory use and careful examination of corneal topography and corneal pachometry have greatly reduced the possibility of postsurgical complications such as ectasia or keratoconus. Treatment of dry-eye with punctal occlusion, anti-inflammatory agents, and tear supplements along with improved lid hygiene before surgery have also reduced complications of discomfort and visual distortions after the procedure.

Future Directions

The future of laser-refractive correction lies in increased accuracy of correction and improved safety profiles of surgical techniques. The focus of current research is safer flap creation in LASIK and nonlamellar (no stromal flap) advanced surface ablations, including laser epithelial keratomileusis (LASEK) and Epi-LASIK. The epithelium is retained in the advanced ablation techniques and removed in PRK. These newer refractive procedures have the

potential to greatly reduce complication rates from those of lamellar procedures (LASIK).

Other nonlaser surgical options on the horizon are scleral expansion and accommodative IOLs for the correction of presbyopia. Of all the refractive disorders, the permanent correction of presbyopia appears to be the most difficult to achieve.

Common Anterior Segment and Red Eye Problems for the Primary Care Specialist: Diagnosis and Management

Introduction

Primary care specialists and other non-ophthalmologists frequently encounter patients who complain of a red eye. The primary purpose of this chapter is to provide an approach to the differential diagnosis and management of conditions that cause red eye. An additional goal is to give the primary care physician guidance in dealing with the following: Which conditions require immediate treatment? In which is a delay in therapy acceptable pending a second opinion from an ophthalmologist? Which conditions require treatment by an ophthalmologist, which can the primary care physician treat without referral, and which require no treatment?

Etiology

Potential causes of ocular and periocular erythema include trauma, chemicals, infection, allergy, systemic conditions, and surgery. Red eye disorders are generally subcategorized as vision threatening or non-vision threatening. Those that threaten vision include corneal infections, perforating trauma, hyphema, endophthalmitis, orbital cellulitis, scleritis, iritis, and acute glaucoma. These require immediate referral to an ophthalmologist. Non-vision-threatening disorders include subconjunctival hemorrhage, hordeolum, chalazion, blepharitis, dry eye, conjunctivitis, and most corneal abrasions. These are commonly and appropriately managed by primary care professionals.

Clinical Presentation

Subjective ocular complaints may be categorized by the mnemonic RSVP: redness, sensitivity to light, vision

decrease, or pain. Specific symptoms may help reveal the underlying cause of the red eye (Table 158-1).

Diagnostic Approach

To evaluate the red eye optimally, the primary care physician needs a Snellen visual acuity chart or near card, topical anesthetic drops, a fluorescein filter paper dye strip, and a penlight with a blue filter cap. The exam should begin with a recording of visual acuity at 20 feet using a Snellen chart, which is usually available in most offices. A near card is an acceptable alternative. Patients who normally wear spectacles or contact lenses should wear these for testing, if possible. Patients older than 40 years are likely presbyopic, and although they may have good distance vision, they probably still need magnifying spectacles for good near vision. When no vision loss is detected, most red eye disorders are treatable without ophthalmology referral. If

Table 158-1 Causes of Subjective Ocular Complaints

Symptom	Cause
Itching	Allergy
Photophobia	Corneal abrasions or surface breakdown, contact lens–related infiltrates or overwear, keratitis, iritis, acute glaucoma, corneal ulceration
Burning, scratchiness	Commonly dry eye but also blepharitis, foreign body material, and trichiasis
Deep intense pain	Corneal abrasions, corneal ulceration, scleritis, iritis, endophthalmitis, severe keratitis, severe surface epitheliopathy, acute angle-closure glaucoma
Localized lid tenderness	Hordeolum, chalazion, meibomitis, cellulitis
Foreign body sensation	Corneal surface breakdown, retained foreign body or debris, trichiasis, surface filaments from dry eye
Halo vision	Corneal edema of any cause (especially contact lens overwear syndrome and acute glaucoma)

Box 158-1 History: Important Questions and Considerations

Are one or both eyes affected? Vision at the time of exam? Is there a decrease in vision?
 Vision before trauma?
 Onset sudden or progressive?
 What is the timeline of symptoms? Hours or days?
 Intermittent?
 Any family members with red eye recently? Recent upper respiratory infection?
 Recent eye surgery? (If yes, refer immediately.)
 History of contact lens use? Do they sleep in them? (If yes, then patients have a 10 times greater risk for cornea ulcer.)
 Pain? Foreign body sensation? Itchiness? Sensitivity to light?
 Discharge? Scant or profuse? Watery or purulent? Chronic or acute?
 Use of any eye medications, past or present, including over the counter?
 Any history of trauma? Environmental associations?
 Systemic conditions?

reduced visual acuity is noted, serious ocular disease is likely, and referral to an eye care specialist is essential. Notably, conjunctivitis is extremely unlikely to reduce visual acuity (Box 158-1).

After the history and visual acuity are recorded, a systematic anatomic exam of the eye and adnexa should be performed. First, the face, lids, preauricular lymph nodes, and orbital area are inspected. Next, the extraocular movements, confrontational visual fields, and pupils are evaluated, followed by examination of the globe, paying particular attention to the conjunctiva, cornea, and sclera. A slit lamp biomicroscope is especially valuable for evaluating the anterior chamber for iritis, hyphema, or angle-closure glaucoma. If a slit lamp is not available, a penlight is a useful alternative. The smoothness and clarity of the corneal surface and the light reflex are especially important components of the exam. A drop of sterile fluorescein dye, when applied to the lower tarsal conjunctiva using a wetted

fluorescein strip, is especially helpful in detecting denuded areas of the corneal epithelium. During blinking, the dye spreads over the corneal surface and adheres only to epithelial defects, which light up with a bright green color under the cobalt blue–capped penlight. Following the fluorescein exam, an intraocular pressure (IOP) measurement is easily performed using either a Tono-Pen or Goldmann applanation tonometry. Gentle digital palpation provides a gross assessment as to whether the globe is very hard due to high pressure from acute glaucoma or painfully tender due to scleritis, acute glaucoma, iritis, or other anterior-segment inflammatory process. Palpation of the globe is contraindicated if there is a history of trauma and if globe rupture is suspected (Fig. 158-1).

Differential Diagnosis

A guide to differentiating common red eye features is shown in Table 158-2.

Management and Therapy

Ocular Adnexal Disorders of the Lids, Lashes, and Lacrimal Apparatus

Hordeolum and Chalazion

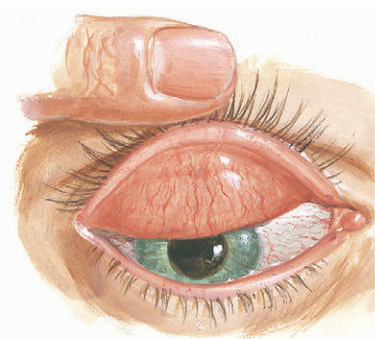

Inflamed or impacted lid margin sebaceous glands may present with local nodular swelling, tenderness, lid injection, and localized or diffuse cellulitis of the lid. A hordeolum is an inflamed lesion on the lid margin, whereas a chalazion presents as a nodule in a more central lid location. Treatment includes hot compresses to the eyelids four times daily for 3 to 5 minutes when the lesion is acute or subacute. Following hot compress application, the patient should massage the lid and lash line in hopes of achieving drainage. This treatment may take several weeks to be effective. If discharge is noted or infection is suspected, a topical antibiotic ointment (e.g., bacitracin, gentamicin, bacitracin-neomycin-polymyxin B) should be applied to the lash line and over the affected area 3 to 4 times daily. Occasionally, oral antibiotics are necessary if

Figure 158-1 Diagnostic Approach.

Foreign bodies

Edge of upper lid grasped and drawn outward and downward; applicator or other rod-like device applied at tarsal fold

Keratitis (inflammation of the cornea)

Lid everted, exposing foreign body which may then be wiped off

Technique of applying fluorescein strip in previously anesthetized eye

Dendritic keratitis (herpes simplex) demonstrated by fluorescein

Acute keratitis (ciliary injection, irregular corneal surface)

Treatment of corneal scars

Corneal ulcer stained with fluorescein hypopyon (pus in anterior chamber)

the accompanying meibomian gland dysfunction reveals marked inspissation or impaction. In these instances, the treatment of choice is doxycycline, 100 mg administered twice daily for 1 month, then tapered to once daily for at least 2 months or longer. Meibomian gland dysfunction is particularly common in white middle-aged men and often accompanies rosacea.

If a chalazion fails to resolve and becomes chronic (i.e., nontender and localized, or persists more than 3 to 4 weeks), then referral to an ophthalmologist is indicated. A persistent or recurring lid mass is an indication for biopsy

because it may represent a rare sebaceous gland carcinoma or squamous cell carcinoma of the lid (Fig. 158-2).

Blepharitis

Blepharitis is chronic lid margin inflammation that is associated with staphylococcal infection, seborrhea, or dry eyes. Its symptoms and signs may include burning; foreign body or gritty sensation; red, thickened lid margins; lash matting and crusting; and sticky lids on awakening in the morning. Blepharitis may also be asymptomatic.

Table 158-2 Differentiating Common Red Eye Features				
	Conjunctivitis	Keratitis (Corneal Inflammation or Foreign Body)	Iritis	Acute Angle-Closure Glaucoma
Vision	Normal or intermittent blurring that clears with blinking	Slightly blurred	Slightly blurred	Marked blurring
Discharge	Prominent, often crusting of lashes; purulent indicates bacterial infection; clear, watery indicates viral infection*; stringy, scant mucus indicates allergy	None to mild	None	None
Pain	None or minor and superficial	Sharp, severe foreign body sensation	Moderately severe; aching and photophobia	Very severe, frequently nausea and vomiting
Injection pattern	Diffuse	Circumcorneal	Circumcorneal, ciliary flush	Diffuse, with prominent circumcorneal injection
Corneal appearance	Clear	Dull or altered light reflex; positive fluorescein staining; opacification present	Clear or slightly hazy	Hazy, steamy, clouded; altered light reflex
Intraocular pressure	Normal	Normal	Normal to low	Very high
Pupil size	Normal	Normal or slightly constricted	Constricted	Fixed, mid-dilated
Pupillary response to light	Normal	Normal	Minimal further constriction	Usually no reaction
Anterior chamber depth	Normal	Normal	Normal	Shallow
Referral advisable	No (unless hyperpurulent)	Yes	Yes	Yes

*Preauricular lymph nodes are characteristic of viral conjunctivitis.

Figure 158-2 Disorders of the Lid.

Treatment includes warm compresses to loosen crusts and proper eyelid hygiene, including eyelid scrubs applied to the base of the eyelashes to remove scurf and collarettes. The patient may use dilute baby shampoo on a small washcloth. Commercially available eyelid scrub kits work particularly well and are recommended. Topical ophthalmic antibiotic ointment applied nightly after the lid hygiene measures for 2 to 6 weeks is necessary if there is associated infection or significant bacterial colonization. Rarely, cultures and susceptibility testing are warranted. Additional dry eye treatment may also be essential to effect control because eye dryness is a contributing factor.

Cellulitis of Extraocular Structures

Preseptal (Anterior) Cellulitis

The symptoms and signs of anterior cellulitis include eyelid erythema, tense edema, warmth, tenderness, and fluctuant lymphedema or swelling that may extend over the nasal bridge to the opposite eyelids. The patient is often unable to open the eyelids because of severe edema, but the eye itself is relatively uninvolved, with minimal to no conjunctival injection. Often there is a history of sinusitis, insect bite, dacryocystitis, local skin abrasion, laceration, or puncture wound. Preseptal cellulitis is usually accompanied by low-grade fever and an elevated white blood cell count. Vision, pupils, and ocular motility are normal, and there is no proptosis and no pain with eye movement.

Treatment includes checking a complete blood count with differential in addition to taking a culture of any open wound, purulent nasal drainage, conjunctival discharge, or weeping vesicles. In mild cases without localized abscess, administration of a broad-spectrum oral antibiotic for 10 days is indicated (e.g., amoxicillin-clavulanate, cefaclor, or trimethoprim-sulfamethoxazole). If secondary conjunctivitis is present, the application of a topical antibiotic ointment (gentamicin, bacitracin, ciprofloxacin, erythromycin, or neomycin-bacitracin-polymyxin B), 1/2-inch ribbon 3 to 4 times daily, is indicated. A computed tomography (CT) scan of the orbits and sinuses is essential in moderate to severe cases in children younger than 5 years and in those who have no noticeable improvement after a few days of oral antibiotics. These patients may require hospital admission and intravenous antibiotics (ceftriaxone, cefuroxime, ampicillin-sulbactam, or vancomycin). If indicated because of a traumatic facial lesion, tetanus toxoid should be administered per Centers for Disease Control and Prevention (CDC) guidelines. If a fluctuant mass or abscess is present, wound exploration, débridement, or drainage may be necessary.

Orbital (Posterior) Cellulitis

The symptoms and signs of posterior orbital cellulitis include eye pain, blurred vision, headache, double vision,

eyelid edema, eyelid erythema, eyelid warmth, eyelid tenderness, and proptosis. Conjunctival chemosis and injection, restricted ocular movement, and pain on attempted eye movement are the critical signs that help differentiate orbital from preseptal cellulitis. Fever, purulent discharge, decreased periorbital sensation, decreased vision, and retinal venous congestion are worrisome signs. A computed tomography (CT) scan often demonstrates sinusitis (commonly ethmoid sinusitis). The periorbital area may be relatively uninvolved. Optic nerve involvement presents with optic disc edema, decreased vision, and an afferent papillary defect.

Treatment includes hospitalization, immediate eye consultation, blood culture, imaging studies (orbit and sinus CT with contrast or magnetic resonance imaging with contrast), ear-nose-throat consultation if sinus disease is present, and broad spectrum intravenous antibiotics. The antibiotics are required for at least 72 hours, followed by oral medication for 1 week. *Staphylococcus* species, *Streptococcus* species, *Haemophilus influenzae*, bacteroides, and gram-negative rods (especially after trauma) are the most commonly associated microorganisms. Infectious disease and pediatric specialist consultation may help to confirm the most current antibiotics and dosages. Ceftriaxone, 1 to 2 g every 12 hours, plus vancomycin, 1 g intravenously every 12 hours, for adults is reasonable initial therapy; however, doses require adjustment based on renal function. The addition of metronidazole, 15 mg/kg intravenously every 6 hours, is necessary for chronic orbital cellulitis or when an anaerobic infection is suspected (not to exceed 4 g/day). Fungal infection must be excluded in immunosuppressed patients because, if confirmed, surgical débridement by an ear-nose-throat specialist is indicated. *Phycomycosis (mucormycosis) is a life-threatening disease that must be considered in all diabetic and immunocompromised patients. Immediate débridement is usually indicated.*

If there is not a rapid response to intravenous antibiotics, or if a subperiosteal abscess is present, surgical intervention is the next step. All patients require careful monitoring for complications, including cavernous sinus thrombosis and meningitis. Severe proptosis is an indication for the use of topical antibiotic ointment 4 times daily to reduce corneal exposure and prevent corneal ulceration.

Nasolacrimal Duct Obstruction

The symptoms and signs of nasolacrimal duct obstruction include: a wet-appearing eye with tears flowing over the eyelid, moist or dried mucoid matter with crusting principally on the medial eyelashes, punctal reflux material expressible with digital pressure on the lacrimal sac (the region between the medial canthus and nose), medial lower eyelid erythema, and swelling of the medial canthus region. If mucopurulent discharge is expressible with palpation of the lacrimal sac, the patient may have an associated dac-

ryocystitis (infected tear sac). The etiology of nasolacrimal duct obstruction is congenital or acquired.

Congenital obstruction is usually due to an imperforate membrane (valve of Hasner) at the distal end of the nasolacrimal duct. It occurs clinically in 2% to 4% of full-term infants and is diagnosed at 1 to 2 weeks of age. Treatment consists of having the parent apply digital index-finger pressure with downward strokes to the common canaliculus and lacrimal sac region 2 to 4 times daily. Ninety percent open spontaneously with this treatment by 1 year of age. If there is no resolution in 6 to 8 months, referral to an ophthalmologist for probing and irrigation is indicated. *If no reflux from the sac occurs with pressure or if the patient keeps the eye closed when exposed to light, timely referral to a pediatric ophthalmologist is necessary.* Rarely, preseptal cellulitis or dacryocystitis may develop.

Acquired nasolacrimal duct obstruction results from chronic nasal or sinus disease, dacryocystitis, previous surgery, tumor, or naso-orbital trauma. Involutional stenosis is the most common cause in older individuals. Treatment includes systemic antibiotics if dacryocystitis is present. In afebrile children who have mild cases and a reliable parent, treatment with cefaclor, 20 to 40 mg/kg/day orally in three divided doses, is usually effective. Fever in children with moderate to severe obstruction and an unreliable parent are indications for hospitalization and administration of intravenous cefuroxime, 50 to 100 mg/kg/day in three divided doses. In afebrile adults with mild disease, cephalexin, 500 mg orally every 8 hours, is appropriate. Febrile adults who appear acutely ill require hospitalization and therapy with intravenous ceftazidime, 1 g every 8 hours. Supplemental topical antibiotic drops (moxifloxacin, gatifloxacin, neomycin, or gentamicin) 4 times daily plus warm compresses and gentle massage to the inner canthal region 4 times daily may aid treatment in all patients. *Use of steroids requires evaluation and supervision by an ophthalmologist.* A pointing abscess is an indication to consider incision and drainage of the lacrimal sac by an ophthalmologist. If the obstruction is chronic or recurrent, referral to an ophthalmologist is also appropriate. Surgical correction by dacryocystorhinostomy with silicone intubation is usually needed once the acute episode has resolved.

Anterior Segment Disorders of the Conjunctiva, Sclera, and Cornea, Including Dry Eye and Trauma

Conjunctivitis

Conjunctivitis can be an isolated problem or can occur in association with any type of ocular inflammation. Symptoms and signs of conjunctivitis include a diffuse pattern of injection (redness) over the bulbar conjunctiva or the palpebral, or tarsal, conjunctiva. In conjunctivitis, the pattern of erythema is not sectoral. Pain is usually not associated (as opposed to episcleritis or scleritis) but may

occur with irritation or a foreign body sensation. In adult patients, both infectious and noninfectious inflammation of the conjunctiva is usually associated with ocular discharge. The characteristics of the discharge imply specific etiologies:

- Bacterial: purulent discharge
- Viral: serous, watery discharge
- Allergic: watery discharge with grayish, scant, stringy mucus

BACTERIAL (NONGONOCOCCAL) CONJUNCTIVITIS. Bacterial (nongonococcal) conjunctivitis presents with a purulent discharge of mild to moderate degree and tarsal conjunctival papillary inflammation. Involvement may be unilateral or bilateral. Common organisms include *Staphylococcus* species, *Streptococcus* species, and *Haemophilus* species (in children). No preauricular lymph node is palpable unless hyperpurulent discharge is present due to *Neisseria gonorrhoeae*.

Treatment includes topical antibiotic drops: moxifloxacin, gatifloxacin, levofloxacin, gentamicin, tobramycin, neomycin-polymyxin B-gramicidin, or sulfacetamide 4 times daily for 5 to 7 days. Alternatively, ointments including bacitracin, gentamicin, ciprofloxacin, neomycin-bacitracin-polymyxin B, or polymyxin B-bacitracin, 1/2-inch ribbon 4 times daily for 5 to 7 days, may be used.

The patient requires follow-up every 2 days initially, then every 3 to 5 days until resolution. If there is no improvement in 3 days, or if vision worsens, referral to an ophthalmologist is indicated. Copious purulent discharge is an indication to perform a Gram stain and culture to exclude gonococcal infection. Referral to an ophthalmologist is wise in this situation. In children, the accepted treatment for *H. influenzae* conjunctivitis is oral amoxicillin-clavulanate, 20 to 40 mg/kg/day in three divided doses, given the risk for development of otitis media, pneumonia, or meningitis.

VIRAL CONJUNCTIVITIS. Viral conjunctivitis is highly contagious because it is usually caused by an adenovirus. Often there is a history of recent upper respiratory infection, contact with someone who had an upper respiratory infection or red eye contact exposure in the prior 5 to 14 days before developing symptoms. Both eyes are affected simultaneously or in sequence (up to 3 days apart). Symptoms and signs include eye irritation or itchiness, a palpable preauricular lymph node, and an inferior palpebral conjunctival follicular or folliculopapillary reaction. Follicles are the macroappearance of aggregated lymphocytes surrounded by mast and plasma cells in the conjunctival stroma. Pseudomembranes (inflammatory debris and fibrin) or true conjunctival membranes herald severe involvement. Small subconjunctival hemorrhages are noted in 43% of adenoviral conjunctivitis cases. Typically, viral conjunctivitis gets worse for the first 4 to 7 days after onset and may not resolve for 2 to 3 weeks. Punctate keratitis

may be detected in 2 days to 1 week. Subepithelial opacities may develop in 7 to 14 days and result in decreased vision, reduced contrast sensitivity, photosensitivity, and glare or haloes around bright lights.

Treatment includes taking steps to prevent transmission and complications as well as to provide symptomatic relief. Patients with suspected viral conjunctivitis should be examined in a separate area to avoid spread of infection to other patients and minimize surface contact within the physician's office. Cleaning and disinfection of all equipment handled during the exam is mandatory. Doorknobs or objects the patient touches in the office should be disinfected as well. Chlorine-releasing solutions (such as 2% sodium hypochlorite solution) and povidone-iodine are effective in eliminating viral pathogens. Recently prepared chlorine solutions should be used because activity is rapidly lost after dilution. Isopropyl alcohol is not effective in disinfecting adenoviral contaminated surfaces. Patients are instructed to avoid personal contacts and the sharing of towels, pillows, or any personal item that could be contaminated by ocular secretions. Patients should wash their hands after touching their eyes. Health care professionals with viral conjunctivitis should not have direct hand-to-patient contact for a minimum of 14 days after onset of symptoms. Chilled artificial tears or cool compresses may help alleviate symptoms. Similarly, antiallergy drops or topical nonsteroidal drops may offer some relief if the itchiness is severe. Topical antibiotics should be prescribed in patients with large epithelial defects or after the removal of membranes or pseudomembranes.

Topical corticosteroids should only be used by eye care professionals in patients with membranous or pseudomembranous conjunctivitis, severe keratitis, or persistent subepithelial infiltrates with visual loss. *Corticosteroids enhance viral replication and promote superinfection. Their use delays viral clearance and can result in a much greater number of infected patients in community epidemics.*

ALLERGIC CONJUNCTIVITIS. Symptoms and signs of allergic conjunctivitis include itching, burning, bilateral presentation, mild conjunctival injection, possible eyelid or conjunctival edema (chemosis), papillary conjunctival reaction, and possible whitish stringy mucus. A seasonal presentation is commonly seen with an associated history of airborne allergies (e.g., animal dander, pollens, ragweed, dust, or mold spores).

Treatment is symptomatic. Elimination of the inciting agent and the use of cool compresses or chilled artificial tears are helpful measures. For cases of moderate severity, useful topical agents include dual antihistamine–mast cell stabilizer agents (olopatadine, epinastine, ketotifen, azelastine); pure topical antihistamines (levocabastine, emedastine); pure mast cell stabilizers (cromolyn, lodoxamide, nedocromil, pemirolast); and decongestant combinations (naphazoline plus pheniramine). The addition of a topical nonsteroidal medication (nepafenac, ketorolac, bromfenac)

can be helpful. Severe cases and those refractory to treatment require referral to an ophthalmologist. *Topical steroids are reserved for severe cases and should only be used after evaluation by an ophthalmologist* (Fig. 158-3).

Subconjunctival Hemorrhage

Usually occurring spontaneously without known cause, subconjunctival hemorrhages (SCHs) may appear after Valsalva episodes (e.g., coughing, sneezing, straining during a bowel movement or with heavy lifting). SCHs are often noted upon awakening. One theory is that tiny blood vessels bridging cystic, thin conjunctiva easily shear or rupture with eye rubbing or pressure from the pillow during sleep. There is a possible association with anticoagulants, aspirin, high-dose vitamin E, accelerated hypertension, or bleeding diathesis—particularly if the hemorrhages occur bilaterally or are recurrent. Patients typically present with an acute, painless, flat, unilateral, dense, blood-red discoloration of the subconjunctival space. There is no loss of vision.

Treatment includes careful examination to rule out traumatic causes (perforating injury or globe rupture). Suspicion of penetration is an indication to shield the eye (using a hard shield, not a soft patch) and to obtain an immediate ophthalmologic evaluation. If there is no perforating injury or globe rupture, no treatment is needed except time (often 2 to 3 weeks before clearing) and reassurance of the excellent prognosis. Re-evaluation is indicated if the hemorrhage does not clear in 3 weeks or if it recurs.

Dry Eye Syndrome

Dry eye syndrome (DES), a tear film deficiency (keratoconjunctivitis sicca), is extremely common in the aging population, especially in women older than 40 years. Symptoms often exceed what can be found on physical exam. Symptoms and signs may include burning, irritation, grittiness, foreign body sensation, mild conjunctival redness, intermittent visual blurring, and reflex tearing. Patients often protest that they cannot have dry eye syndrome because their eyes are constantly tearing. However, the tear film is mostly oil (about 85% mucin and lipid), with the central aqueous portion making up only 15%. Therefore, educating the patient on the difference between poor tear film lubrication (lack of surface oil) and the body's compensatory response of watery reflex tearing to make up for the oil deficiency is often helpful. Typically patient's symptoms worsen as the day progresses.

DES symptoms are often exacerbated by prolonged reading, staring at the television, or working at the computer because of the decreased blink rate and increased evaporative loss associated with these activities. Symptoms are aggravated by smoke, high-airflow environments (e.g., car air conditioner or vent fan), low-humidity conditions (especially during the winter months when heaters are on), and fatigue due to lack of sleep.

Figure 158-3 Conjunctivitis, Subconjunctival Hemorrhage, Episcleritis.

Bilateral low tear meniscus (height of the tear lake measured as less than 0.3 mm at the inferior eyelid margin), rapid tear break-up time (discontinuity in the precorneal tear film recorded as less than 10 seconds), and punctate epithelial erosions (PEE) of the conjunctiva or cornea (best visualized with fluorescein dye or lissamine green staining using slit lamp biomicroscopy) are hallmarks of the disorder. Excess mucus, tear film debris, corneal filaments, and lid margin froth (denoting staphylococcal colonization) may also be noted. Visual blurring or glare occurs when PEE are in the optical pathway (i.e., in the pupil area), and these symptoms tend to be intermittent and variable.

Associated conditions abound. Dry eye after laser-assisted in situ keratomileusis (LASIK) is very common. This is due to relative corneal denervation disrupting the normal corneal sensation and feedback loop to the lacrimal gland with subsequent reduced tear production. Confocal microscopy has demonstrated that the number of stromal nerve fiber bundles decreases by 90% immediately after LASIK. By 1 year, their numbers improve, but remain less than half of their original value.

Connective tissue diseases such as Sjögren's syndrome, rheumatoid arthritis, Wegener's granulomatosis, and systemic lupus erythematosus may manifest significant dry eye keratopathy. Conjunctival scarring disorders that often have associated DES include ocular cicatricial pemphigoid (typically severe), Stevens-Johnson syndrome, trachoma, and chemical burns. DES may be a side effect of drugs, including diuretics, antihistamines, antidepressants, dermatologic drying agents, and anticholinergics.

Incomplete lid closure resulting in increased corneal exposure and DES may occur as a result of Bell's palsy, thyroid-related (Graves') exophthalmopathy, or scarred or malpositioned eyelids. Miscellaneous causes of DES include vitamin A deficiency, infiltration of the lacrimal glands (sarcoidosis, tumor), and postirradiation fibrosis of the lacrimal glands.

Initial treatment measures may include artificial tears instilled every 2 to 4 hours, cyclosporine 0.2% drops twice daily, and lubricating gels or ointment at bedtime. If corneal exposure is present when the patient is asleep, taping the eyelids closed during sleep or wearing a pair of moisture-chamber eye goggles (e.g., tranquileyes and goggles by eyeeco) is often helpful. Patients should not patch their eyes closed because the eyelids may creep open under the patch, thereby potentiating an abrasion. Lubricating gels are typically preferred over ointments because they cause less visual blurring. Humidifiers at the bedside may also prove helpful. Oral omega-3 fatty acids (wild-caught fish oil brands recommended), about 2000 mg/day, are also useful for improving the quality (oily mucin layer) of the precorneal tear film.

If the DES is severe or unresponsive to the above measures, ophthalmology referral for punctal plugs to help the patient retain more natural tears is the next step. (*Intracanalicular style plugs should never be used because bacterial biofilm may develop and induce canaliculitis.*) If the patient does not develop epiphora with plugs in place, plug removal with punctal cautery may prove especially beneficial. Long-term retention or utilization of punctal plugs is discour-

aged owing to loosening and bacterial biofilm formation. In profound DES, upper and lower punctal cautery closure may become necessary. Adjunctive preservative-free hydroxypropyl cellulose lubricant lacrisert inserts (3.5 mm long by 1.27 mm diameter, placed in the lower lateral fornices) stabilize and thicken the precorneal tear film and are useful in moderate to severe dry eye syndromes.

Pinguecula and Pterygium

Pingueculae and pterygia are benign masses of elastotic degeneration arising from the interpalpebral bulbar conjunctiva (nasal or temporal) caused by actinic (ultraviolet light) exposure, wind, dust, dry eye, or chronic irritation. Pingueculae are yellow-white nodules, typically asymptomatic, and confined to conjunctiva. Pterygia are triangular fibrovascular growths that extend onto the cornea.

Treatment includes ocular lubrication management as in dry eye, starting with artificial tears 4 to 6 times per day plus protection from ultraviolet light or irritants (e.g., sunglasses or safety goggles if appropriate). Topical nonsteroidal anti-inflammatory drugs (NSAIDs) are useful to alleviate inflammation (e.g., nepafenac 3 times daily, ketorolac 4 times daily, or bromfenac 2 times daily) for 2 weeks. An actively enlarging pterygium and refractory or severe inflammation are indications for referral to an ophthalmologist.

Corneal Abrasion

Symptoms and signs characteristic of corneal abrasion include sharp pain, photophobia, foreign body sensation, tearing, redness, a history of scratching the eye, and an epithelial defect that stains bright green with fluorescein. If there is no recent history of trauma and if symptoms occurred upon awakening, then recurrent erosion syndrome is likely.

Treatment should begin by using fluorescein dye to map the size and location of the epithelial defect. Except for the defect, the cornea should be clear. Evaluation for infiltrate, corneal laceration, penetrating trauma, and anterior chamber reaction is essential. If corneal haze is present, a superinfection is possible, and an ophthalmology consultation is needed. The eyelid should be everted to ensure that no retained foreign body is present. Pain may be relieved with cycloplegic drops (1% cyclopentolate, 5% homatropine). Oral analgesics with codeine or other appropriate narcotic agent can be prescribed if the patient's pain is marked. *Topical anesthetics are contraindicated!* They are used only to aid the exam and to confirm the diagnosis because immediate relief occurs within seconds of their instillation.

Topical antibiotics are recommended for infection prophylaxis. Contact lens wearers must have *Pseudomonas* species coverage (e.g., ciprofloxacin, tobramycin, gentamicin, moxifloxacin, gatifloxacin) and should have daily follow-up until the epithelial defect resolves. Drops are used 4 times daily; ointments should be used every 2 to 4 hours.

Ointments offer better barrier function between eyelid and abraded surface, but they blur vision. If drops are used concurrently with ointments, then drop instillation should always occur before the ointment to enhance penetration.

Taping the patient's eyelid closed may increase comfort but is not advised in contact lens wearers. Also, the use of patching or taping is contraindicated if the abrasion was due to trauma by plant matter (e.g., tree branch), vegetable matter, or false fingernails. To promote healing and alleviate pain, the patient should keep the eye closed as much as possible. Topical NSAIDs (nepafenac 3 times daily, ketorolac 4 times daily, or bromfenac 2 times daily) enhance comfort but can retard epithelial healing.

If the abrasion is not healed within 24 to 48 hours, referral to an ophthalmologist is indicated. Central or large abrasions must be followed daily. If infiltrates are noted at any time, prompt cultures and an ophthalmology consultation should be instituted because these patients require more aggressive therapy.

Chemical Injury

ACID INJURY. Acids such as car battery acid (H_2SO_4), bleach, refrigerant (H_2SO_3), fruit preservatives, and glass-etching chemicals precipitate tissue proteins and do not penetrate the cornea as deeply as alkali substances. However, acids do cause immediate corneal damage.

Treatment of acid injuries begins with immediate copious irrigation, preferably with saline or Ringer's lactate, for at least 30 minutes. It is helpful to place topical anesthetic and an eyelid speculum or a Morgan irrigating lens in the eye to facilitate irrigation. Five to 10 minutes after irrigation, the pH of the inferior conjunctival cul-de-sac is measured to ensure that a neutral pH (7.0) has been achieved. If not, irrigation must continue. The volume needed to neutralize the pH may range from 2 to 8 liters. If there is a persistently abnormal pH, sweeping the fornices with a moistened cotton-tipped swab is effective in removing retained particulates that may be lodged in the deep forniceal space.

Acid injuries are treated the same as corneal abrasions, and referral to an ophthalmologist is necessary.

ALKALINE INJURY. Alkali injuries from lye (NaOH), caustic potash (KOH), and ammonia (NH_4) tend to have worse outcomes than those from fresh lime $Ca(OH)_2$ or magnesium hydroxide $Mg(OH)_2$. Household cleaners, fertilizers, and refrigerants contain ammonia. Cement, mortar, plaster, and whitewash contain fresh lime. Flares and sparklers contain magnesium hydroxide. Alkali injuries cause both immediate and delayed damage to the eye because of deeper substrate penetration as compared with acid burns. Alkali burns also have a greater potential for serious ocular damage.

Treatment of alkaline injuries begins with immediate copious irrigation as for acid injury. Immediacy is imperative, even if nonsterile water is the only irrigation solution

available! The timeliness of irrigation is the most important therapeutic and sight-saving measure. Acidic solutions should never be used to neutralize alkaline burns (or vice versa). Alkaline injuries require immediate referral to an ophthalmologist after appropriate irrigation has been commenced.

Contact Lens Overwear Syndrome

Hypoxic stress to the corneal epithelium leads to the same symptoms and complications as corneal abrasions, which include pain, tearing, and photophobia. This syndrome is often associated with sleeping in contact lenses or a tight contact lens fit and presents with corneal edema, blurred vision, conjunctival hyperemia, and occasional corneal infiltrates. The inciting factor is often poor tear exchange and clearance of metabolic byproducts from beneath the lens.

Treatment is the same as for corneal abrasion. Contact lens wear must be discontinued, and monitoring for potential corneal ulcer or infiltrates is essential. Re-evaluation should occur daily with referral to an ophthalmologist if there is no improvement within 1 to 2 days.

Infectious Keratitis

Infectious keratitis results from destruction of corneal epithelium and stroma due to inflammation from an infectious organism. It is typically unilateral. Risk factors include contact lens wear, trauma, dry eyes, chronic ocular surface disease, topical corticosteroids, lid abnormalities, exposure, and corneal hypesthesia.

Symptoms of *bacterial* infectious keratitis include redness with mild to severe pain, photophobia, decreased vision, and purulent discharge. A discrete gray or white corneal opacity (infiltrate) is visible with penlight or slit lamp examination. Urgent referral to an ophthalmologist is indicated for diagnosis and treatment.

Viral infectious keratitis is most commonly caused by recurrent herpes simplex virus type 1. Associations include sun exposure, stress, illness, trauma, menses, and immunosuppression. Symptoms and signs include red eye with watery discharge and foreign body sensation. A dendrite, or branching figure, is the characteristic epithelial lesion of the cornea and is best seen with fluorescein staining (see Fig. 158-1). Urgent referral to an ophthalmologist is indicated. Topical steroids should never be used in the setting of possible herpes keratitis.

Other etiologies of keratitis are multiple, but infectious etiologies more commonly include: fungal (particularly common after trauma with plant or vegetable matter) and parasitic (e.g., *acanthamoeba*, which is particularly painful and commonly seen with poor soft contact lens hygiene or hot tub use).

Hyphema

Hyphema is blood in the anterior chamber, usually following blunt trauma. The patient may present with pain,

redness, blurred vision, and red blood cells, either suspended (microhyphema: cells only detectable by slit lamp) or layered along the dependent portion of the anterior chamber (usually at 6-o'clock position and detectable by penlight). The pupil may be irregular, peaked, or sluggish on the affected side (Fig. 158-4).

Evaluation includes confirmation of visual acuity, if possible, and performance of an initial screening exam with minimal globe manipulation because concurrent injury may be present. If the hyphema is reported as occurring spontaneously in a child, child abuse is always suspected. Treatment includes shielding the eye and keeping the patient at rest with the head elevated at least 30 degrees. NSAIDs or aspirin products are contraindicated. The patient should not read because the associated eye movement may promote rebleeding. Television watching is okay. Immediate ophthalmology referral is indicated.

Episcleritis and Scleritis

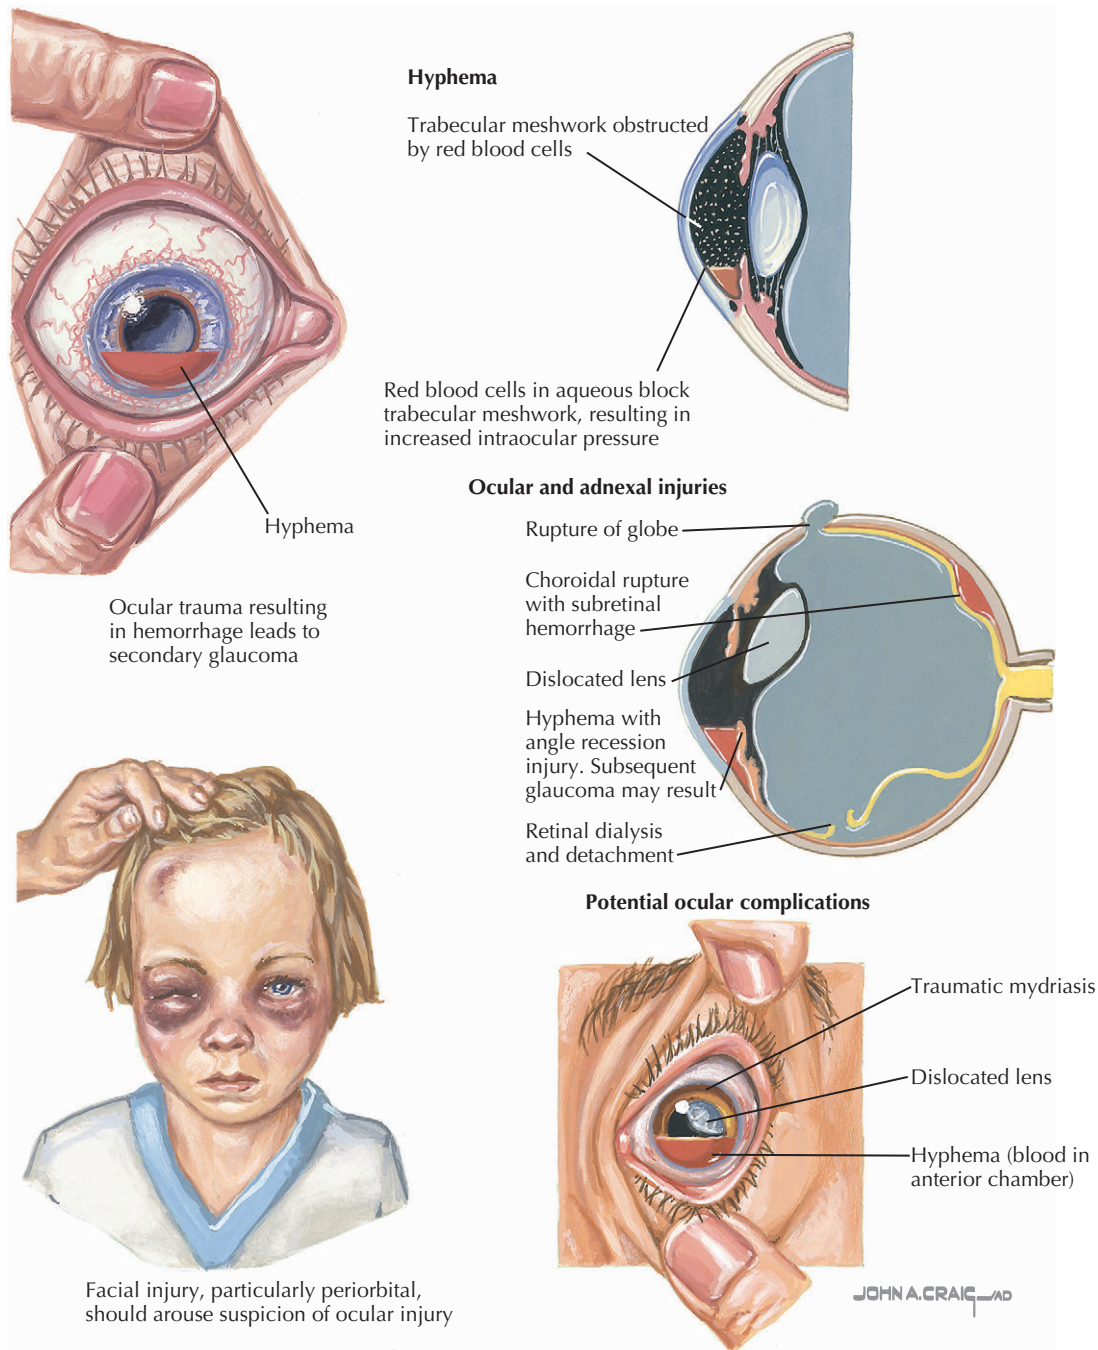

Symptoms and signs of *episcleritis* include acute onset of redness (70% sectoral, 30% diffuse) in one or both eyes, typically in young adults, which blanches on application of topical phenylephrine 2.5% (unlike scleritis, which does not); mild pain described as a dull ache localized to the eye; normal vision; and no ocular discharge. A history of recurrent episodes is common.

Most cases of episcleritis are self-limited and resolve in about 3 weeks. However, referral to ophthalmology is necessary for confirmation. Some cases require topical NSAIDs (nepafenac 3 times daily), oral NSAIDs, or both. Resistance to treatment may signify systemic disease and the need for a systemic workup by the primary care specialist.

Scleritis usually has a gradual onset. The hallmark symptom is severe and boring eye pain that may radiate to the brow, forehead, temple, or jaw. Pain may awaken the patient at night. Redness does not blanch with phenylephrine 2.5%, and the eye has a bluish hue in natural light by gross inspection. Vision is normal or mildly decreased. Photophobia is prominent because 30% have associated iritis. Tearing may be present, but there is no ocular discharge. Of patients with scleritis, 25% to 50% have underlying systemic disease, commonly connective tissue disorders such as rheumatoid arthritis, Wegener's granulomatosis, or relapsing polychondritis. Less commonly, the underlying disease is ankylosing spondylitis, systemic lupus erythematosus, polyarteritis nodosa, inflammatory bowel disease, gout, post-herpes zoster ophthalmicus, sarcoidosis, Lyme disease, tuberculosis, Reiter's syndrome, or microbial (bacterial or parasitic) infection. Hence, a thorough workup by rheumatology or an internal medicine specialist is needed.

Patients with scleritis require an ophthalmology evaluation because vision-threatening complications can occur. A team approach between the internist or rheumatologist

Figure 158-4 Hyphema.

and the ophthalmologist is essential to guide the systemic therapy. The ophthalmologist reports on the persistence of ocular inflammation and the internist or rheumatologist prescribes and monitors the systemic immunosuppressive agents.

Iritis

Iritis is inflammation of the anterior chamber. Its symptoms and signs include circumlimbal redness, eye pain, headache (described as a boring pain), photophobia,

decreased vision, miosis (small pupil, may be fixed or poorly reactive due to posterior adhesions), hypopyon (layering of white blood cells in anterior chamber), and keratic precipitates. Possible associated conditions are arthritis, infections, sarcoidosis, urethritis, and inflammatory bowel disorders. If there is a history of blunt ocular trauma, onset of iritis may be delayed 1 to 3 days. Complications of iritis include elevated eye pressures, chronic angle-closure glaucoma, and cataract. Prompt referral to an ophthalmologist is indicated (Fig. 158-5).

Figure 158-5 Iritis.

Acute Angle-Closure Glaucoma

Acute angle-closure glaucoma is due to an acute blockage of aqueous outflow from the eye. It is characteristically seen in persons with narrow angles who experience an acute rise in IOP when the pupil dilates. Predisposing factors include dim light, topical mydriatics, some systemic medications, and emotional stress. Typically unilateral, acute angle-closure glaucoma presents with severe ocular pain, eye redness, a mid-dilated nonreactive pupil, corneal cloudiness, blurred vision, frontal headache, haloes around lights, nausea, or vomiting. The affected eye may be firm or hard to palpation.

Optimal treatment requires referral to an ophthalmologist immediately. If treatment by the ophthalmologist is to be delayed by 1 hour or more, initial treatment should include the following:

- Pilocarpine 2%, 1 drop, then repeat in 15 minutes
- Timolol maleate 0.5%, 1 drop (if no asthma or heart failure)
- Apraclonidine 0.5%, 1 drop
- Acetazolamide, 500 mg by mouth or intravenously (if no contraindications)
- Consider intravenous mannitol 20% solution if no contraindications.

Avoiding Treatment Errors: Therapeutic Warnings

Topical Anesthetics

Topical anesthetics should never be prescribed or dispensed for analgesia. First, they inhibit the growth and healing of the corneal epithelium. Second, they eliminate the protective blink reflex and lead to exposure, dehydration, and epithelial breakdown, predisposing the patient to infection and corneal melting (ulcerative breakdown). Third, they create a punctate epitheliopathy that degrades vision. Finally, they have the tendency to be abused by health care workers and patients alike.

Topical Corticosteroids

Topical corticosteroid drops or ointments (alone or in combination with an antibiotic) should never be administered or prescribed by primary care physicians unless under the direct supervision and close monitoring of an ophthalmologist. This recommendation is based on several observations. First, topical corticosteroids inhibit wound healing, delay re-epithelialization, and can lead to perforation in neurotrophic conditions such as herpes zoster keratitis. They can mask inflammation, leading the patient to have

a false sense of security, when in fact an ulcerative breakdown may be developing. Further, topical steroids potentiate fungal and herpes simplex keratitis and promote posterior subcapsular cataract formation with prolonged use.

Corticosteroid-induced glaucoma is a form of open-angle glaucoma caused by prolonged use of topical, periocular (including skin creams), inhaled, or systemic corticosteroids. About one third of all patients demonstrate some steroid responsiveness, but only a small percentage have a clinically significant elevation in IOP. The type and potency of the agent, the agent's route and frequency, and the intrinsic susceptibility of the patient all affect the duration of time before the IOP rises and the extent of the rise. If the pressure rise is severe, then asymptomatic optic nerve damage and permanent loss of vision can occur. Hence, when the primary care specialist prescribes systemic steroids, it is recommended that patients have their eye pressure monitored by an eye care specialist about every 3 months. When topical steroids are stopped, the IOP elevation may persist for many months. When systemic steroids are stopped, the IOP usually normalizes to pretreatment levels within a few days.

Future Referral Considerations

Any pupillary inequality in a patient with red eye is a warning sign of serious ocular disease and merits ophthalmology referral. Further, if vision is acutely and significantly decreased, then a diagnosis of conjunctivitis is extremely unlikely and ophthalmology referral is indicated. Finally, if a patient with red eye wears soft contact lenses, referral to ophthalmology is strongly advised because an experienced interpretation of slit lamp findings is crucial to differentiate complications. Close communication and cooperation between the primary care specialist and the ophthalmologist is essential for early diagnosis and successful management of the red eye.

Future Directions

Viral conjunctivitis (especially secondary to adenovirus) remains a common red eye problem and a substantial source of ocular morbidity. Viral isolation by culture is currently the gold standard for the direct detection of adenovirus, but results are typically not available for several days or weeks. As a consequence, cultures are of no use for clinical therapeutic decision making. Current polymerase chain reaction testing provides the accuracy needed for the diagnosis of adenoviral conjunctivitis but lacks the speed and simplicity needed for a useful and widely deployable office-based test. The medical community needs a rapid and highly accurate method to identify adenoviral conjunctivitis in a relatively short time span (with results available in less than 30 minutes) in order to be clinically useful and potentially curtail widespread community outbreaks. Furthermore, efficient topical antiviral agents need to be developed that can shorten the course of the viral disease,

reduce viral replication, and decrease viral antigen load. At the time of this writing, the only standard commercially available topical antiviral drop is trifluridine (Viroptic), which is preserved with thimerosal, a mercurial derivative that is commonly irritative. In a prospective masked trial involving trifluridine, there was no difference between the treatment group and the group receiving artificial tear therapy. Other tests under development lack sensitivity. Until these future advances are realized, health care professionals involved in direct patient contact who acquire epidemic keratoconjunctivitis will continue to be restricted in their activities for a minimum of 14 days. Adults should also avoid close contact during periods of high communicability, or at least during periods of significant ocular discharge.

Additional Resources

Cataract Evaluation and Management

Introduction

Cataracts are the leading cause of blindness worldwide and may develop as a result of aging, various diseases, certain medical therapies, genetic anomalies, or can be congenital in origin. Because a normal lens is transparent, any opacification or discoloration in the lens capsule or substance, irrespective of its size or the amount of induced visual impairment, is technically defined as a cataract. However, clinically the term *cataract* is used to describe lens opacities that reduce or affect vision.

Most patients over the age of 70 are expected to have some degree of cataract formation or lenticular aging changes. Age-related cataract occurs in 50% of patients between the ages of 65 and 74 and in approximately 70% of patients over age 75. The prevalence roughly doubles each 10 years of age after age 30. In the United States, cataracts are the leading cause of decreased vision not correctable by spectacles and are the most common reason for Medicare beneficiary visits to ophthalmologists. Approximately 1.6 million cataract surgeries with the implantation of an intraocular lens are performed annually in the US. Cataract surgery is arguably one of the most successful surgical procedures in medicine (in terms of reducing morbidity and improving quality of life). A prospective study demonstrated that cataract removal was associated with a 50% drop in motor vehicle accidents. Furthermore, uncorrected chronic vision loss in elderly residential care patients has been associated with an increased risk of falls and tumbling-related injuries. The Framingham study noted an increase in the relative risk of hip fracture over 10 years with moderate vision impairment (1.54 if overall vision is reduced to 20/30 to 20/80) and severe vision loss (2.17 if vision is worse than 20/100). Moderate vision loss in only one eye demonstrated a relative risk of 1.94, which underscores the significance of maintaining good stereoscopic vision in potentially preventing falls and related fractures. When decreased vision affects a patient's activities of daily living by limiting the ability to drive safely, read, participate in hobbies such as knitting or other recreational activities, then the practitioner needs to consider referral for cataract evaluation after ensuring that other more serious causes of visual loss have not been overlooked.

Etiology and Pathogenesis

Etiologies of acquired cataract are shown in Box 159-1.

Clinical Presentation

Patients' symptoms include image blur initially followed by slowly progressive visual loss over months to years affecting one or both eyes (Fig. 159-1). Additionally, patients may experience glare in bright sunlight or at night (especially with oncoming car headlights), image ghosting or distortion, brownish or yellowish discoloration of

objects, star-bursting around images, multiple images, mildly decreased color discrimination, and, sometimes, the surprising ability to read at near without glasses that were previously required. This unexpected visual improvement is referred to as *second sight* and is due to increased nuclear sclerosis of the lens, which leads to increased refractive power and a myopic shift. Reduced color perception, dyschromatopsia, does not occur to the same degree as in optic neuropathies, and a cataract alone does not cause a relative afferent pupillary defect as is observed in optic neuropathy. A patient's particular symptoms are based on the location and density of the lens opacification (Fig. 159-2).

Box 159-1 Etiologies of Acquired Cataract

Age related: most common

Intraocular inflammation: iritis

Diabetes: juvenile form develops white snowflake opacities in the anterior and posterior subcapsular regions, and adult form develops age-related cataracts at an earlier age

Trauma: direct penetrating injury from foreign objects, ocular or head concussive trauma, ionizing radiation to intraocular tumors, electrocution, or infrared radiation (e.g., glassblowers)

Drugs: steroids—both systemic and topical, antipsychotics (chlorpromazine), anticholinesterases, gold, allopurinol, amiodarone, busulfan

Intraocular tumors: melanoma associated with sector cortical changes

Systemic associations: hypocalcemia—small white iridescent cortical changes (usually seen in presence of tetany); myotonic dystrophy—multicolored needle-like opacities (Christmas tree cataract); atopic dermatitis (subcapsular, shield-like cataract); Down syndrome; congenital rubella

Cataracts are most commonly classified by morphology but also can be classified according to maturity. The morphologic classification includes nuclear, subcapsular, cortical, and the uncommon “Christmas tree” cataract. The maturity classification scheme includes immature, mature, hypermature, and morgagnian cataracts.

Nuclear cataracts demonstrate yellow or brown discoloration of the central portion of the lens on slit lamp biomicroscopy. These typically blur distance vision more than near vision. They are typical of aging and generally take many years to advance and become visually significant. Cortical cataracts may involve the anterior, posterior, or equatorial cortex and are often asymptomatic until the changes extend into the optical axis. The opacities start as tiny clefts and small vacuoles between the outer lens fibers due to hydration of the cortex. With time, these progressively enlarge to become radial, gray, spoke-like opacities densest in the lens periphery. They remain visually asymptomatic until they encroach on the central pupillary region. Subcapsular cataract opacities may appear near the anterior lens capsule but more commonly appear near the posterior aspect of the lens, often forming a plaque-like opacification. They may develop rapidly over a few months or a few years and are best visualized by retroillumination against a red fundus reflex with slit lamp biomicroscopy or direct ophthalmoscopy. Posterior subcapsular cataracts may be associated with prolonged steroid use, diabetes, trauma, ocular inflammation, or radiation and commonly occur in patients younger than 50 years.

The maturity classification is not commonly used except to describe the most severe forms of lens opacification such as the mature, hypermature, or morgagnian cataracts. An immature cataract is one in which the lens is partially

opaque and a posterior segment view is possible. In a mature cataract, the lens is completely opaque, and no posterior segment view is possible. A hypermature cataract is a mature cataract with a shrunken and wrinkled capsule due to leakage of water out of the lens. Total liquefaction of the outer cortex allows the hardened central nucleus to sink inferiorly and form a hypermature morgagnian cataract.

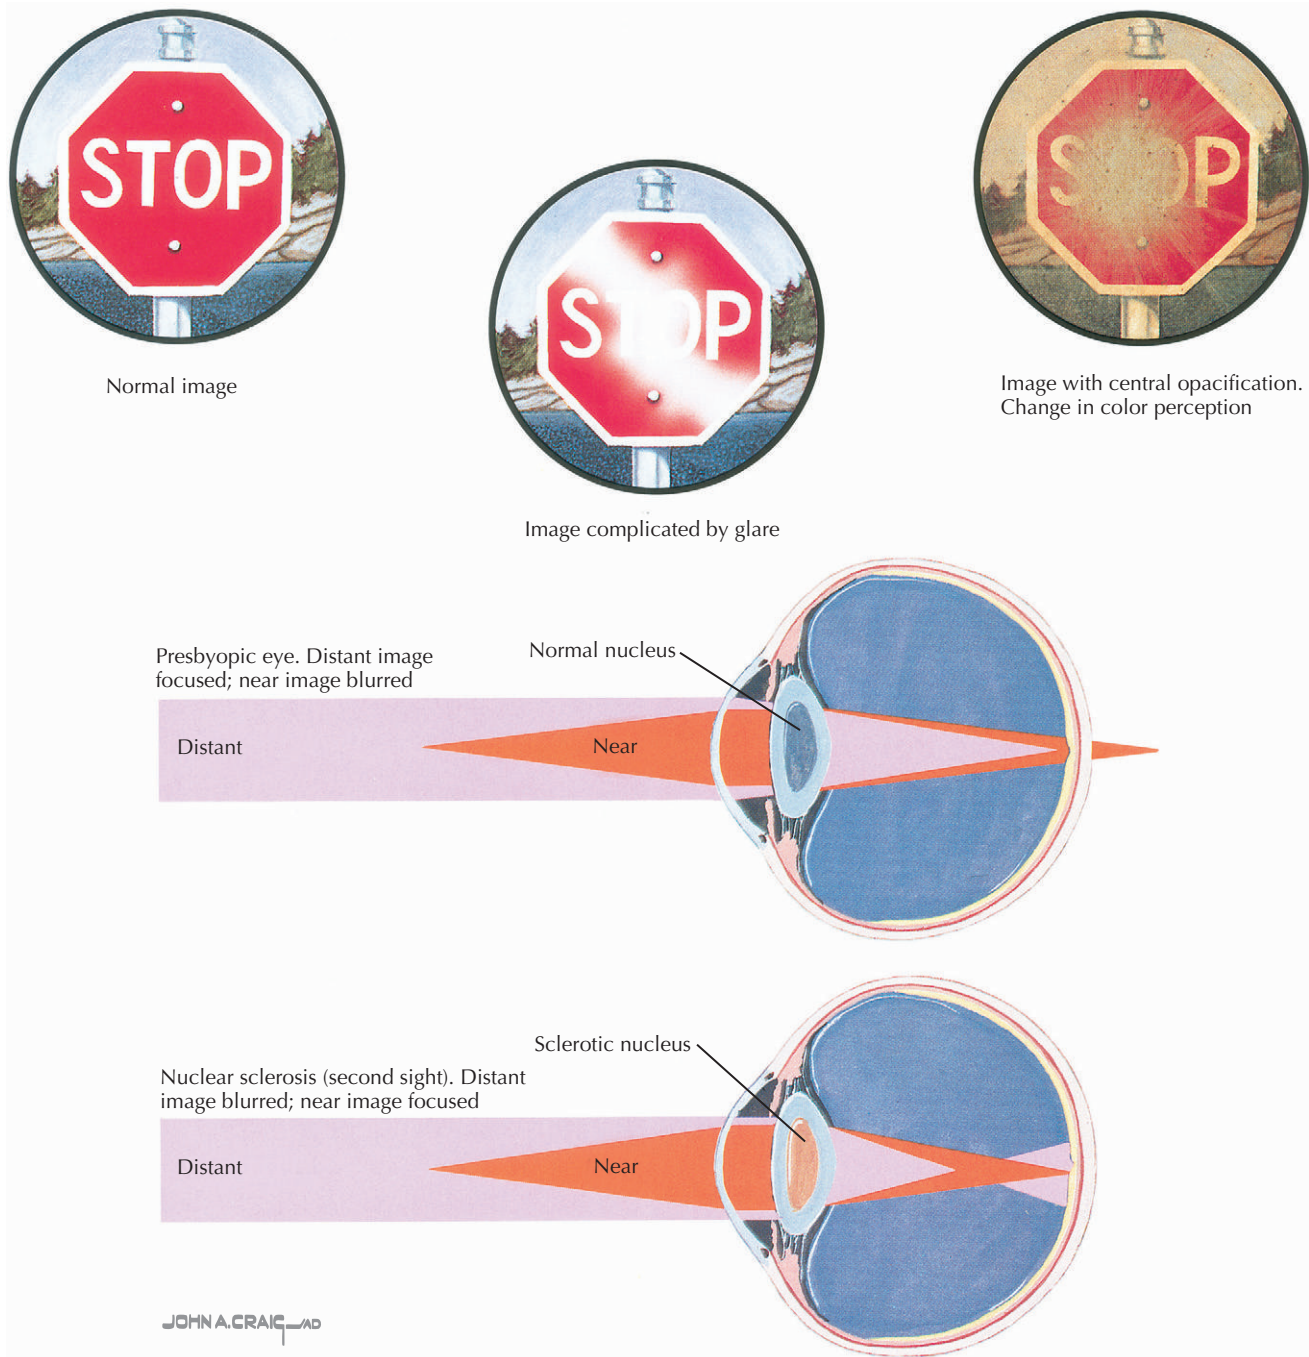

Diagnostic Approach

A patient with decreasing vision requires a complete examination to determine the etiology. Evaluation of the visual significance of a cataract must also include an evaluation of the optic nerve and retina to detect coexisting diseases that might also be the cause of decreased vision. For example, if patients complain of either difficulty with near work or metamorphopsia (waviness or distortion of central vision), special analysis is directed toward the central macula or fovea. If the lens is densely cataractous, the direct ophthalmoscope may not afford an adequate view of fundus detail to permit a reliable assessment of optic nerve or retinal pathology. If a patient has diabetic retinopathy in one eye and decreased vision in the contralateral eye, but the presence of a cataract precludes adequate examination of the fundus, a high level of suspicion for diabetes-related visual loss in the cataractous eye should be maintained. Removal of the cataract is often warranted to permit evaluation and possible treatment of retinal pathology, even if cataract surgery may not improve the patient's visual acuity.

The following are the appropriate steps for the patient's workup (Fig. 159-3):

1. *Obtain an accurate history of visual decline.* Ask about timing, onset, ocular disease, or poor vision in youth or young adulthood (before the cataract), side affected (unilateral or bilateral), ocular trauma, medications, and systemic diseases.
2. *Record a distance visual acuity using a Snellen chart.* Usually, vision is tested at a distance of 20 feet, or 6 meters, because 20 feet is equated with optical infinity for the eye. If a patient uses glasses for distance vision, these should be worn. The right eye is tested and recorded first, with the left eye occluded. The patient is asked to read the smallest line in which more than one half of the letters can be distinguished. Record the acuity measurement as a notation (e.g., 20/20) in which the numerator represents the distance at which the test is performed and the denominator represents the numeric designation for the line read. This is repeated for the left eye. If the vision is 20/40 or less in one or both eyes, have the patient view the chart through a pinhole occluder and record the results. The pinhole occluder may be used over the patient's glasses. If an illiterate E chart is used, have the patient point in the same direction in

Figure 159-1 Cataract Symptoms.

which the strokes of the E point. If the patient cannot see the largest Snellen letters, reduce the distance between the patient and the chart. Record the new distance as the numerator of the acuity designation (e.g., 10/400 or 5/400). If the patient is unable to see the big E (20/400) at 3 feet, hold up 1 or 2 fingers and record the distance at which counting fingers is done accurately (e.g., CF at 1 ft). If the patient cannot count fingers,

record whether vertical and horizontal hand motion can be accurately detected (e.g., HM at 3 ft). If hand motion cannot be detected, use a penlight to determine whether the patient can detect the direction or perception of light. Record as LP (light perception), either with projection (patient able to determine direction of the light source) or without projection, or NLP (no light perception).

Figure 159-2 Age-Related Cataracts.

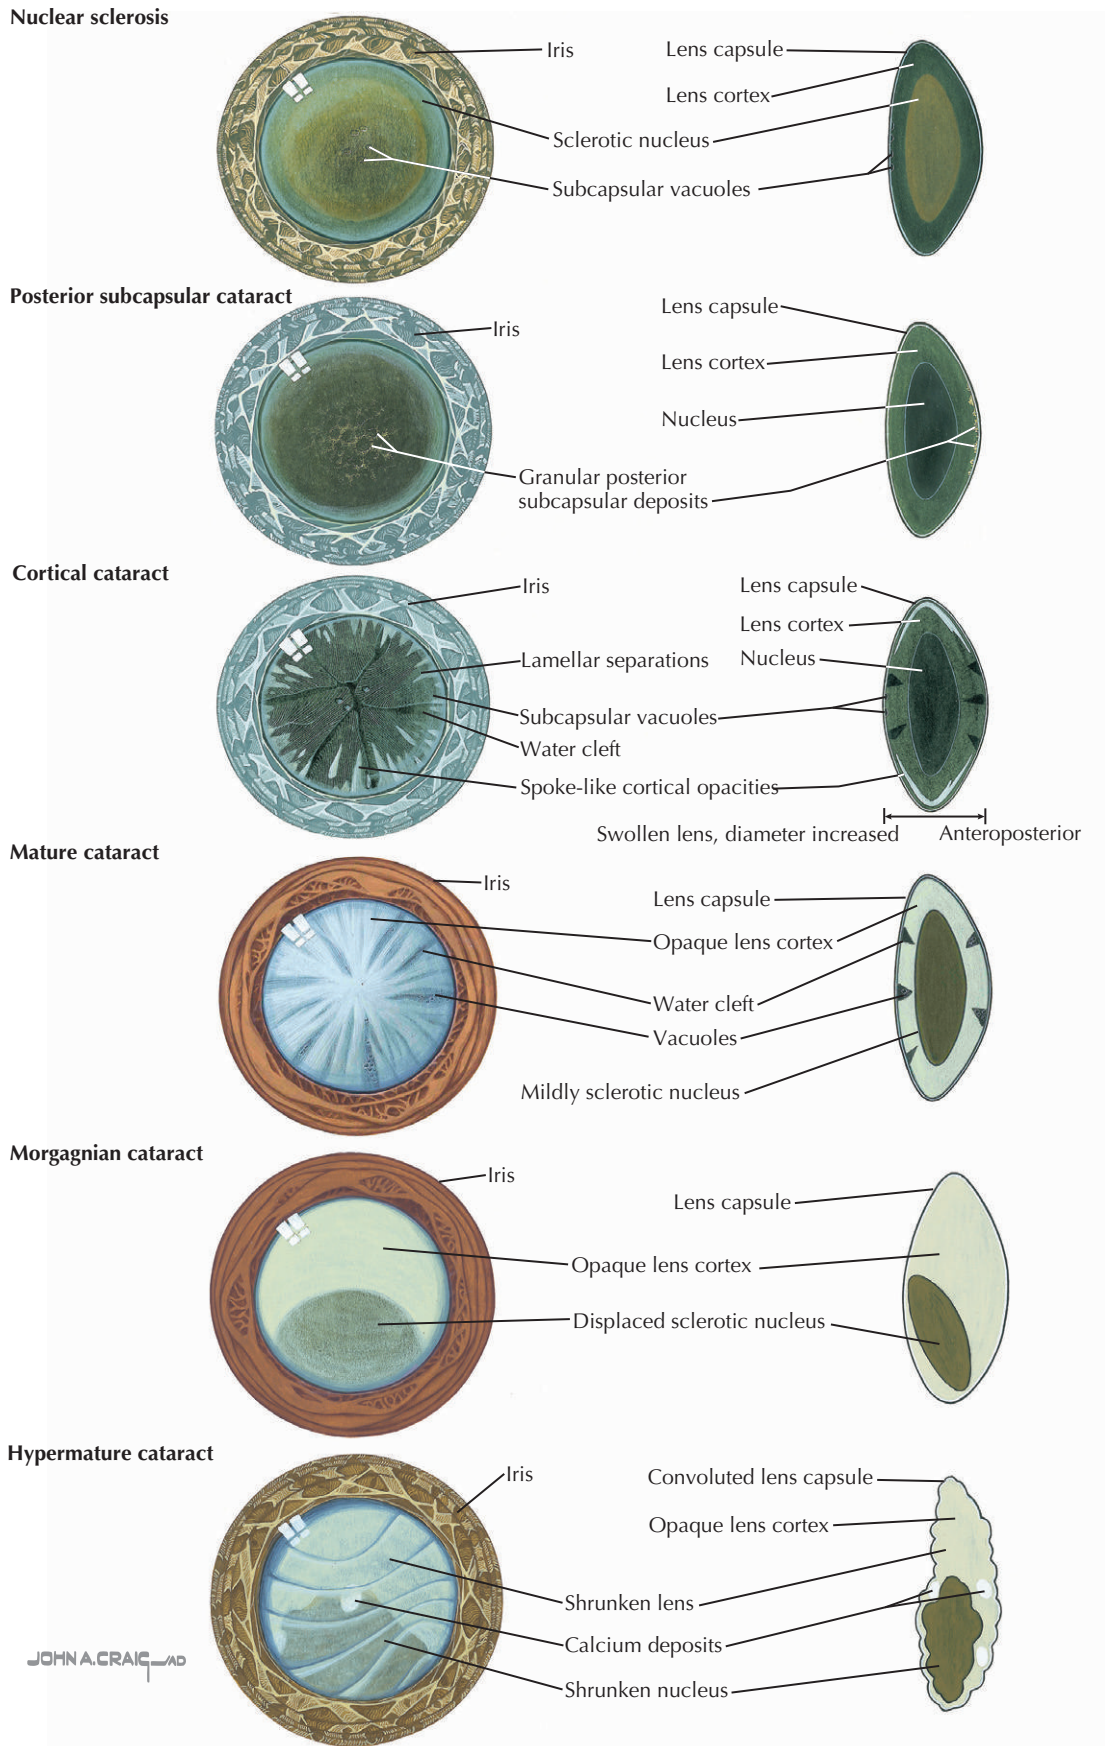

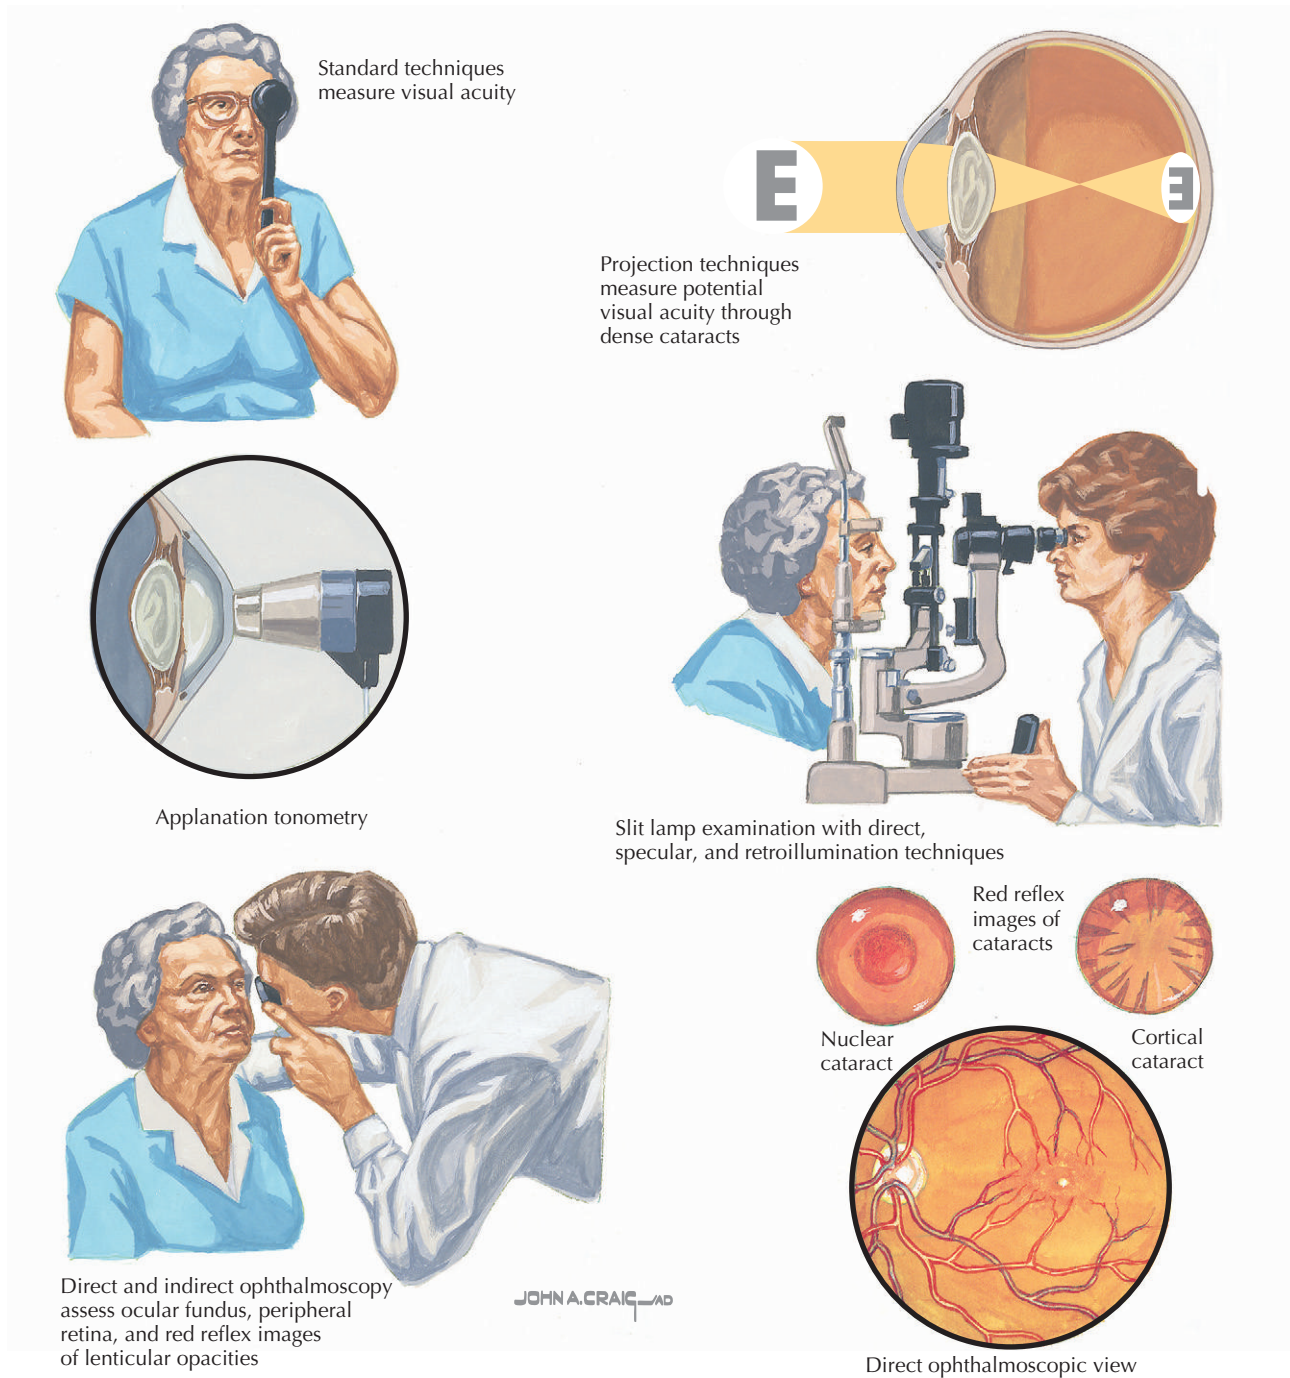

Figure 159-3 Diagnostic Evaluation.

Near vision testing is performed only if distance testing is difficult or impossible (exam confined to bedside). It is only valid if the test is done at the recommended distance with a standard near-vision card. If the patient is older than 40 years, reading glasses may be necessary to accurately see the near card.

3. *Evaluate pupillary responses, being careful to use a bright-enough light source to rule out a relative afferent pupillary*

defect (RAPD). Advanced cataracts do not produce a RAPD.

4. *Ophthalmoscopy of the lens, retina, and optic nerve.* Pharmacologic dilation of the pupils greatly facilitates this examination. Recommended agents include phenylephrine hydrochloride 2.5% and tropicamide 1%. Dilation should not be done if assessment of anterior chamber depth suggests a narrow angle or shallow chamber

because an attack of angle-closure glaucoma could result. The examiner's view into the eye should be about the same as the cataract patient's visual acuity (i.e., the physician's view into the patient's eye through the direct ophthalmoscope will be degraded to about the same extent as the patient's view out). Special attention is concentrated on the macula and fovea.

5. An eye physician will also routinely do a refraction to assess a patient's best corrected visual acuity and perform a slit lamp examination, which provides a magnified stereoscopic view of the cornea, lens, macula, and optic nerve. If the fundus is obscured by a dense cataract, B-scan ultrasonography is performed to rule out posterior-segment pathology such as a tumor or retinal detachment. Typically, cataract surgery is indicated if a patient has functional visual symptoms and visual acuity that has decreased to a level of 20/50 or worse by means of standard Snellen acuity testing or by Brightness Acuity Testing (BAT). BAT indicates the level of vision degradation in glare or sunlight conditions that may be experienced by a patient while driving a car. In addition, the potential acuity meter or laser interferometry can be used to estimate the patient's vision potential before cataract surgery when there is concurrent posterior segment disease. When cataract surgery is planned, additional measurements, including axial length of the eye (done with A-scan ultrasonography) and keratometry (corneal curvature readings), are required to determine the power of the desired intraocular lens to be implanted at the time of surgery. Specular microscopy and pachymetry are occasionally needed to evaluate the status and health of the corneal endothelium and its ability to withstand intraocular surgery (Fig. 159-4).

Management and Therapy

Optimum Treatment

Cataract surgery is typically performed to improve visual function or to facilitate examination and management of posterior segment disease (e.g., diabetic retinopathy, glaucoma) (Fig. 159-5). In some instances, cataract surgery is performed because the cataract itself is causing another ocular disease (e.g., uveitis, phacolytic glaucoma). Phacoemulsification or extracapsular cataract extraction techniques with the implantation of an intraocular lens are constantly evolving and improving and enjoy a success rate greater than 95% for *routine* cataract surgery.

If the patient declines cataract surgery, refractive errors are corrected by spectacles to the extent possible given the limitations involved. In some patients with small central opacities, a trial of mydriatic therapy (tropicamide 1% with or without phenylephrine 2.5% 3 times daily) may be temporarily helpful to allow the patient to view around the central visual axis opacities until the opacities enlarge

further in the rare instances when a patient cannot undergo surgery. Patients who decline surgery are generally re-examined yearly but may be reevaluated sooner if there is a symptomatic decrease in vision or if they have other associated ocular diseases.

After cataract extraction, about 50% of patients develop posterior capsule opacification (PCO) causing decreased vision, glare, or symptoms described as a film or smudging of vision. Some patients may complain of diminished contrast or even monocular diplopia. Treatment involves a painless opening of the posterior capsule with the neodymium : yttrium-aluminum-garnet (Nd : YAG) laser. Anterior capsule opacification or fibrosis can result in constriction of the capsular opening (phimosis) and may similarly require YAG capsulotomy enlargement. PCO treatment has led to the popular misconception among patients that a cataract can be removed with a laser (Fig. 159-6).

Perspective

The operating surgeon needs to do a preoperative examination on all patients contemplating cataract surgery and discuss the risks, benefits, alternatives, and potential complications. Using an eye model greatly facilitates a patient's understanding of the eye and how vision works. In an established university eye practice, greater than 50% of the time patients incorrectly guessed where the lens, cornea, retina, or optic nerve was located. Most patients do not know what a cataract is and are too embarrassed to admit this to their physician. Hence, it is very important never to assume that patients know the most basic ocular anatomy or understand the physiology of vision. Physicians need to remember that patients cannot begin to comprehend explanations or the need for surgical referral if they have not had a review of the most basic ocular anatomy and vision principles.

Avoiding Treatment Errors

Obtaining an accurate visual acuity measurement in each eye is essential because visual loss is a common symptom of cataracts as well as many other ophthalmic conditions. The patient's subjective description of the loss often correlates poorly with objective findings. Some patients with profound loss of vision present long after the onset of their symptoms and may have relatively minor complaints. Others may have minimal visual disturbance and overstate their complaints. Others inaccurately report the onset and timing of their symptoms. For example, a patient may have chronic ocular disease and vision loss in one eye, yet not recognize the problem until some vision decrease occurs in the other eye. The patient then mistakenly interprets the problem as acute bilateral visual loss because each eye is now being assessed individually. Hence, all reports of vision loss need to be evaluated.

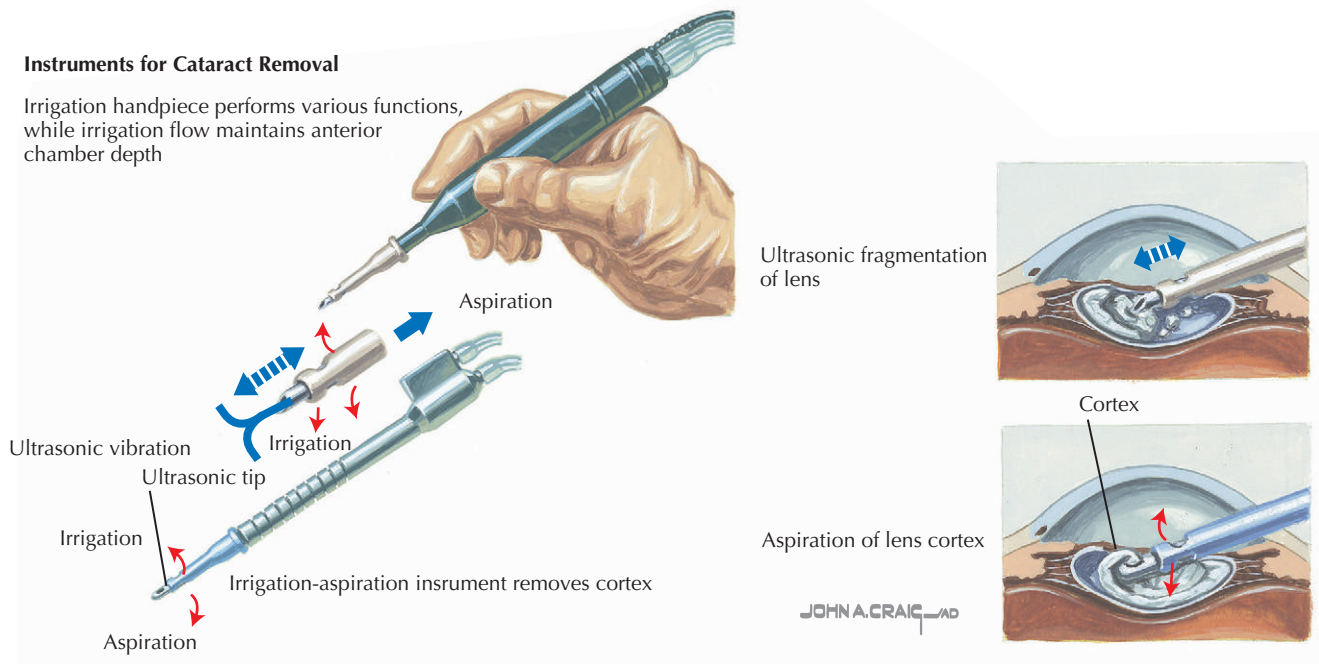

Figure 159-4 Intraocular Lens (IOL) Studies.

If an RAPD is noted, visual loss is likely due to either optic nerve disease (e.g., optic neuritis or ischemic optic neuropathy) or widespread retinal damage. Only rarely is a mild RAPD seen with a cataract or dense ocular media opacity (e.g., vitreous hemorrhage in a diabetic patient). The primary care physician should also remember to perform confrontational visual field testing because hemianopic defects (blindness involving half of the visual field) may have normal visual acuity. Furthermore, color vision should be assessed because, if it is aberrant, optic nerve or central retinal disease is likely.

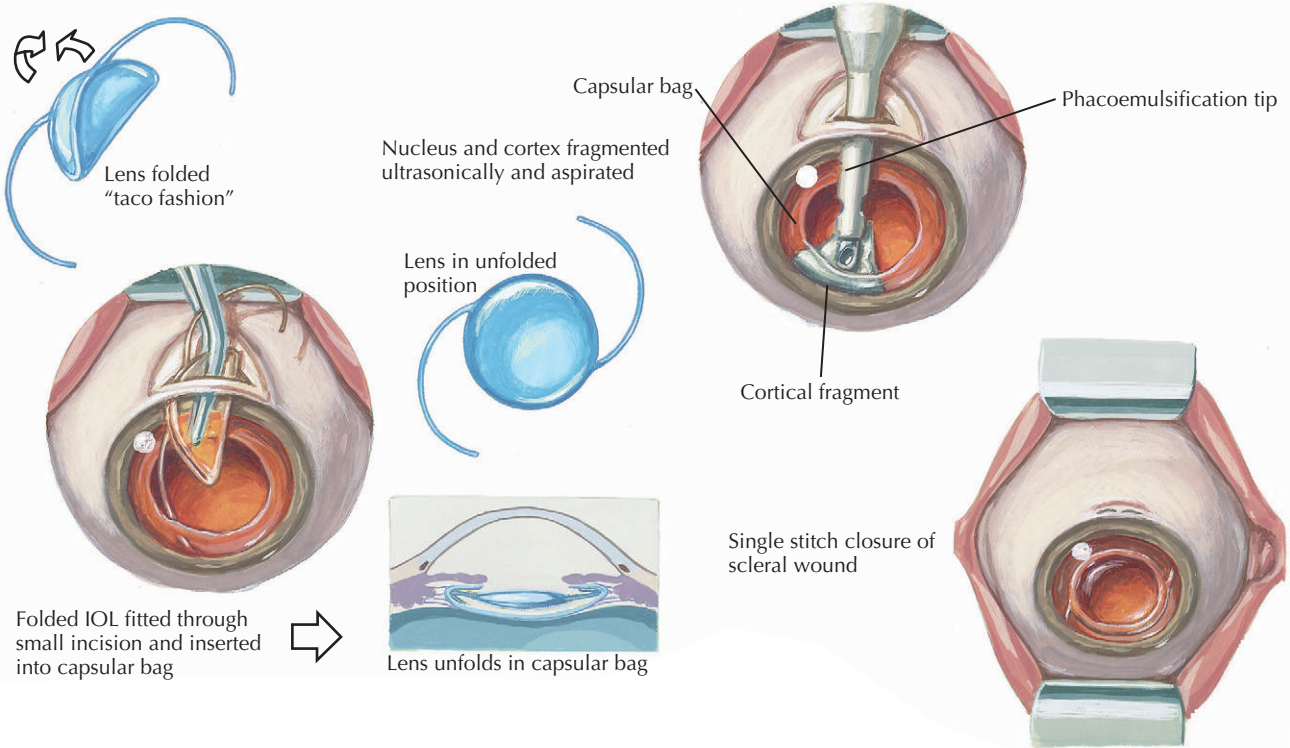

If transient vision loss is reported and tends to fluctuate with blinking, dry eye is likely the cause, and the ocular surface tear film needs to be improved. Other causes of visual fluctuation may be due to new-onset diabetes from

elevations in blood glucose levels causing swelling of the lens and progressive nearsightedness. Uncorrected presbyopia should be suspected when patients older than 40 years report blurring when they change focus from distance to near, or vice versa. If a patient reports a 2- to 5-minute dimming of vision with either a curtain or cloud over the visual field, amaurosis fugax is likely, and a cardiovascular and neurologic assessment is indicated. Transient visual changes associated with carotid artery or vertebrobasilar insufficiency may be precipitated by movements of the neck, especially extension. Increased intracranial pressure may cause papilledema, resulting in transitory, bilateral visual blurring or loss lasting a few seconds. Finally, many systemic medications, particularly those associated with hypotension as a side effect, may cause transitory visual symptoms.

Figure 159-5 Phacoemulsification and Insertion of Flexible Intraocular Lens (IOL).

Phacoemulsification and Insertion of Flexible IOL

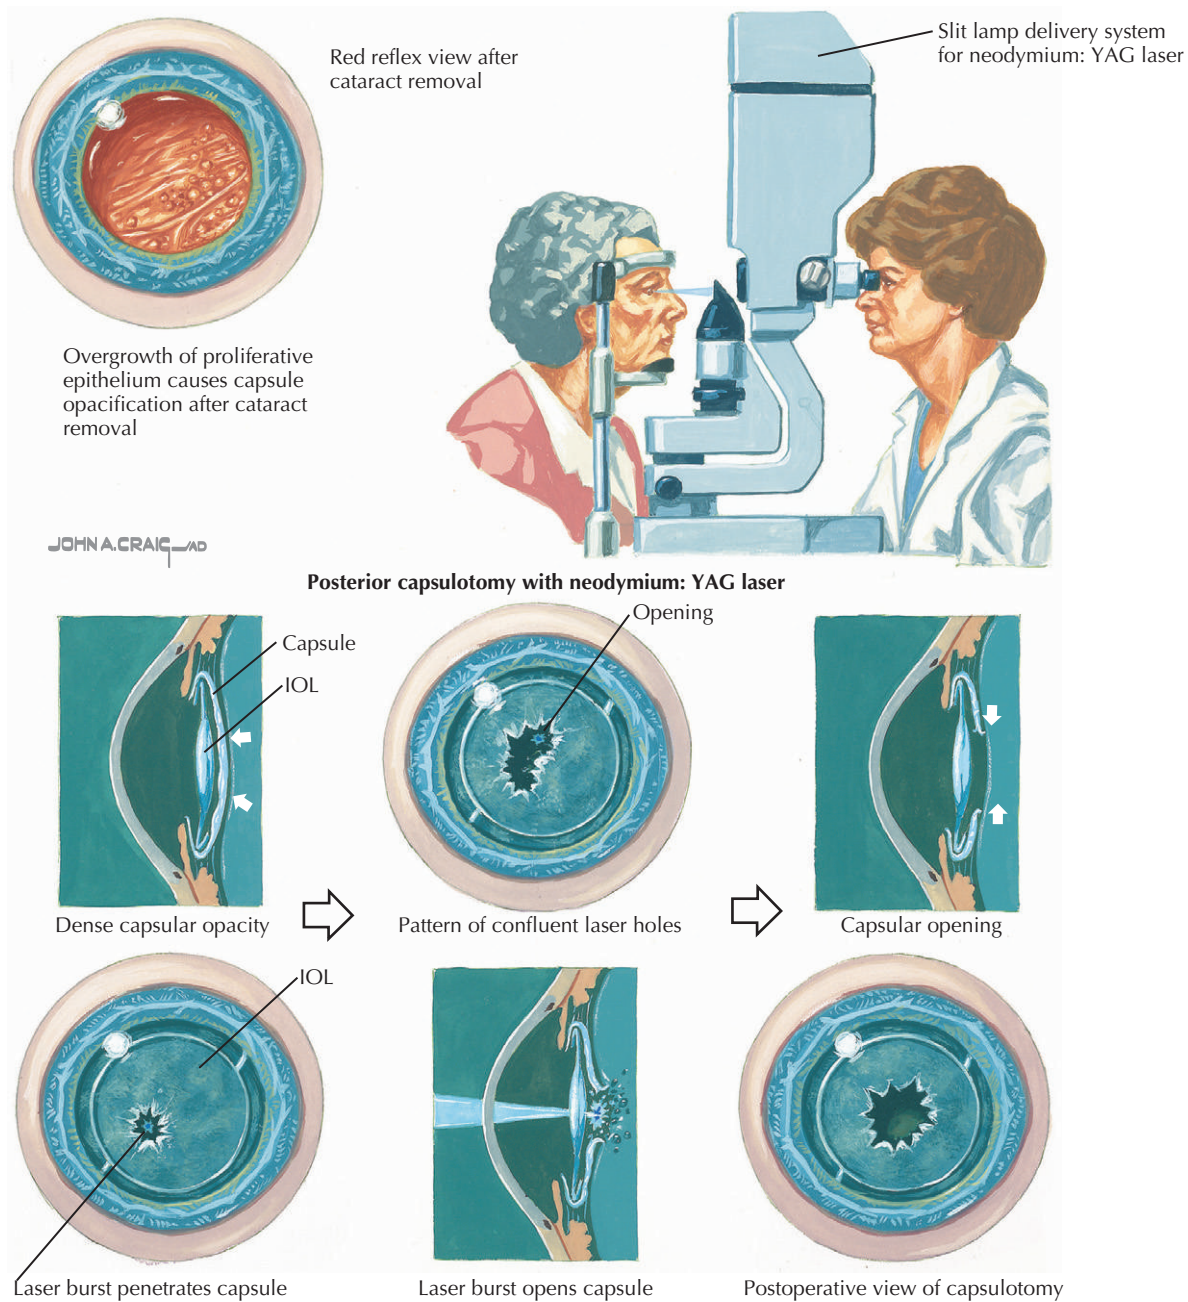

If the visual loss is painful and acute, immediate referral is necessary. Discussion and management of these common anterior segment and red eye problems are reviewed in Chapter 158. If the visual loss is chronic and progressive, cataracts or a refractive error is likely. However, the primary care specialist should remember that glaucoma, atrophic macular degeneration, and brain tumor are also possible causes. Brain tumor patients may report headache,

nausea upon awakening, or variable neurologic symptoms. It is important to remember that only rarely are ocular problems a source of headache.

Future Directions

Cataract surgery is arguably one of the most effective surgeries in medicine. Smaller incision sizes made possible by

Figure 159-6 Posterior Capsule Opacification.

improved lens fragmentation technologies along with advancements in intraocular lens technology continue to evolve and facilitate rapid visual recovery. Laser-adjusted intraocular lenses, multifocal lenses, and refractive lens implants are being refined and offer promise for the future to help correct myopia, hyperopia, astigmatism, and presbyopia. In fact, lens implantation technologic advances may one day compete favorably with laser vision correction surgery as an excellent alternative to spectacles or contact lenses for correction of refractive error.

Glaucoma

Introduction

Glaucoma, a leading cause of blindness in the United States and the world, is defined as an optic neuropathy with characteristic visual field defects, often associated with elevated intraocular pressure (IOP). About 80,000 Americans are blind due to glaucoma, and it is the leading cause of blindness in African Americans. Primary open angle glaucoma (POAG) is the most common form in the United States, Europe, and Africa. Referral of at-risk patients for early detection and treatment is essential because only advanced and irreversible vision loss is recognized by an afflicted patient. Traditional risk factors include African American ancestry, family history of the disease, elevated intraocular pressure, and age. Ocular parameters such as baseline cup-to-disc ratio and corneal thickness are important in the assessment of the risk for damage from elevated eye pressure. Glaucoma is also associated with the vascular risk factors of diabetes mellitus and hypertension, as well as myopia, or nearsightedness. In the United States, the number of cases is increasing because of the aging population.

Etiology and Pathogenesis

As we age, IOP characteristically elevates within the normal range of 10 to 21 mm Hg. IOP level is primarily determined by the rate of aqueous production and the resistance to outflow across the trabecular meshwork (Fig. 160-1). Elevated IOP is usually caused by increased resistance to outflow, but glaucoma without elevated IOP does exist. Because patients can have both pressure-dependent and pressure-independent glaucoma, other poorly understood factors are thought to predispose optic nerve axons to damage. Factors under consideration include structure of the lamina cribrosa and optic nerve blood flow.

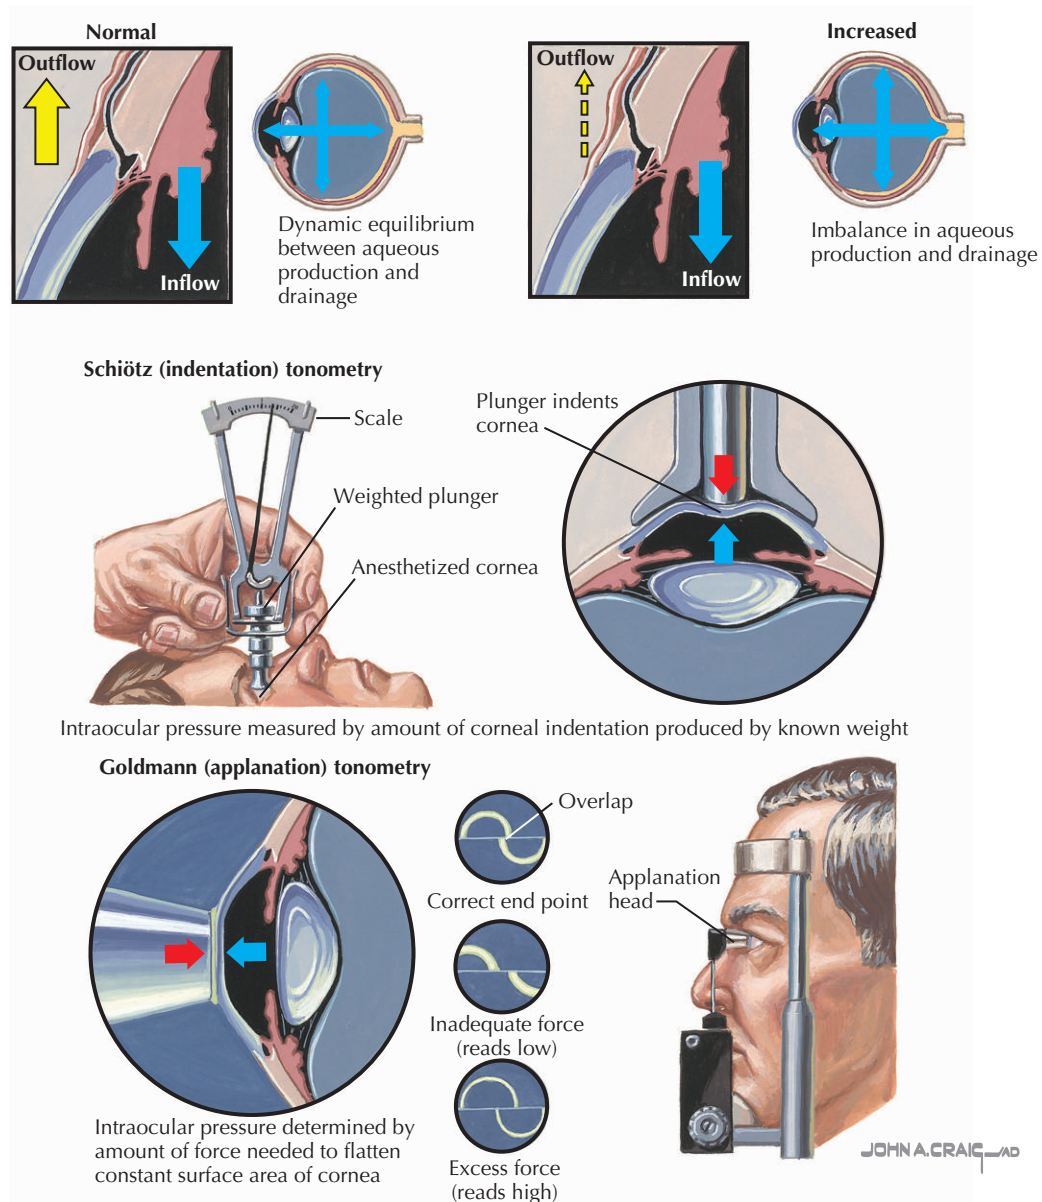

In primary open angle glaucoma, the anterior segment angle structures all appear normal. The angle, which is the junction between the cornea and iris, contains the trabecular meshwork. The use of special lenses in a technique referred to as *gonioscopy* provides a view of the angle. In secondary open angle glaucoma, the angle is open, but a cause of malfunction or obstruction is detected on examination or in the history. For example, corticosteroid use may increase resistance to outflow in about one third of patients, with a minority demonstrating a clinically significant rise in IOP. A higher percentage of glaucoma patients will demonstrate elevation of IOP. Elevated episcleral venous pressure, which may be idiopathic or secondary,

causes secondary open angle glaucoma. Conditions leading to elevated episcleral venous pressure include carotid-dural fistulas, Sturge-Weber syndrome, thyroid ophthalmopathy, retrobulbar tumors, and superior vena cava syndrome. Trauma may also lead to malfunction of an open angle.

Closed or narrow angle glaucoma, as defined by gonioscopy, is the other major category of glaucoma and is more prevalent in Asian populations and increases with aging. This may result from baseline anatomic factors such as anterior chamber depth, which lead to pupillary block. Angle closure may also be secondary to a disease process that pulls the iris over the trabecular meshwork, such as neovascular glaucoma or to a process, such as an intraocular tumor, that pushes the iris forward causing obstruction of the angle.

Clinical Presentation

There is some variation in the presentation of glaucoma. In significant open angle glaucoma, the presentation is one of painless vision loss. A patient with acute angle closure glaucoma will present dramatically with a red painful eye, blurred vision, nausea, and vomiting (Fig. 160-2). Neovascular glaucoma secondary to retinal vascular disease such as proliferative diabetic retinopathy may present in much

Figure 160-1 Intraocular Pressure.

the same as acute angle closure. Both of these types of glaucoma involve angle closure and acute elevation of IOP, which results in their shared symptoms. An infant may be born with a developmental defect in the outflow system leading to congenital glaucoma with characteristic photophobia, tearing, and a cloudy cornea.

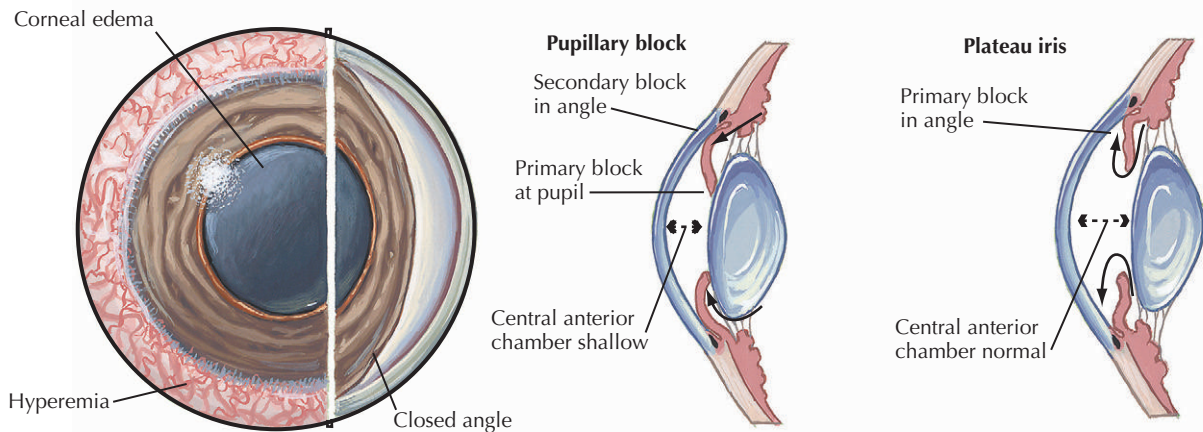

Differential Diagnosis

The differential diagnosis of glaucoma based on a patient's symptoms is broad. A patient with painless loss of vision could have a retinal detachment, macular degeneration, cataract, or artery occlusion. The differential of acute

angle closure is that of a red eye and includes conditions such as infectious keratitis, conjunctivitis, orbital cellulitis, and uveitis.

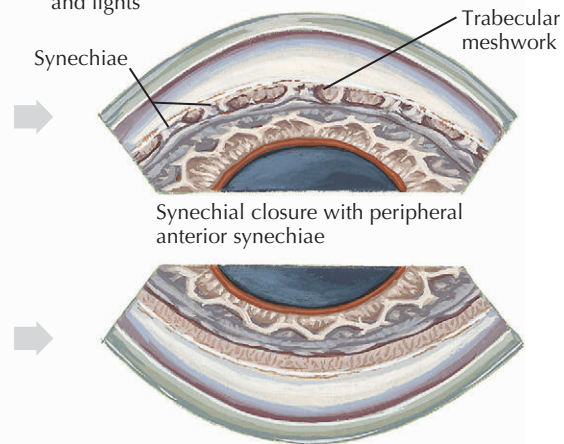

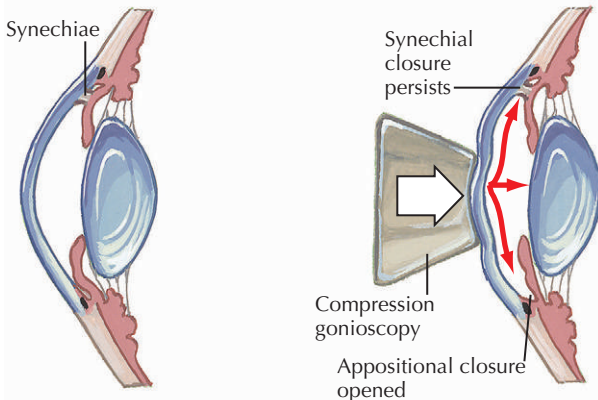

The differential diagnosis of glaucoma based on ocular examination includes other optic neuropathies, including acute ischemic optic neuropathy, toxic optic neuropathies such as vitamin B₁₂ deficiency, and previous optic neuritis. Pituitary adenomas can cause optic nerve and visual field defects that resemble glaucoma. In general, other optic neuropathies display more pallor than cupping when compared with glaucoma, in which loss of ganglion cells leads to cupping or thinning of the neuroretinal rim much more than pallor.

Figure 160-2 Primary Closed Angle Glaucoma.

Acute angle closure results in marked increase in intraocular pressure with conjunctival hyperemia, corneal edema, and fixed mid-dilated pupil. Subacute and chronic forms may be relatively asymptomatic

Angle closure may result from primary pupillary block with bulging iris or from less common plateau iris (primary occlusion at periphery of iris)

Long-term angle closure may result in synechiae that can permanently close angle. Compression gonioscopy differentiates appositional closure from synechial closure

Appositional closure opened by compression gonioscopy

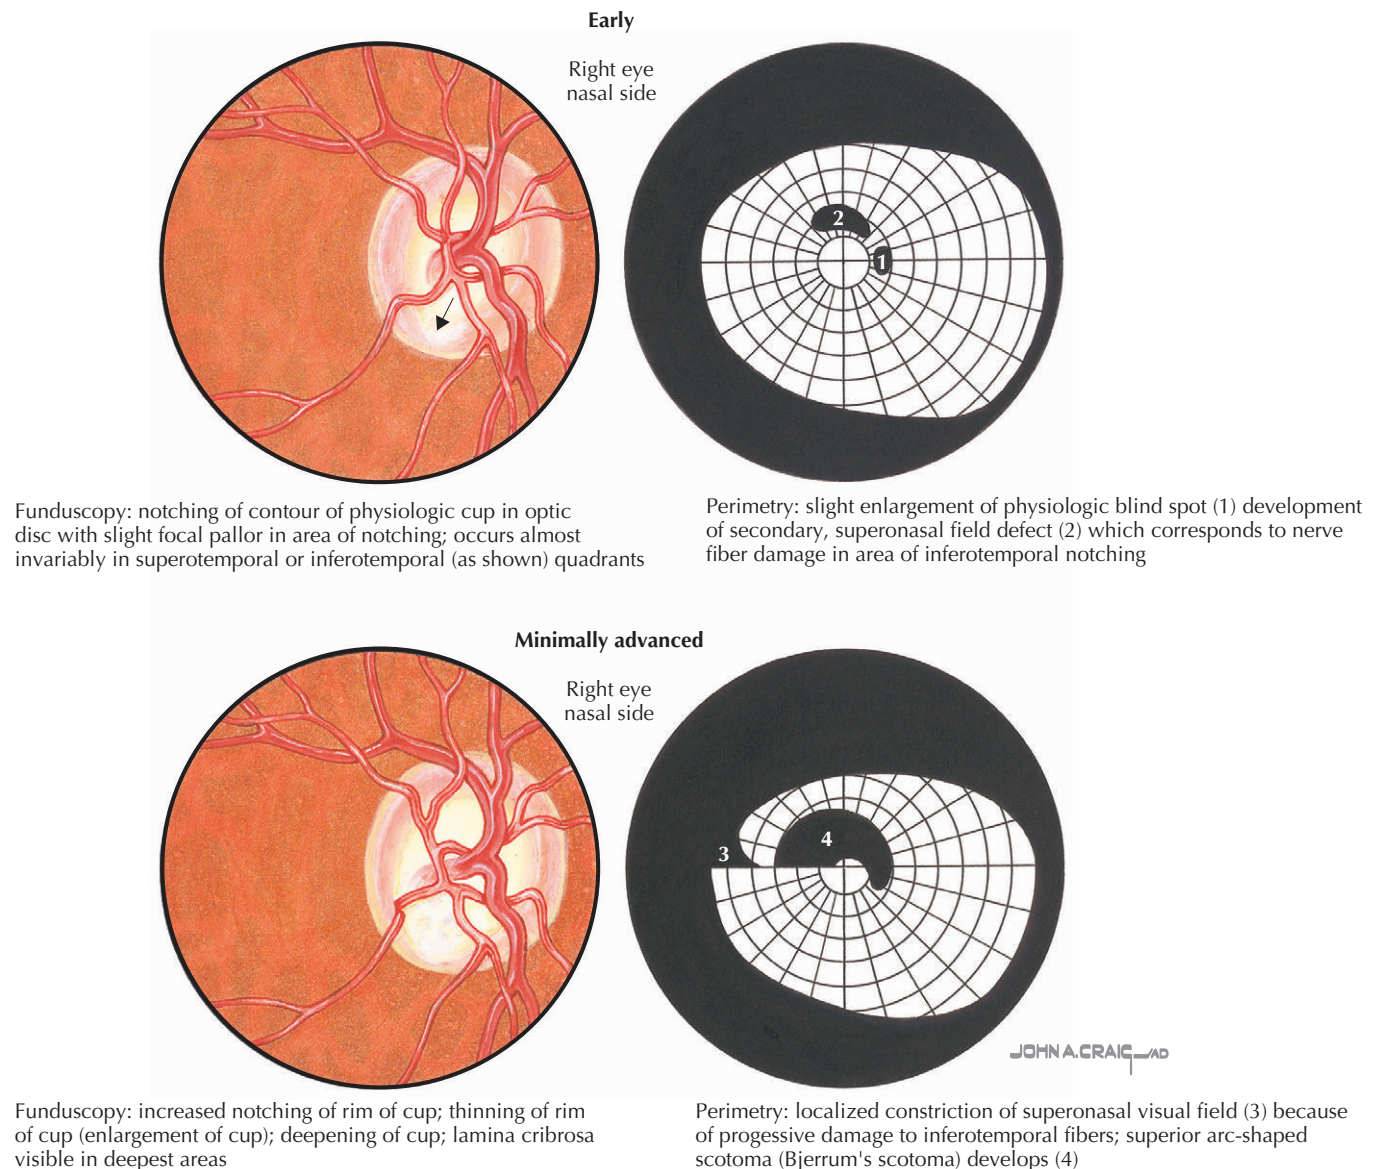

Diagnostic Approach

The diagnosis requires a complete eye examination, including gonioscopy and automated visual field testing. Gonioscopy determines whether the glaucoma is an open or a closed angle type or is likely to progress to a closed angle. Examination of the intraocular structures establishes whether a patient has a secondary cause of glaucoma. IOP is measured, and the optic nerve is closely inspected. Automated visual field testing is done to assess the function of the optic nerve and to measure relative scotomas not

detected on confrontational visual field testing. Central corneal thickness is measured to help assess the risk for glaucomatous damage from elevated IOP. The type of correlation seen between the disc features and visual field findings are depicted in Figure 160-3.

Management and Therapy

Most glaucoma cases in the United States are treated medically with topical drug therapy (Table 160-1), followed by laser, then incisional surgery.

Figure 160-3 Optic Disc and Visual Field Changes in Glaucoma.

Optimum Treatment

The principle that guides the aggressiveness of treatment is the concept of target IOP. After the clinical assessment is complete, the ophthalmologist chooses a treatment goal that is the level of IOP that he or she believes will not cause further glaucomatous damage. This level of IOP is guided by many major National Eye Institute–sponsored glaucoma clinical trials. The overall choice of treatment involves noting the patient's medical history and taking quality-of-life issues into account. If a patient progresses, then the IOP target is reassessed. Progression versus stability is determined by visual field and optic disc evaluations.

For open angle glaucoma, laser trabeculoplasty is used when medical therapy fails. Its effect can last from months

to years. Some patients receive multiple treatments per eye.

After the IOP has been decreased as much as possible by medications, the management of angle closure glaucoma is laser peripheral iridotomy (LPI). This procedure uses a laser to create an opening in the superior peripheral iris to permit an alternate route of aqueous flow from the posterior to anterior chamber. LPI, like trabeculoplasty, is an office procedure with minimal pain and a high success rate.

Patients who have failed both the maximum tolerated medical therapy and laser therapy often progress to incisional surgery. In the most common filtering surgery, trabeculectomy, a small hole is created through which aqueous fluid can flow from the anterior chamber to the subconjunctival space. The fluid collection, under the upper lid,

Table 160-1 Commonly Used Topical Medicines for Management of Glaucoma

Drug Class	Members	Major Systemic Interactions	Common Ocular Side Effects*
β Blockers	Timolol, metipranolol, carteolol, betaxolol, levobunolol	Bradycardia, exacerbate lung disease, depression, malaise	Nonspecific
Prostaglandin analogues	Latanoprost, travoprost, bimatoprost, unoprostone	Rare	Lash thickening or darkening, caution in inflammation, iris darkening
Topical carbonic anhydrase inhibitors	Dorzolamide, brinzolamide	Avoid in true sulfa allergy	Nonspecific
Adrenergic agents	Brimonidine, apraclonidine	Hypotension, sleepiness, dry mouth	Allergy, including lids

*All eye drops can cause ocular irritation manifested by foreign body sensation, hyperemia, or stinging or burning.

is termed a *bleb*. The bleb wall is thinned conjunctiva. In many circumstances, it is a thin barrier against penetration of bacterial organisms that can gain access to the intra-ocular space and cause a significant infection. Any patient who has had filtration surgery and in whom a red eye develops should have prompt evaluation. The other major filtering procedure, used for patients with or at risk for conjunctival scarring, involves placing a plate in a superior quadrant with a small tube from the plate placed into the anterior chamber. These devices, referred to as glaucoma shunts or tube implants, shunt aqueous fluid to the plate and then into the subtenon's space.

Developmental glaucoma in infants is a surgical disease like acute angle closure. Surgery is done after some stabilization of pressure by medications. Angle surgery, called *goniotomy* or *trabeculotomy*, is usually the first-line procedure and is curative in many infants.

Avoiding Treatment Errors

The most common source of treatment error in choosing topical therapy is disregard for the patient's medical history. One of the most frequent underlying misconceptions is that eye drops are not true medications that can be absorbed and produce systemic effects. The most common systemic interactions result from topical β-blocker use. Table 160-1 provides an overview of the major systemic interactions for the common classes of glaucoma medications.

Future Directions

Research in glaucoma includes identifying the genetics of the disorder and more elegantly understanding the process by which the trabecular meshwork develops sclerosis. Exploring whether there are optic nerve structural or vascular characteristics that are inherited and predispose individuals to glaucomatous optic neuropathy is especially important. One gene, present in about 16% of POAG patients, has been identified, and a screening test can now

be used clinically in select cases. Another large area of study is optic nerve head blood flow, which, given its anatomic location and number of vascular supplies, has been difficult to image to date. Technology to image the retinal ganglion cell layer and the optic nerve, to reliably screen for the disease, and to follow its progression more precisely and objectively continues to evolve. Progress continues in understanding the cascade leading to ganglion cell death, new knowledge that may lead to the development of new approaches to pharmacologic neuroprotection. This research overlaps with other neurobiology studies of diseases such as stroke and Alzheimer's disease.

Research on medical therapy will continue to focus on improving patient compliance through the development of simpler medical regimens and newer pharmacologic agents, such as the prostaglandin analogues, which only require daily dosing. Most other topical agents can now be used twice daily. The development of combination drugs is also likely to improve patient compliance and convenience. Surgical research includes procedures that shunt the aqueous past the obstruction of the trabecular meshwork into the Schlemm canal, a more physiologic route.

promoter with the severity of primary open-angle glaucoma. *Clin Genet* 60(3):220-225, 2001.

This work on the myocilin gene has been the major breakthrough in the genetic study of glaucoma.

2. Jampel HD, Quigley HA, Kerrigan-Baumrind LA, et al: Risk factors for late-onset infection following glaucoma filtration surgery. *Arch Ophthalmol* 119:1001-1008, 2001.

These authors reviewed 131 cases of bleb-associated endophthalmitis to identify risk factors for infection. The risks included use of mitomycin during surgery and continued use of topical antibiotics after surgery.

3. Kass MA, Heuer DK, Higgenbotham EJ, et al: The Ocular Hypertension Treatment Study: A randomized trial determines that topical ocular hypotensive medication delays or prevents the onset

of primary open-angle glaucoma. *Arch Ophthalmol* 120(6):701-713, 2002.

This study identifies risk factors for the development of glaucoma in patients with elevated intraocular pressures. It provided evidence on the utility of central corneal thickness and cup-to-disc ratio assessments in assessing risk for glaucoma in these patients.

4. Sommer A, Tielsch JM, Katz J, et al: Relationship between intraocular pressure and primary open angle glaucoma among white and black Americans. The Baltimore Eye Survey. *Arch Ophthalmol* 109(8):1090-1095, 1991.

This study illustrates the increased risk for glaucoma with black race and age. It also shows that intraocular pressure measurements alone are not definitive in the diagnosis of glaucoma.

Diabetic Retinopathy

Introduction

Diabetic retinopathy is the most significant cause of visual loss in working-age adults in the United States. Nearly all persons who have had diabetes for 20 years or more develop diabetic retinopathy, a startling statistic because as many as 16 million patients in the United States are affected with diabetes mellitus. Diabetic retinopathy becomes more common with increased duration of the disease. The Early Treatment Diabetic Retinopathy Study (ETDRS) developed and popularized a classification scheme that recognizes that diabetic retinopathy goes through a number of discrete stages until it reaches a severity leading to visual loss. The earliest stages are termed *nonproliferative retinopathy*. These stages can be subdivided into mild, moderate, moderately severe, and severe. *Proliferative retinopathy*, a later stage, occurs when abnormal blood vessels grow on the surface of the retina or the optic nerve and can be differentiated into early and high-risk phases.

Etiology and Pathogenesis

The precise sequence of events in diabetic retinopathy is complex and, despite multiple studies, is not entirely understood. Hyperglycemia is the major driving force in the development of the many abnormalities that ultimately result in visual loss in untreated patients. With increased blood glucose, hemoglobin A1C is increased, as is growth hormone. Intracellular sorbitol increases. Basement membrane thickening is an early pathologic change and can be seen in the ciliary body epithelium. Capillary basement membranes develop thickening, and there is a selective loss of the mural cells (pericytes). Endothelial cells proliferate in some capillaries, whereas others become acellular. With the progression of disease, some areas deteriorate to a nonperfused capillary bed consisting of acellular strands of thickened basement membrane. Microaneurysms consisting of outpouchings of the capillary wall develop in other areas of the retina. Eventually microaneurysms become hypercellular, obliterated, and sometimes thrombosed.

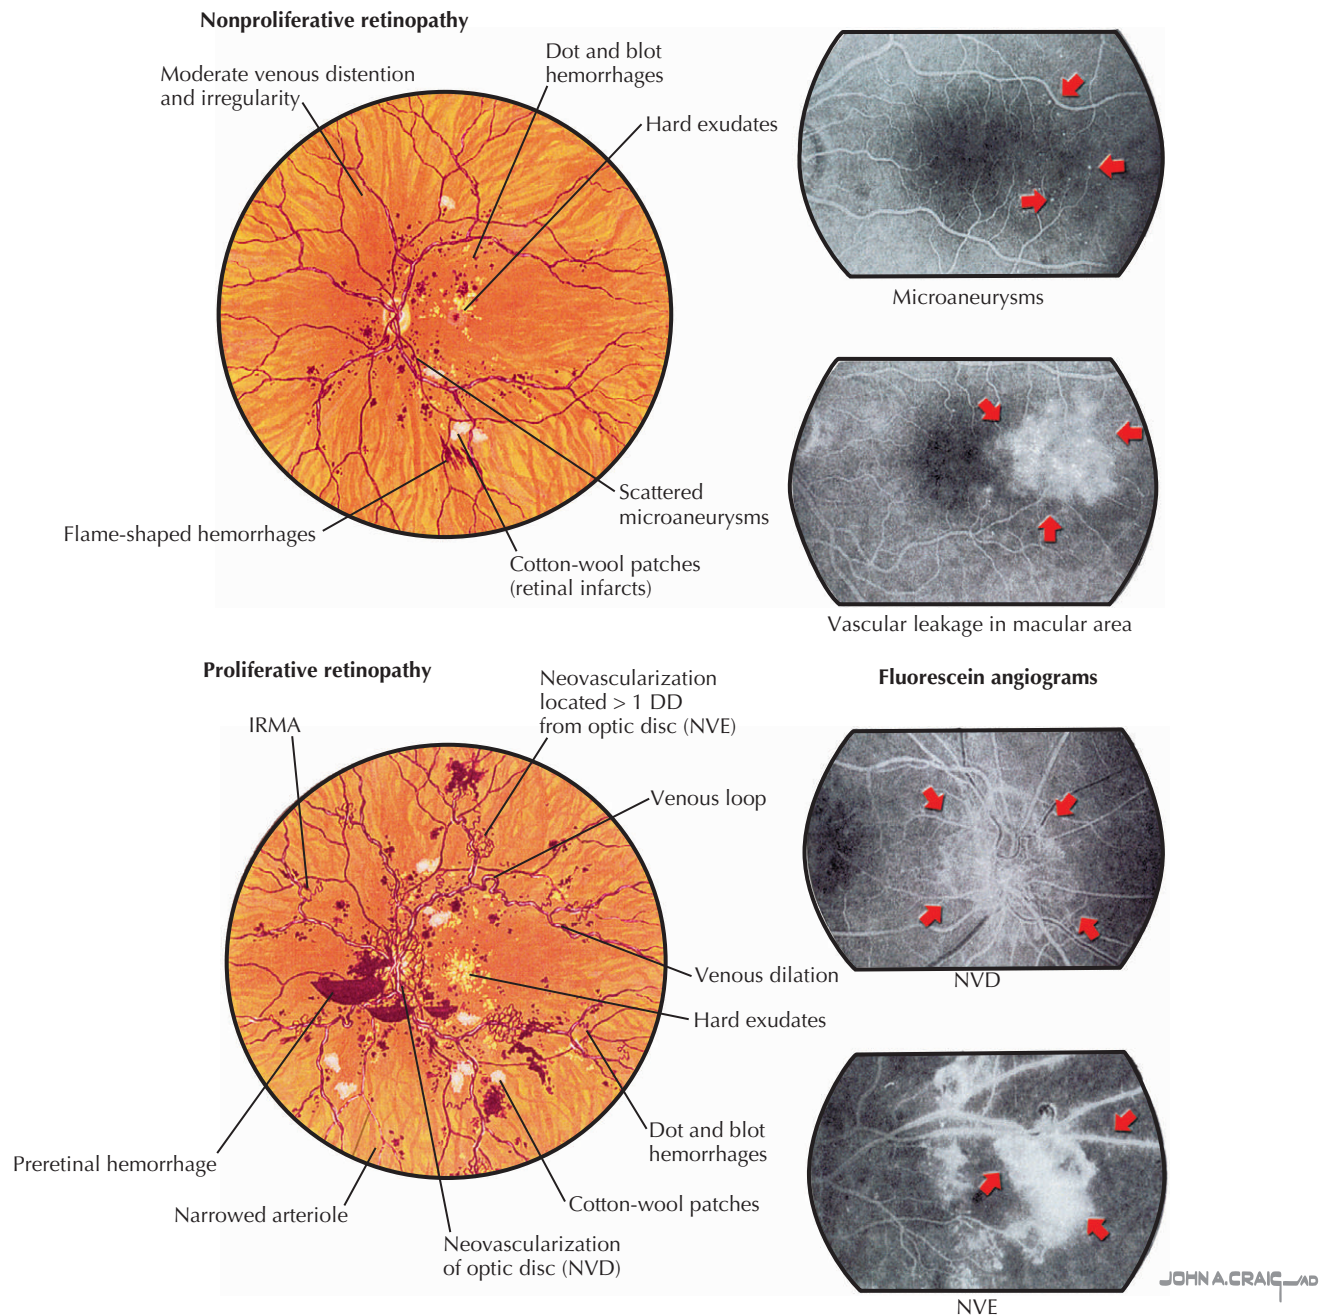

Blood flow within the retina changes as the disease progresses. Retinal blood vessels are not directly regulated by the autonomic nervous system and instead are governed by an autoregulation process that is lost as the disease progresses. Systemic hypertension often further damages

the retinal vascular system and is associated with an increased risk for diabetic retinopathy incidence, progression, and visual loss.

As focal hypoxia occurs, two significant concomitant processes begin to involve the retina. Vascular endothelial growth factor (VEGF) contributes to a breakdown of the blood retinal barrier in early diabetic retinopathy. Of special note from the therapeutic standpoint (see later), VEGF kinase inhibitors have been shown to decrease this VEGF-induced blood retinal barrier breakdown. Increased permeability of the vascular capillaries leads to *macular edema*. When this edema involves the central macular area, mild to moderate visual loss begins to occur.

The second major process is the development of abnormal new blood vessels called *proliferative diabetic retinopathy* or neovascularization. These new vessels are most often seen on the optic nerve and on the retinal surface but in extreme cases may grow on the iris and over the trabecular meshwork, producing neovascular glaucoma in eyes with marked retinal ischemia. VEGF has been shown to be sufficient for the development of retinal neovascularization, and induced expression of VEGF in the retina results in neovascularization. However, when VEGF kinase inhibitors are administered in an experimental setting, retinal neovascularization is blocked.

Figure 161-1 Diabetic Retinopathy.
IRMA, intraretinal microvascular abnormalities.

Clinical Presentation and Diagnostic Approach

The earliest manifestations of diabetic retinopathy are microaneurysms or small round red dots in the retina created by outpouchings of the capillary walls (Fig. 161-1). Injection of a fluorescent dye into the antecubital veins allows photographs of the inner eye to light up these areas of microaneurysms and demonstrate that more are present than can be seen through simple fundus ophthalmoscopic

examination. Small intraretinal hemorrhages called *dot-and-blot hemorrhages* are the next manifestation. These circular hemorrhages tend to occur in the outer plexiform layer where bipolar and Mueller cells are oriented vertically. Closer to the optic nerve where the nerve fiber layers are tightly packed, the hemorrhages may be more superficial and, by following the nerve fiber layer, assume a flame-shaped appearance.

As capillary permeability breaks down further, fluid accumulates within the retina, typically in the middle

Figure 161-2 Ocular Coherence Tomograms.

An ocular coherence tomography image of a macula with diabetic macular edema (*top*) and a normal macula (*bottom*) for comparison.

retinal layers, and is seen ophthalmoscopically as a thickening of the retina. When the thickening involves the macula, the central area takes on a cystic appearance (*cystoid macular edema*) and is associated with mild to moderate visual loss. Greater degrees of altered permeability cause deposition of lipoprotein in the middle retinal layers leading to the formation of *hard exudates*, patchy yellow accumulations within the retina often associated with areas of thickening and edema. These macular changes are seen dramatically using a new retinal imaging device, called *ocular coherence tomography* (Fig. 161-2).

At the later stages (often associated with severe systemic hypertension), focal nerve fiber layer infarcts called *cotton-wool patches* (soft, white, superficial changes in the retina with fluffy indistinct borders) develop. When a fluorescein angiogram is performed, these areas correspond to areas of capillary obstruction and capillary dropout. As ischemia develops, the veins take on multiple focal areas of irregularity called *beading*. Arteries become narrowed, and on a gross level, loops may occur in the major veins. Smaller intraretinal changes at the small vessel and capillary level consist of dilation of microvasculature, referred to as *intra-retinal microvascular abnormalities* (IRMA).

The development of hypoxia then leads to elaboration of vasogenic factors including VEGF, which stimulates the formation of neovascular tufts on the retinal surface and optic nerve surface (Fig. 161-3). These small new abnormal vessels break through the internal limiting membrane

of the retina and begin to grow on the posterior hyaloid face using the hyaloid as a scaffold. These vessels are fragile and are prone to rupture and hemorrhage, particularly in association with vitreous traction. As vessels grow more exuberantly, they begin to be accompanied by fibrous tissue in their development. The hyaloid then contracts, elevating the fibrovascular tissue and sometimes exerting sufficient force on the retina to produce *traction retinal detachment*. Vision may be lost either from vitreous hemorrhage, blocking access of visual images to the retina, or by the detachment of the macula by the fibrovascular proliferation. Typically, many of these findings are in the fundus at one time. The precise findings, their severity, and their extent throughout the fundus are combined into the grading scale that is used in clinical studies.

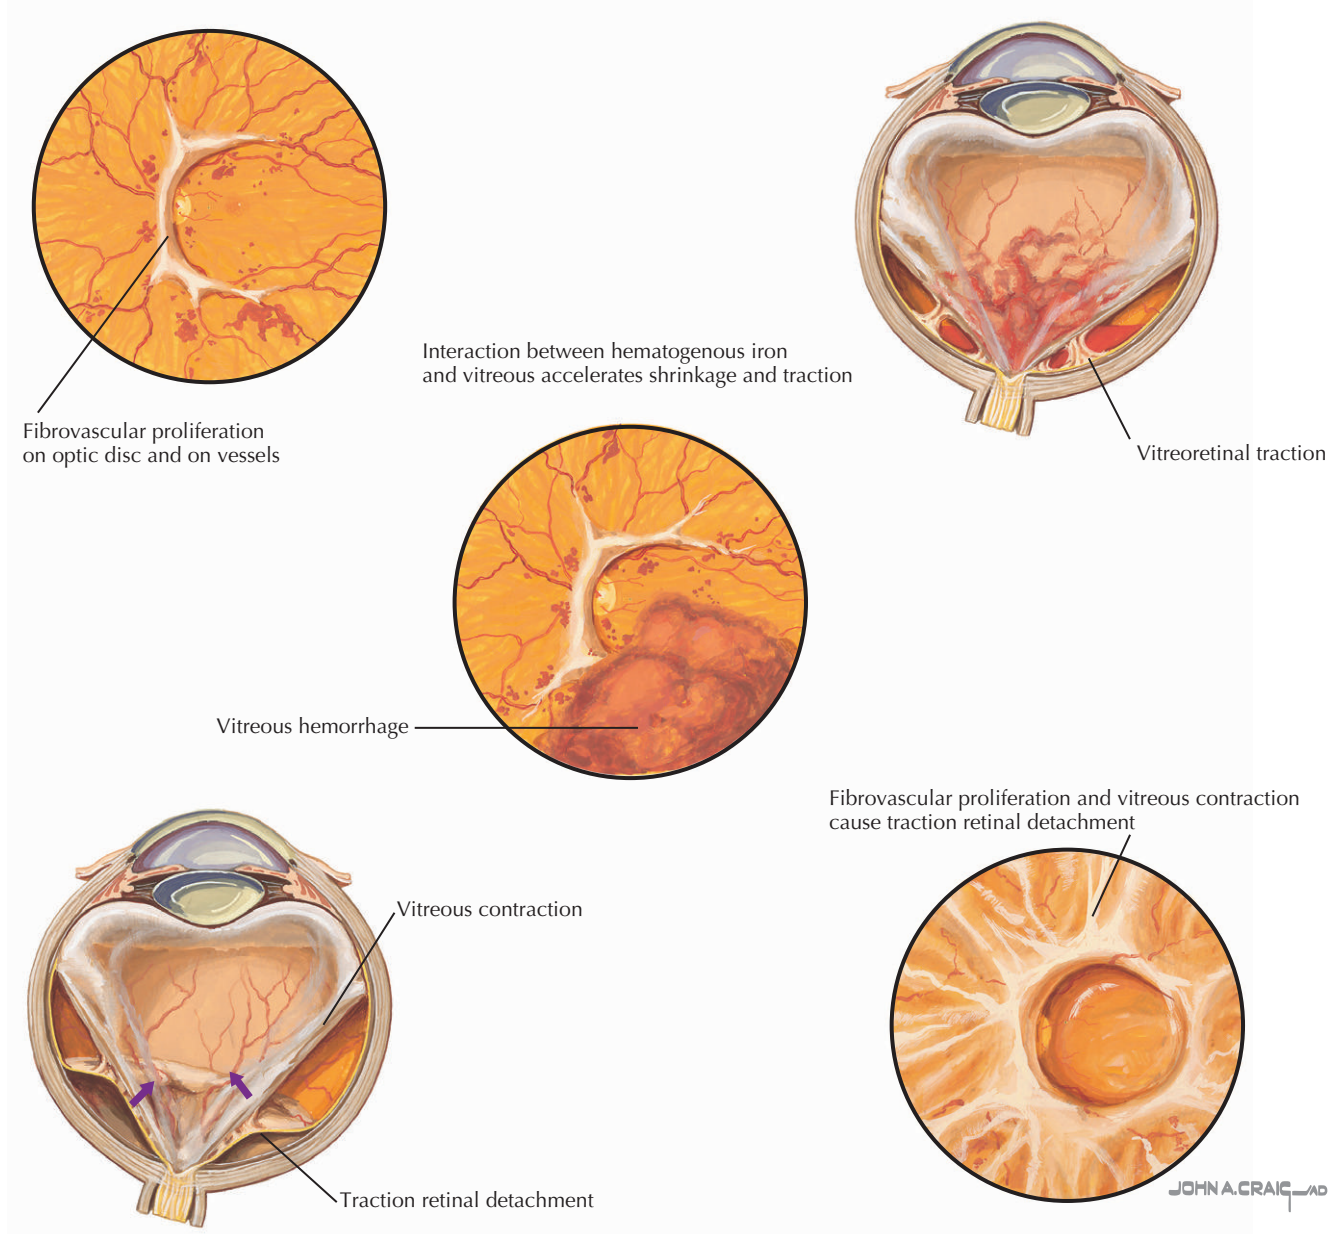

Management and Therapy

Optimum Treatment

Management of diabetic retinopathy encompasses three strategies: (1) systemic control of diabetes and its complications to prevent the occurrence and progression of diabetic retinopathy; (2) regular ocular examinations to detect lesions that become vision threatening; and (3) direct ocular management, including laser photocoagulation, pars plana vitrectomy surgery, and local administration of therapeutic agents through the vitreous cavity or sub-Tenon's space.

The Diabetes Control and Complications Trial (DCCT) and the United Kingdom Prospective Diabetes Study (UKPDS) demonstrated conclusively that intensive glycemic control in patients with type 1 and type 2 diabetes has beneficial effects for preventing vision loss associated with diabetic retinopathy. Patients placed on intensive insulin therapy in the DCCT had a slight initial worsening of retinopathy that reversed after 18 months. Subsequently, patients with intensive glycemic control fared considerably better on every measurement, with a 76% risk reduction on onset of retinopathy, a 63% reduction of progression of retinopathy, and a 56% reduction in need for laser treatment. These benefits persisted 4 years after the period when intensive control was instituted. In a study of type 2 patients, the UKPDS demonstrated a reduction in aggregate microvascular end points with improved glycemic control.

An association between hypertension and diabetic retinopathy has been demonstrated in multiple studies. In the UKPDS, intensive blood pressure control significantly reduced the need for photocoagulation, reduced the risk for diabetic retinopathy progression, and reduced moderate visual loss. Elevated total cholesterol, high-density lipids, and triglycerides have been associated with the faster development of hard exudates in the retina; more extensive hard exudates are correlated with a higher risk for moderate visual loss. Definite improvement of retinopathy by administration of lipid-lowering agents has not

Figure 161-3 Complications of Proliferative Diabetic Retinopathy.

been demonstrated but appears reasonable in view of the positive effects on cardiovascular morbidity.

Regular ocular examinations are important to detect diabetic retinopathy in its early stages and allow early intervention when high-risk characteristics occur. Earlier intervention has a strong correlation with a better prognosis for avoiding moderate visual loss. Numerous studies indicate that only 60% of the American population is being appropriately screened at regular intervals.

Laser photocoagulation performed as an office procedure is the mainstay of treatment of proliferative diabetic retinopathy and diabetic macular edema (Fig. 161-4). Using either a fundus contact lens or indirect ophthalmoscopy, brief laser pulses are emitted and focused onto the

retina. The laser acts by inducing thermal damage (a “burn”) after absorption of the energy by tissue pigments. In the case of argon wavelengths, the light energy is absorbed by hemoglobin pigment and hence acts at the level of small vascular structures. When treating microaneurysms, this burn seals the microaneurysm and decreases the leakage. Most energy from krypton, argon, and diode wavelengths is absorbed by melanin in the retinal pigment epithelium and by choroidal melanocytes.

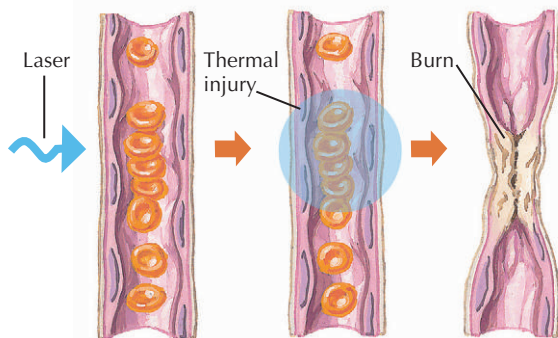

When abnormal blood vessels proliferate on the optic nerve surface or the retinal surface, a panretinal or full scatter photocoagulation is carried out. In this treatment, about 1200 to 1600 laser burns are diffusely placed throughout the peripheral retina avoiding the nerve, the macula,

Figure 161-4 Photocoagulation.

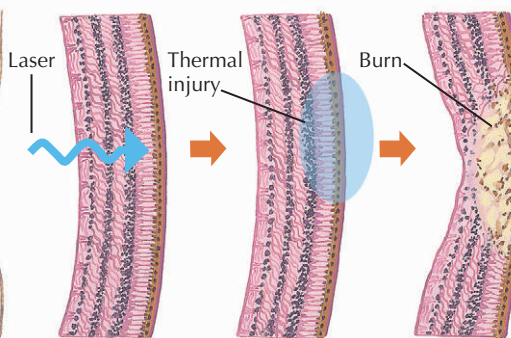

Light energy emission by source (nm)					Light energy absorption		
Wavelength (nm)	Xenon	Argon	Ruby	Krypton	Hemoglobin	Xanthophyll	Melanin
Ultraviolet <400

Vascular photocoagulation

Abnormal or leaking vessels sealed or destroyed by light wavelengths absorbed by hemoglobin (argon, 514 nm, or krypton, 568 nm)

Retinal photocoagulation

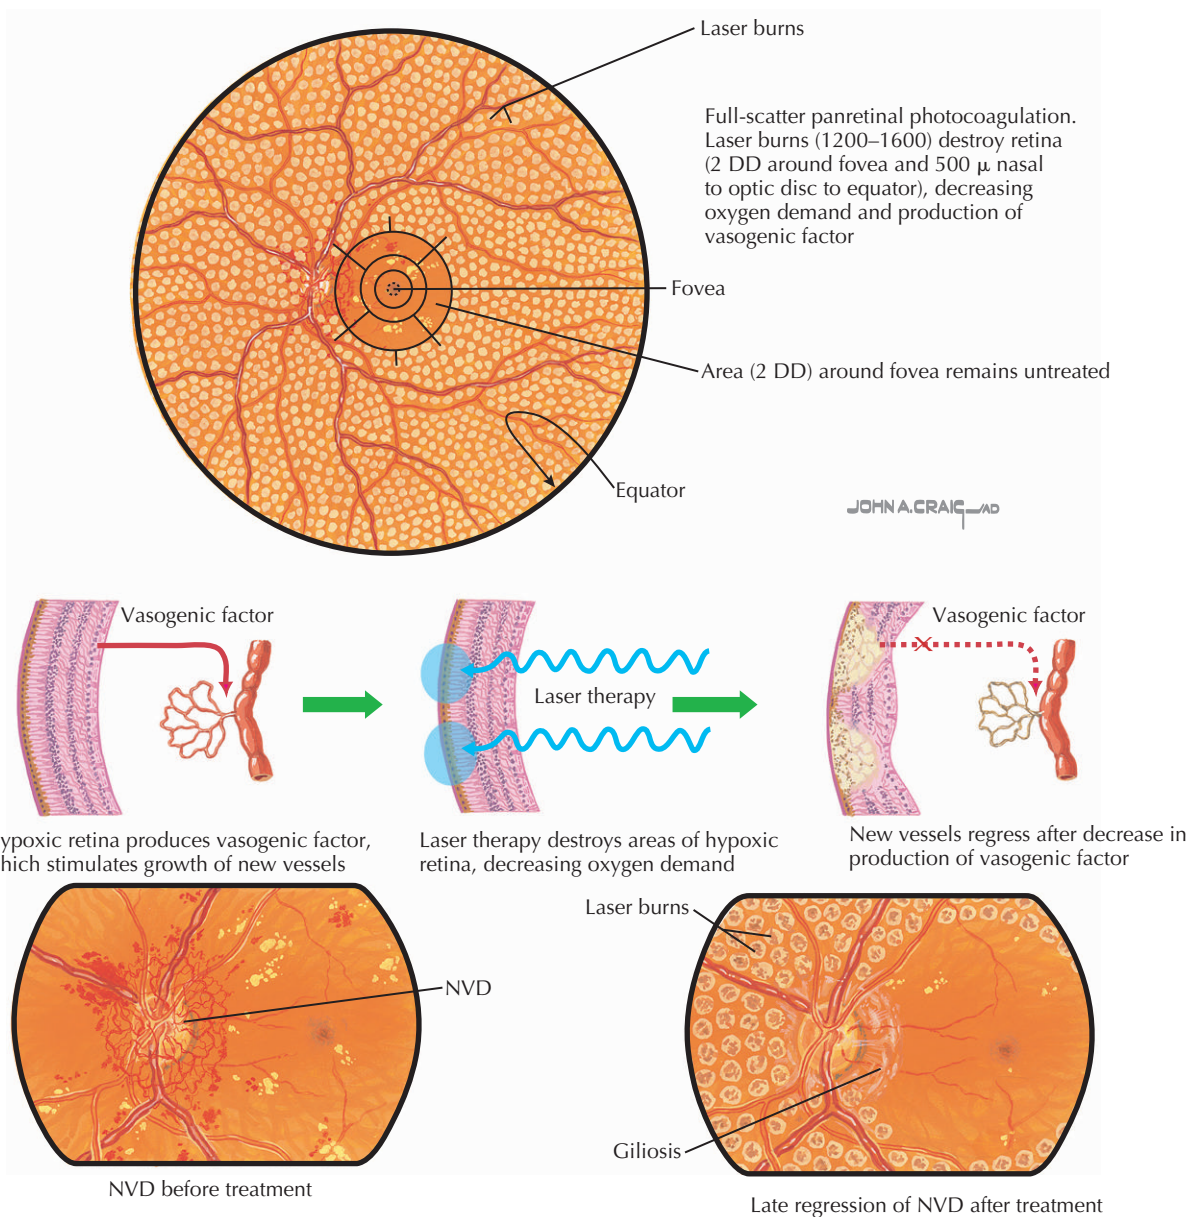

Retinal areas destroyed by light wavelengths absorbed by melanin and retinal xanthophyll (argon, 488 nm and 514 nm)

and large vessels (Fig. 161-5). Burn sizes range from 200 to 500 μm in diameter. It is possible that by ablating a large area of ischemic retinal tissue in this manner, less VEGF is secreted, thereby decreasing the stimulus for neovascularization. The risk for visual loss correlates with the

number of risk factors present. When one or two risk factors are present, the 2-year risk for severe visual loss is reduced from 7% to 3%. When three or four risk factors are present, the risk for severe visual loss is reduced from 26% to 11%.

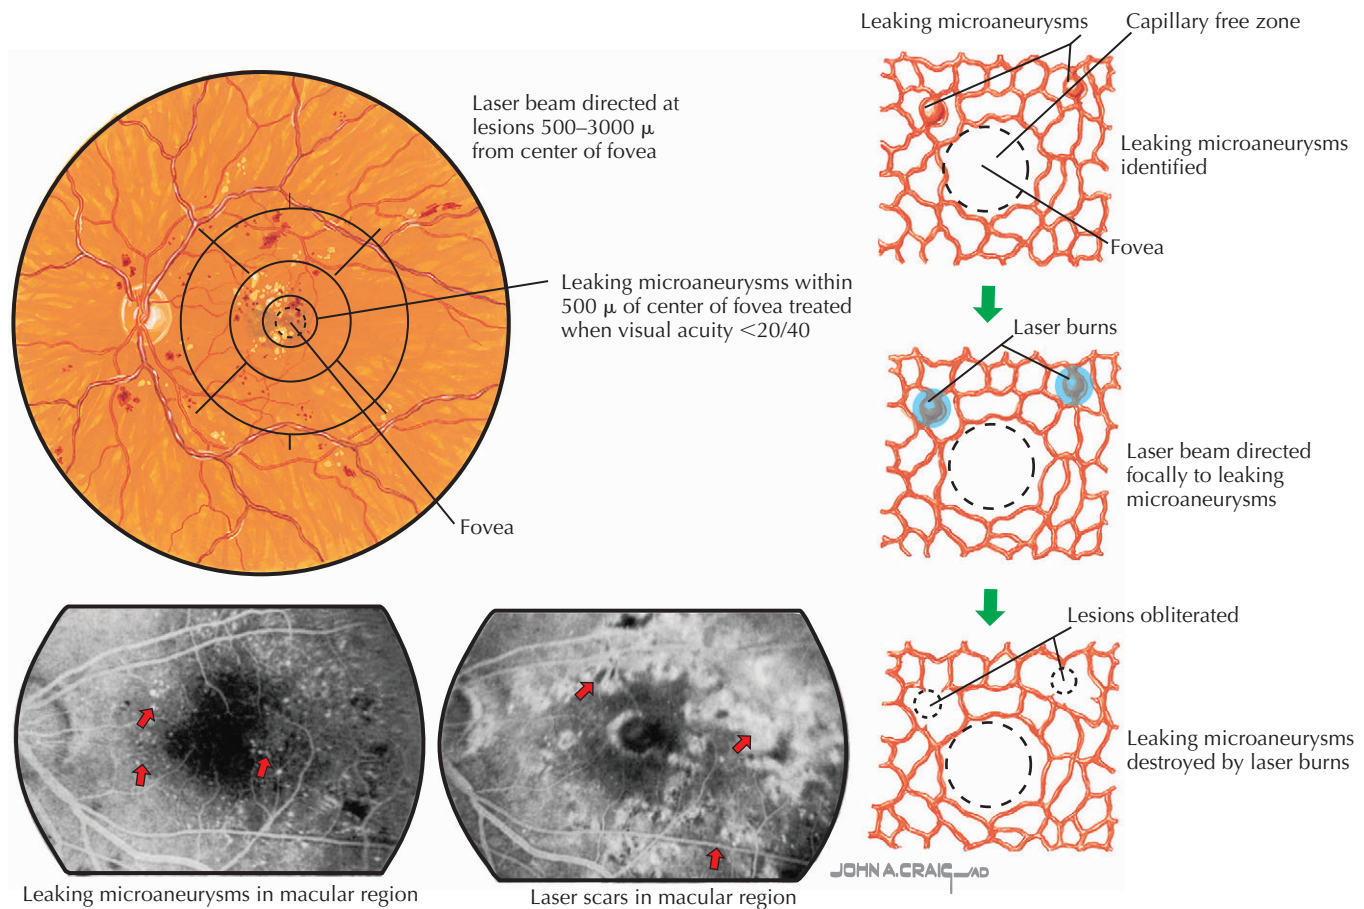

Figure 161-5 Panretinal Photocoagulation.
NVD, neovascularization of disc.

Clinically significant diabetic macular edema has been defined as (1) retinal thickening within 500 μ m of the fovea, (2) hard exudates associated with thickening within 500 μ m of the fovea, or (3) a disc area of edema within one disc diameter of the fovea. The decision for treatment is made on the basis of the thickening noted on ophthalmoscopic examination (see Fig. 161-6). Treatment is then directed at leaking microaneurysms within 500 μ m of the center of the fovea. Laser burn size is generally 50 to 100 μ m. Most physicians now will treat even 20/20 eyes if the position of the aneurysm seems favorable and the risk for treatment can be minimized. Appropriate and timely laser photocoagulation for macular edema can reduce the

risk for severe visual loss by more than 95% and reduce the risk for moderate visual loss from 25% to 12%.

Although laser photocoagulation has dramatically improved visual outcome and decreased the need for vitrectomy in diabetic patients, there remains a subset of patients in whom diabetic retinopathy persists or progresses. The need for further improvement has led to widespread local administration of steroid and anti-VEGF compounds. Ranibizumab and bevacizumab are anti-VEGF agents initially approved for macular degeneration and colorectal cancer, respectively. Reports of rapid resolution of neovascularization have generated increased off-label use of these agents. A small volume (50 μ L) of the

Figure 161-6 Focal Photocoagulation for Macular Edema.

agent is injected directly into the vitreous cavity using a small-gauge needle.

Triamcinolone acetonide has grown in popularity for treatment of diabetic macular edema refractory to laser photocoagulation. This steroid has been injected directly into the vitreous cavity as well as into the sub-Tenon's space, adjacent to the posterior scleral wall. Intravitreal placement of long-acting steroid depots are also currently under investigation. Several multicenter, randomized control clinical trials are underway to assess these agents.

When early treatment of proliferative disease is not carried out or is ineffective, vitreous hemorrhage or traction retinal detachment may develop. Surgical intervention is then indicated with the goals of removing the blood, reattaching the retina, and arresting the proliferative process. Specific instrumentation has been developed that can cut and suck out the blood and vitreous from the internal eye under microscopic control. A variety of scissors, knives, and other instruments have been devised to cut proliferative tissue away from the retina, allowing retinal reattachment. When necessary, intraocular photocoagulation can be performed once the retina is visualized and reattached. Because of the success in controlling the proliferative process, surgical intervention is sometimes

indicated before vision is lost when fibrovascular proliferation is growing in a particularly aggressive fashion.

Avoiding Treatment Errors

The most common treatment error in diabetic retinopathy is delay in diagnosis and treatment. It is therefore imperative that patients at risk for complications from diabetic retinopathy be evaluated at regular intervals by an experienced ophthalmologist. Worsening of macular edema and a decrease in vision can follow either panretinal photocoagulation or focal laser treatment. It is customary to perform macular laser first and then to wait about 1 month before performing panretinal ablation to reduce the likelihood of this risk. Wrong-sided procedures may be avoided by having efficient systems in place to ensure correct-sided laser or vitrectomy surgery. A thorough informed consent process should be undertaken before any procedure.

Future Directions

Future directions in the management of diabetic retinopathy will center on improved early detection, medical management of the systemic condition, development of

medications that may control vascular proliferation and vascular permeability, and improved laser and surgical strategies particularly for macular edema. Efforts are underway to ensure that a higher percentage of diabetic patients are screened so that early disease may be detected and managed properly. These include mandated screening programs by health maintenance organizations and special screening initiatives put forward through a collaboration of Medicare and eye care provider organizations. Telemedicine screening initiatives are being studied in which photographs may be taken through nondilated pupils and referred to expert reading centers where detection of retinopathy can be achieved without an actual dilated examination by a trained ophthalmic examiner.

Improved cooperation between internists and ophthalmologists will undoubtedly lead to better management of diabetic retinopathy. The end-organ effects of hypertension and elevated lipids may be viewed directly in the fundus examination by the ophthalmologist, who can then emphasize to the patient and the treating physician the importance of better control of these parameters. Patients will often value the advice of a second physician who reinforces the diabetic care provider's recommendations regarding the importance of good blood glucose control.

Compounds that block the protein kinase C pathways may reduce the progression of retinopathy to the proliferative stage. Anti-VEGF compounds reduce vascular permeability and continue to be studied in clinical trials. Macular edema remains the main cause of visual loss from diabetic retinopathy, and new strategies are being devised for its management. At this time, direct injection of intraocular steroids, implantation of intraocular steroid devices, sustained-release intraocular steroid devices, and surgery removing the internal hyaloid membrane are investigational approaches to achieve better control and reduction of macular edema.

Personality Disorders

Introduction

Personality refers to each individual's enduring patterns of behavior, mental state, and interaction with others. Although each personality is unique, attempts have been made throughout history to categorize types of personality. Presently the nomenclatures of the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) and the *International Statistical Classification of Diseases and Related Health Problems*, 10th revision (*ICD 10*) use similar categories for personality pathologies that create functional impairment. When evaluating personality, the borders of normality and pathology may blur, so diagnosis relies on clinical judgments about the degree of impairment and associated distress, including distress to others. A recent representative survey of the U.S. civilian, noninstitutionalized population aged 18 years and older found that 15% met criteria for at least one personality disorder. Personality disorders have an untold impact on society given the underdiagnosis and undertreatment of these complex conditions and given that the impact of personality disorders spreads out through families and other social networks.

Etiology and Pathogenesis

All aspects of the human experience can influence the development of personality. Biologic temperaments and vulnerabilities, the intentions of caregivers, and the vagaries of fate—all levels of accumulating personal experience shape the individual personality. In every facet of development, harmful factors (or a lack of beneficial factors) can impede personality development and potentially lead to a personality disorder. Clearly, damaging events such as abuse, neglect, poverty, and war can scar a developing mind, but no personality development can be reduced to a sum of positive and negative experiences. During development, each person is increasingly an agent in his or her own personal growth. Each of the innumerable theories of personality development adds a perspective to this complex ontogeny.

In clinical psychiatry, the diagnosis of a personality disorder is one of the most common comorbidities with almost every other adult diagnosis. A personality disorder, given its usually early roots, could be seen as a risk factor for the development of any subsequent psychiatric disorder during the life of the individual.

Clinical Presentation

The common features of all personality disorders include deviation from cultural norms in the areas of social cogni-

tion, emotional expression, social interaction, and impulsivity. Such deviations must be strong tendencies of the individual, not just occasional events or the products of personality regression at times of great stress. These deviations must also interfere with function. Specific personality disorders are defined by specific criteria relating to these four areas.

Social cognition refers to the person's patterns of perceiving and interpreting the social world, including one's own place in that world. Common abnormal findings related to social cognition include idealizing or devaluing one's self or other people. A person might tend to see all problems as catastrophes, to feel like an outsider in every situation, or to believe all his or her problems are caused by external circumstances. Strong tendencies to misunderstand one's place in the world through such distortions in thinking are characteristic of personality disorders.

Emotional expression varies widely across cultures and families. When a person's emotional expression is maladaptive in its range, intensity, volatility, and mismatch to the situation, a personality disorder is likely. Limitations of range might be exemplified by incapacity to feel anger or empathy or by the tendency to express all emotions through somatic symptoms. Intensity of emotional expression is a problem when one expresses emotion in an exaggerated or theatrical fashion. Emotional volatility or mood lability is manifested by spiraling extremes of anxiety or

rage or by rapid, unpredictable changes in mood. Judgments on whether an emotion is appropriate depend on understanding the patient's perspective, but tendencies such as hostility toward all members of the opposite sex or rage reactions to any criticism would clearly be a mismatch to the situation.

Problems in *social interaction* can range from inhibitions to imbroglis. Tendencies to get into power struggles, to expect and provoke abandonment, or to take advantage of others are all examples of such problems. Excessive neediness, repetitive attractions to unavailable people, or ingratiating submission also suggests a personality disorder. Peculiar tendencies in communication such as vagueness or verbosity might represent another form of impaired social interaction.

Impulse control is frequently weak or inconsistent in a person with a personality disorder. Acting on thoughts of self-hatred by cutting or burning one's self frequently brings personality disordered patients to acute medical attention. Patterns of overcontrol alternating with bursts of ill-advised behaviors such as alcohol or drug binges, sexual promiscuity, or angry outbursts demonstrate poor impulse control.

These four categories encompass most of the traits and behavioral patterns typically disturbed with a personality disorder. As mentioned previously, some tendencies appear to cluster together often enough that we can usefully speak of specific personality disorders. The specific personality disorders are defined by *DSM-IV* or ICD 10 using various criteria. For simplicity, the following descriptions are based on the *DSM-IV*. The *DSM-IV* personality disorders are commonly grouped into three clusters: cluster A (the *odd* cluster), cluster B (the *erratic* cluster), and cluster C (the *anxious* cluster). To repeat, all descriptions are based on prototypes of purity when in reality admixtures are the rule.

Cluster A includes paranoid, schizoid, and schizotypal personality disorders. Those with *paranoid* personality dwell on doubts about others and on suspicions of loyalty or exploitation. Feeling victimized, they bear grudges, counterattack when they perceive insults, and avoid confiding for fear others will take advantage. The person with a *schizoid* personality prefers solitude, lacks close or sexual relationships, and appears cold and indifferent. Lacking social graces, the person seems indifferent to the feelings of others. Those with *schizotypal* personality also have few close relationships and vague suspicions of others, but in addition they strike others as peculiar in manner or appearance. They may hold unusual beliefs that do not reach delusional proportions. Schizotypal personality may represent subsyndromal or prodromal schizophrenia.

Cluster B includes antisocial, narcissistic, histrionic, and borderline personality disorders. The person with *antisocial* personality demonstrates disregard for others through deceit, exploitation, manipulation, and reckless pursuit of immediate pleasures. This person does not honor commit-

ments and threatens harm as a way to influence others. Frequently living on the wrong side of the law, such individuals often manifest little empathy and express no remorse. Furthermore, they tend to blame others for their misdeeds. Those with *narcissistic* personality manifest grandiosity by considering others as an audience to their specialness and by seeking preferential treatment. Lacking empathy, they require excessive attention and recognition while disregarding the emotional desires of others and expressing arrogance. Those with *histrionic* personality also seek to be the center of attention commonly by employing exaggerated emotions, seduction, or other provocative behaviors. Seen as shallow and suggestible by others, they rapidly develop unrealistic expectations in relationships.

Borderline personality subsumes a broad range of patients commonly seen in clinical practice. They may be emotionally labile, frequently threatening or attempting self-harm when inconsolable, thereby engaging others in the regulation of their emotions. They also may engage others through power struggles, expressing hostility and contrarian ways while feeling powerless and mistreated. Fears of abandonment fuel such maladaptive engagements with others and lead to intense entanglements that can also include idealizations of the other party. Such expressions as "the help-rejecting complainer" and "I hate you; don't leave me" capture the type of engagements frequently seen with borderline personality disorder. Often impulsive and reckless, they may lack a stable sense of self or identity, leading to searches for ways to feel belonging and fight empty feelings. Borderline personality is also associated with dissociation and brief psychosis under stress.

Cluster C includes avoidant, dependent, obsessive-compulsive personality disorders. The person with *avoidant* personality expresses a sense of inferiority and shame through inhibited social interactions, avoidance of risk, and preoccupation with humiliation or rejection. Reserved and awkward, this person feels inept and inadequate. Those with *dependent* personality submit themselves to relationships in which another person may make their decisions and even abuse them. Requiring frequent reassurances from others, they avoid disagreements and consent to unpleasant activities for fear of losing the other and subsequently being left to care for themselves. Those with *obsessive-compulsive* personality prefer orderliness, rules, productivity, and standards. Conscientious, stubborn, and perfectionistic, they get bogged down in details and hesitate to delegate. Seen as miserly, they hoard money and objects.

Differential Diagnosis

Personality disorders are not diagnosed when it is judged that the personality features of concern are caused by other psychiatric or medical problems. For example, personality changes can frequently follow psychotic illnesses, head

injuries, or heavy metal poisoning. Likewise, substances of abuse can induce personality changes during intoxication and sometimes during prolonged withdrawal. Mental retardation can globally affect personality function. All such personality pathology attributable to another specific cause is viewed as secondary to that primary problem.

Many patients with a personality disorder prefer to think of their problems as primarily a biologic illness over which they can exert no control. For example, commonly patients with borderline personality will identify with bipolar disorder. Bipolar disorder is a psychiatric illness characterized by *episodes* of mood disturbance and impulsivity followed by interepisode periods of stable euthymia and good impulse control. Rapid-cycling bipolar disorder is defined in *DSM-IV* by four episodes of depression, mania, or hypomania in a 12-month period. Chronic mood swings in the course of the day are far more likely to be symptoms of a personality disorder than rapid-cycling bipolar disorder. Yet commonly such patients pursue aggressive treatment regimens for bipolar disorder despite deriving minimal benefit rather than pursuing treatment plans designed for personality disorders.

Diagnostic Approach

A detailed psychiatric evaluation is required to make the diagnosis of a personality disorder with confidence. The symptoms of personality disorder may be initially too subtle to be detected by a limited contact. Many experienced clinicians can make a presumptive diagnosis based on observations of personality functioning in a clinical situation, but the differential diagnosis should retain all other possibilities until they are reasonably excluded.

Psychological testing can provide additional evidence for a diagnosis based on self-reported tendencies, rated behaviors, or inferences from responses to projective tests. Like any other testing, psychological testing must be interpreted in the clinical context, but it can be invaluable in some cases in which pathology is not obvious.

Management and Therapy

Most personality disorders are untreated or undertreated. Typically others around the patient feel more burden and distress than the patient does, and effective treatment can be reasonably conducted only with patients motivated to make changes for their own reasons. Those patients who engage in treatment should expect to engage in difficult work for extended periods in order to reap realistic change.

Some personality disorders more frequently than others reach the point of intervention and treatment. This is due to unequal prevalences of the disorders, to their relative likelihoods of coming to clinical attention, and to differing prognoses with treatment. Undoubtedly, borderline personality disorder is the most commonly diagnosed and

treated personality disorder. Narcissistic, histrionic, and the cluster C personality disorders also frequently present for treatment usually with other psychiatric comorbidity such as a mood or anxiety disorder. However, cluster A and antisocial personality disorders are more rarely targeted. Antisocial personality disorder in particular does not respond well to any known treatment.

Optimum Treatment

The appropriate treatment of personality disorders relies primarily on psychosocial interventions, although medications can play an adjunctive role in some cases. A range and variety of psychotherapeutic interventions can offer substantial benefit, and matching the patient to the proper therapy involves not only careful assessment of the targeted pathology but also an awareness of the strengths and resources that the patient can bring to bear as a collaborative partner in the process. One generalization about treatment relates to the level of impulse control the patient possesses. More impulsive patients should be in treatment situations that can contain them through predictable and more focused agendas. Those with stronger impulse control can withstand and benefit from more anxiety-provoking treatments such as exploratory psychotherapies.

Although treatment of the personality disorder itself may not always be pursued, such patients are commonly encountered in all clinical arenas, and the treatments required for their more acute conditions can be compromised or disrupted by the patient's personality disorder. Noncompliance, refusal of treatment, inordinate consumption of resources, and clashes with providers can make these patients a challenge in any clinical setting. Management of the personality disorder becomes an essential part of a comprehensive treatment plan for whatever other problems are being addressed more directly. The basis of such management relies on avoiding common errors.

Avoiding Treatment Errors

Patients with personality disorders typically evoke strong feelings from others, ranging from annoyance, dread, and hatred to unusual attraction. When faced with strong emotions, care providers understandably make missteps in the management of these patients (Fig. 162-1). These patients draw others into interactions that can be detrimental to both parties.

The general principles of managing patients with personality disorders include recognition of heightened emotion and tension in the relationship along with impartial assessment of what is best recommended for the acute condition being treated. In other words, the maintenance of objectivity in the face of an emotional challenge is the goal (Fig. 162-2). That means withstanding temptations to avoid, to rescue, to control, to punish, or to react to provocation with retaliation. Robotic detachment is not in order,

Figure 162-1 Patients with Personality Disorders Provoke Strong Feelings That Physicians Must Manage Internally.

but management of patients with personality disorders often requires bearing strong emotions internally while keeping the focus on the needs (not the desires or demands) of the patient.

Clinicians (and others) frequently conceptualize such patients as willfully oppositional, morally weak, or less worthy of care. It is vital to understand that personality develops to adapt to the environment. Patients with a personality disorder have adapted to early situations (or at least perceived situations) that called for their currently

maladaptive tendencies. Recognizing that the behaviors have meaning related to other contexts can allow the clinician to avoid taking those behaviors personally. Patients are usually doing their best based on what they have learned in life.

In the rapidly moving clinical world where doctors often terminate clinical interactions with prescriptions, it is tempting to hope that psychopharmacology will provide a buffer from the patient who is too demanding, irrational, or emotionally charged. Some medications show limited

Figure 162-2 Physicians Must not Disregard the Medical Needs of Patients with Personality Disorders.

efficacy (such as selective serotonin reuptake inhibitors in borderline personality), but expectations should be tempered. Benzodiazepines in particular are generally contraindicated in patients with impulsivity or hostility.

Given the sensitivities of these patients or the hopelessness sometimes felt by the clinician, personality problems are not easily brought into discussion in most clinical settings. Most clinicians offer treatment or referral when the patient requests help, but patients with a personality disorder infrequently ask directly for help. When they do, they often expect a medication or some other “magical” relief. Referrals for psychotherapeutic interventions can be delicate, but most patients can handle the recommendation of “talking to someone.” Thus, the referral to mental health providers should not be avoided.

Future Directions

Research into personality disorders and effective treatments has lagged behind in the era of biologic research in psychiatry. There is growing interest in outcomes research

for therapies that can address the challenges in treating personality disorders.

With contributions from dozens of authors, this comprehensive text covers each personality disorder in detail, including etiology, clinical evaluation, treatment, and research.

Anxiety and Panic

Introduction

Most patients with psychiatric symptoms are seen in the general medical setting exclusively. This is particularly true for patients with anxiety disorders, in whom somatic symptoms often predominate. Although detection of these disorders remains poor, the direct and indirect costs of untreated anxiety are enormous, and effective evidence-based treatments are available.

Anxiety is tension or apprehension that is disproportional to the actual stimulus (Fig. 163-1). There are five principal anxiety disorders in adults: panic disorder (PD) with or without agoraphobia, social phobia (SP), obsessive-compulsive disorder (OCD), generalized anxiety disorder (GAD), and post-traumatic stress disorder (PTSD). Simple phobias (e.g., specific fear of storms or heights) are common also but rarely present in the primary care setting. In the general medical setting, PD is the most prevalent of the principal disorders. The lifetime prevalence is nearly 5%, with a twofold increased risk for women, and onset in the 20s is most frequent. Often, PD has a complicated medical presentation and a significant burden of comorbidities. The remaining principal disorders will not be covered in detail here. OCD (see Chapter 167) usually requires early psychiatric referral. GAD, SP, and PTSD require multimodal therapies and are often too time intensive to be exclusively managed in the general medical setting. Table 163-1 summarizes these disorders.

Etiology and Pathogenesis

As with most psychiatric disorders, it is likely that psychological and environmental triggers unmask a biologic predisposition to PD.

Neurobiologic

There is an explosion of research in this area, including the study of the fear and anxiety centers in the brain, such as the amygdala, locus ceruleus, and hippocampus. Preliminary neuroimaging studies highlight deficits in these neuroanatomic areas. Provocative agents, including sodium lactate, carbon dioxide, caffeine, yohimbine, m-chlorophenylpiperazine, fenfluramine, and cholecystokinin, can induce panic states in patients with PD. Supporting neurochemical hypotheses is the fact that similar states cannot be induced in normal control subjects. No specific etiologic determinants have emerged in this likely heterogeneous disorder. Family studies also suggest that PD is familial, with increased risk for first-degree relatives of those with the disorder.

Cognitive-Behavioral

Progressive fear of recurrent attacks is a large part of PD and is even more important when agoraphobia (avoidance of activities secondary to fear of having an attack) occurs. Many believe that this conditioning leads to catastrophic misinterpretation of bodily sensations starting a cycle of escalating anxiety.

Clinical Presentation

Given the primacy of their somatic symptoms, most patients with PD (85%) make their initial contact in the medical setting, most often in the emergency department, followed by visits to their primary care physician. Onset of PD usually occurs in the third or fourth decade. The criteria for a panic attack (Box 163-1) should be differentiated from PD (Box 163-2) because panic attacks can occur in the context of multiple illnesses and do not necessarily represent PD.

The hallmark difficulty in recognizing PD is that patients usually do not complain of anxiety, but instead present with as many as 10 to 15 somatic symptoms, several

Figure 163-1 Panic Disorder.

Somatic symptoms, such as chest pain or difficulty breathing, are the hallmark of panic attacks. Patients often do not recognize that they are anxious, and have a very real sense of impending doom. It is easy to understand why they seek emergency care.

**Table 163-1** Other Common Anxiety Disorders

	Social Phobia	Generalized Anxiety Disorder	Post-traumatic Stress Disorder
Defining features	Excessive fear of public scrutiny in single or multiple situations; may have panic attacks	Unrealistic or excessive worry about common life circumstances; chronic autonomic hyperarousal	Occurs after threat to life or body, followed by intrusive memories, avoidance, and hyperarousal
Lifetime prevalence	5%-13%	5% (2 : 1 female)	1%-14% (varies with specific trauma)
Common comorbidities	Depression, substance abuse	Depression, substance abuse, panic disorder	Substance abuse, depression, somatoform disorders
Treatment	*SSRI, benzodiazepines, venlafaxine, CBT	*SSRI, benzodiazepines, venlafaxine	*SSRI, antiadrenergic agents (clonidine, propranolol)
Referral threshold	Low: therapy enhances medications	Depends on symptom severity and number of comorbidities	Low: patients are usually time intensive

*See Table 163-2 for SSRI and benzodiazepine dosing.
CBT, cognitive behavioral therapy; SSRI, selective serotonin reuptake inhibitor.

of them quite dramatic. The most common cluster of symptoms is cardiac, including chest pain and tachycardia. Gastrointestinal and pulmonary symptoms are also common, and nearly half of PD patients report neurologic symptoms (headache and dizziness are the most frequent). PD may also be complicated by agoraphobia (Box 163-3).

Differential Diagnosis

Psychiatric

Major depression and bipolar disorder often present with predominant anxiety symptoms and should always be considered as a primary diagnosis in the differential diagnosis of the anxious patient. Depression also develops later in

Box 163-1 Panic Attack Diagnostic Criteria

A discrete period of intense fear or discomfort, in which four (or more) of the following symptoms develop abruptly and reach a peak within 10 minutes:

1. Palpitations, pounding heart, or accelerated heart rate
2. Sweating
3. Trembling or shaking
4. Sensations of shortness of breath or smothering
5. Feeling of choking
6. Chest pain or discomfort
7. Nausea or abdominal pain
8. Feeling dizzy, unsteady, lightheaded, or faint
9. Paresthesias (numbness or tingling sensations)
10. Chills or hot flushes
11. Derealization (feelings of unreality) or depersonalization (being detached from oneself)
12. Fear of losing control or going crazy
13. Fear of dying

Adapted from American Psychiatric Association: Diagnostic and Statistical Manual of Mental Disorders, 4th ed, text rev. Washington, DC, American Psychiatric Association, 2000.

Box 163-2 Panic Disorder Diagnostic Criteria

1. Both (A) and (B):
 - A. Recurrent unexpected panic attacks
 - B. At least one of the attacks has been followed by 1 month (or more) of one (or more) of the following:
 - Persistent concern about having additional attacks
 - Worry about the implications of the attack or its consequences (e.g., losing control, having a heart attack, going crazy)
 - A significant change in behavior related to the attacks
2. The panic attacks are not due to the direct physiologic effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hyperthyroidism).
3. The panic attacks are not better accounted for by another mental disorder, such as social phobia, specific phobia, obsessive-compulsive disorder, or post-traumatic stress disorder.

life in one third to one half of patients with PD. Many drugs of abuse, including cocaine, marijuana, amphetamines, and caffeine, may also induce panic states independent of PD.

Medical

PD and anxiety symptoms coexist with one third or more of several common conditions, including atypical chest pain, Parkinson's disease, irritable bowel syndrome, and chronic obstructive pulmonary disease (Box 163-4). The diagnosis of PD should not be conceptualized as mutually exclusive from "medical" illness. Current medications, including sympathomimetic medications such as cold and allergy preparations, should also be investigated as causes

Box 163-3 Agoraphobia Diagnostic Criteria

1. Anxiety about being in places or situations from which escape might be difficult (or embarrassing) or in which help may not be available in the event of having an unexpected or situationally predisposed panic attack or panic-like symptoms. Agoraphobic fears typically involve characteristic clusters of situations that include being outside the home alone, being in a crowd or standing in a line, being on a bridge, or traveling in a bus, train, or automobile.
2. The situations are avoided (e.g., travel is restricted) or else are endured with marked distress or with anxiety about having a panic attack or panic-like symptoms, or require the presence of a companion.

 Angina
 Arrhythmias
 Asthma
 Congestive heart failure
 Electrolyte disturbance
 Hyperthyroidism
 Hypoxia
 Hypoglycemia
 Myocardial infarction
 Parathyroid disorder
 Pulmonary embolism
 Seizures
 Transient ischemic attacks
 Vertigo

of anxiety symptoms. Alcohol and other sedative withdrawal can also cause anxiety symptoms.

Diagnostic Approach

A high index of suspicion for PD and related disorders should be maintained for patients who are young, have multiple somatic complaints, and visit the doctor frequently. A search for PD, as well as comorbid depression and substance abuse, should be a priority. (PD sufferers are more than 4 times as likely to abuse alcohol.) If a primary anxiety disorder seems likely, defer extensive system-specific workups (e.g., endoscopy, cardiac catheterization). A thorough medical, psychiatric, family, and social history will usually lead to the correct diagnosis.

The medical workup includes physical examination, with a thorough neurologic examination; medication history (include over-the-counter medications); electrocardiogram (if older than 40 years, having current chest

Table 163-2 Medications for Panic Disorder

Class	Agent	Starting Dose	Maintenance
SSRI	Citalopram [†]	10 mg/day	20-40 mg/day
	Escitalopram [†]	5-10 mg/day	10-20 mg/day
	Fluoxetine*	5-10 mg/day	20-80 mg/day
	Fluvoxamine	25 mg/day	50-300 mg/day
	Paroxetine	10 mg/day	20-60 mg/day
	Sertraline [†]	25 mg/day	50-200 mg/day
SNRI	Venlafaxine XR	37.5mg/day	75-300mg/day
Benzodiazepines	Alprazolam	0.25-0.5 mg tid	2-6 mg/day total
	Clonazepam	0.5 mg bid to tid	1-4 mg/day total
	Lorazepam [†]	0.5-1.0 mg bid to tid	2-10 mg/day total

*Fluoxetine has a long half-life and may not be the best choice for a patient with known sensitivity to drug side effects.

[†]These medications are used to treat panic disorder, but do not have that specific U.S. Food and Drug Administration indication. SNRI, serotonin norepinephrine reuptake inhibitor; SSRI, selective serotonin reuptake inhibitor.

pain, or with a significant family history of heart disease); and selected laboratory tests, including complete blood count, chemistry panel, and thyroid-stimulating hormone. If the patient is older than 40 years, nonpsychiatric medical diagnoses should be suspected and excluded.

Management and Treatment

Significant evidence has emerged to guide the treatment of anxiety disorders, specifically PD. The greatest challenge remains in detecting these disorders and in prescribing adequate treatment (Table 163-2). Most importantly, clinicians must routinely consider the possibility of a PD diagnosis. Once detected, the goals of treatment include reduction of the frequency and intensity of symptoms and management of the anticipatory anxiety associated with panic attacks.

Optimum Treatment

Both medications and behavioral therapy have proved equally efficacious in psychiatric populations. Pharmacotherapy in PD has been well studied, with similar monotherapeutic efficacy among the tricyclic antidepressants, monoamine oxidase inhibitors, high-potency benzodiazepines, a serotonin norepinephrine reuptake inhibitor (venlafaxine XR), and selective serotonin reuptake inhibitors (SSRIs). However, side effects, potential drug interactions, dietary restrictions, and risk for dependence have limited the utility of the first three classes. SSRIs have supplanted these older agents for first-line therapy due to a more favorable side-effect profile, whereas venlafaxine is routinely considered a second-line agent. The 3- to 4-week latency in response to pharmacologic treatment of depression may be shorter for PD (2 to 3 weeks), but PD patients generally have greater sensitivity to side effects.

Benzodiazepines, which have a rapid onset of action (several days), are best used adjunctively in the acutely ill patient to bridge delayed response to SSRIs or venlafaxine. Alprazolam, clonazepam, and lorazepam have the most data supporting their use. Adequate standing doses of benzodiazepines should be prescribed, as opposed to as-needed doses.

Use of medication in the treatment of anxiety disorders should begin at the lowest possible dose and should be titrated slowly but assertively to the maximum dose necessary for symptom improvement, which is often higher than that required for depression (start low, go slow, but go . . . and go). Adequate duration of this dose is 6 weeks before determining medication failure.

Cognitive behavioral therapy (CBT; e.g., psychoeducation, symptom monitoring, breathing training, cognitive restructuring focusing on correction of catastrophic misinterpretations of bodily sensations, and exposure) designed to address panic symptoms has proven efficacy but requires trained therapists and committed patients. This may be an important referral point for patients desiring a nonpharmacologic intervention. Patients should be informed that studies show that the best success is seen with the combination of medications and CBT.

Response rates vary, but controlled trials suggest that 50% to 60% patients become panic free during most proven treatments, with improved outcomes as treatment is extended. Venlafaxine has been shown to reduce severity of panic and agoraphobic symptoms, but was no better than placebo in achieving a panic-free state. PD is a chronic illness usually requiring maintenance therapy and often characterized by residual symptoms. Optimal length of treatment has not been fully elucidated, and relapse is common, particularly without maintenance therapy. Agoraphobia and other psychiatric comorbidities are thought to be predictors of poorer outcomes. PD, particularly in

association with depression and substance abuse, also places the patient at increased risk for suicide.

Optimal management of PD includes assessing for suicide risk, evaluating and acknowledging the degree of functional impairment, establishing and maintaining a therapeutic alliance, providing patient and family education, communicating with other physicians (which plays a large role in preventing unnecessary diagnostic tests), and helping the patient learn how to address early signs of relapse. Patients should be encouraged to limit consumption of caffeine and sympathomimetic drugs and to abstain from use of illicit substances.

Recent studies suggest that a model of collaborative care based in the primary care setting is a more effective and cost-efficient way to treat PD. The model includes algorithm-based medication management by the primary care physician (with guidance available from a psychiatrist) supplemented by six sessions of CBT and telephone follow-up provided by a midlevel behavioral health specialist.

Consider referral to a psychiatrist for diagnostic clarification (consultation); for suicidal patients; after two trials of first-line treatment have failed; for treatment of agoraphobia; when psychotherapy is indicated (e.g., significant life stressors, limited support systems); when patients have psychiatric comorbidity that is unstable (e.g., unremitting depressive symptoms, active substance abuse); or when optimal management exceeds the time constraints of the primary care setting.

Avoiding Treatment Errors

The primary treatment errors encountered with panic disorder are under-recognition and undertreatment. Pharmacologic treatment should be both long enough (6 weeks) and at a high enough dose (up to maximum) before a therapeutic trial is considered a failure. Educating the patient that they may experience a weeks-long delay in symptom response to treatment is important. Furthermore, evidence suggests that a combination of pharmacologic and psychotherapeutic interventions is more successful than either treatment modality alone, so making a referral to a therapist can be an important adjunct to drug therapy. Physicians should also be cautious in the long-term use of benzodiazepines, especially given the risk for dependency.

Future Directions

The complexity and challenge presented by anxious patients must be embraced and integrated into primary

care. Researchers should continue their search for new therapeutic agents, especially given that 40% to 50% of patients may not respond to current therapies. More research on collaborative care and self-help models of care (including Internet-based resources) is being pursued. Neuroimaging technologies are quickly evolving to help answer some of these questions, and psychotherapeutic principles are being equally explored. Efficient and feasible methods to detect these common disorders must also be further investigated. Interdisciplinary communication and multimodal interventions will continue to be crucial in the successful management of the anxious patient.

Depression

Introduction

The word *depression* signifies a common and nonpathologic emotional experience. It also signifies a specific biopsychological disorder. The two are not the same. Depression, the illness, is a coherent syndrome with a constellation of specific signs, symptoms, and features. A lifelong recurrent disorder, it occurs in 10% to 20% of the population worldwide. It interferes with work and family life and has a mortality rate of 15%.

Etiology and Pathogenesis

Depression results from disturbances in monoamine neurotransmission. It may be maintained by secondary neurohormonal changes involving the hypothalamic-pituitary-thyroid and hypothalamic-thyroid axes. These combined changes ultimately result in altered nucleic acid transcription. The strongest etiologic factor is inheritance. Risk for depression can also be acquired through early life trauma, which may “wire-in” exaggerated neurohormonal stress responses. Other medical illnesses or interventions may cause a secondary depressive syndrome, most notably hypothyroidism, and medications such as antihypertensive agents that affect central monoamine neurotransmission. A variety of substances may also induce secondary depression during intoxication or withdrawal, most notably alcohol, cocaine, and stimulants.

Clinical Presentation

Although clinically evident depression presents in the third or fourth decade typically, the initial onset of depression can occur at any point in the life cycle, including early childhood. The presentation varies from individual to individual and across the life cycle, but the core features are always present during an episode (Figs. 164-1 and 164-2). As codified in the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*), these include depressed mood, or anhedonia (required); increased or decreased appetite; increased or decreased sleeping; slowed activity; fatigue; exaggerated self-criticalness, worthlessness, or guilt; decreased libido; mental slowing, decreased memory, or inattention; and recurrent thoughts of death or suicide.

DSM-IV requires five signs or symptoms concurrently for at least 2 weeks for an unequivocal diagnosis, but most clinicians recognize that patients can qualify for the diagnosis with as few as three or four symptoms. Depressed mood is not always the most prominent symptom and may even be absent. Often the presenting symptom is insomnia, nervousness, somatic pain, or memory change. Depression is often accompanied by anxiety and may be complicated by striking symptoms of psychosis such as auditory hallucinations and delusions of impoverishment or guilt. Depressive episodes may occur with or without evident stressors, and reported stressors often are actually the result of incipient depression rather than the cause.

Differential Diagnosis

Adjustment Disorder

In adjustment disorder, depressed mood follows clear-cut stressors, but the full depressive syndrome is not present or is transient (<2 weeks). Adjustment disorder does not respond to antidepressant medication.

Bipolar Disorder, Depressed Phase

About 20% of individuals who present with depression actually have unrecognized bipolar mood disorder. The recognized forms of bipolar disorder, bipolar I and bipolar II, differ primarily in the severity of the manic phase. Bipolar I requires the occurrence of full-blown mania at some point in the life cycle. Bipolar II requires only the occurrence of hypomania. Because hypomania is often transient and nondysfunctional, it can be easily overlooked.

Figure 164-1 The Face of Depression.

Because the depressed phase of bipolar disorder is usually indistinguishable from simple depressive disorder (unipolar), bipolar II disorder can easily masquerade as unipolar depression. This distinction is important because bipolar disorder requires a different treatment approach, emphasizing mood stabilizers over antidepressants.

Substance-Induced Depression

Depression can be a direct result of substance use, but it can also exist as an independent comorbid condition complicating substance abuse. Depression that is purely secondary to a substance clears within several days to a week of substance discontinuation. If depression does not resolve within this time frame, it requires treatment in its own right. Comorbid substance use disorder affects the occurrence, course, and treatment of depression. Depression is frequently comorbid with alcohol, cocaine, and opiate addiction. With alcoholism comes an increased risk for suicide, and all individuals who present with depression and alcoholism should have a suicide assessment. Alcohol dependence increases the odds that one would have a major

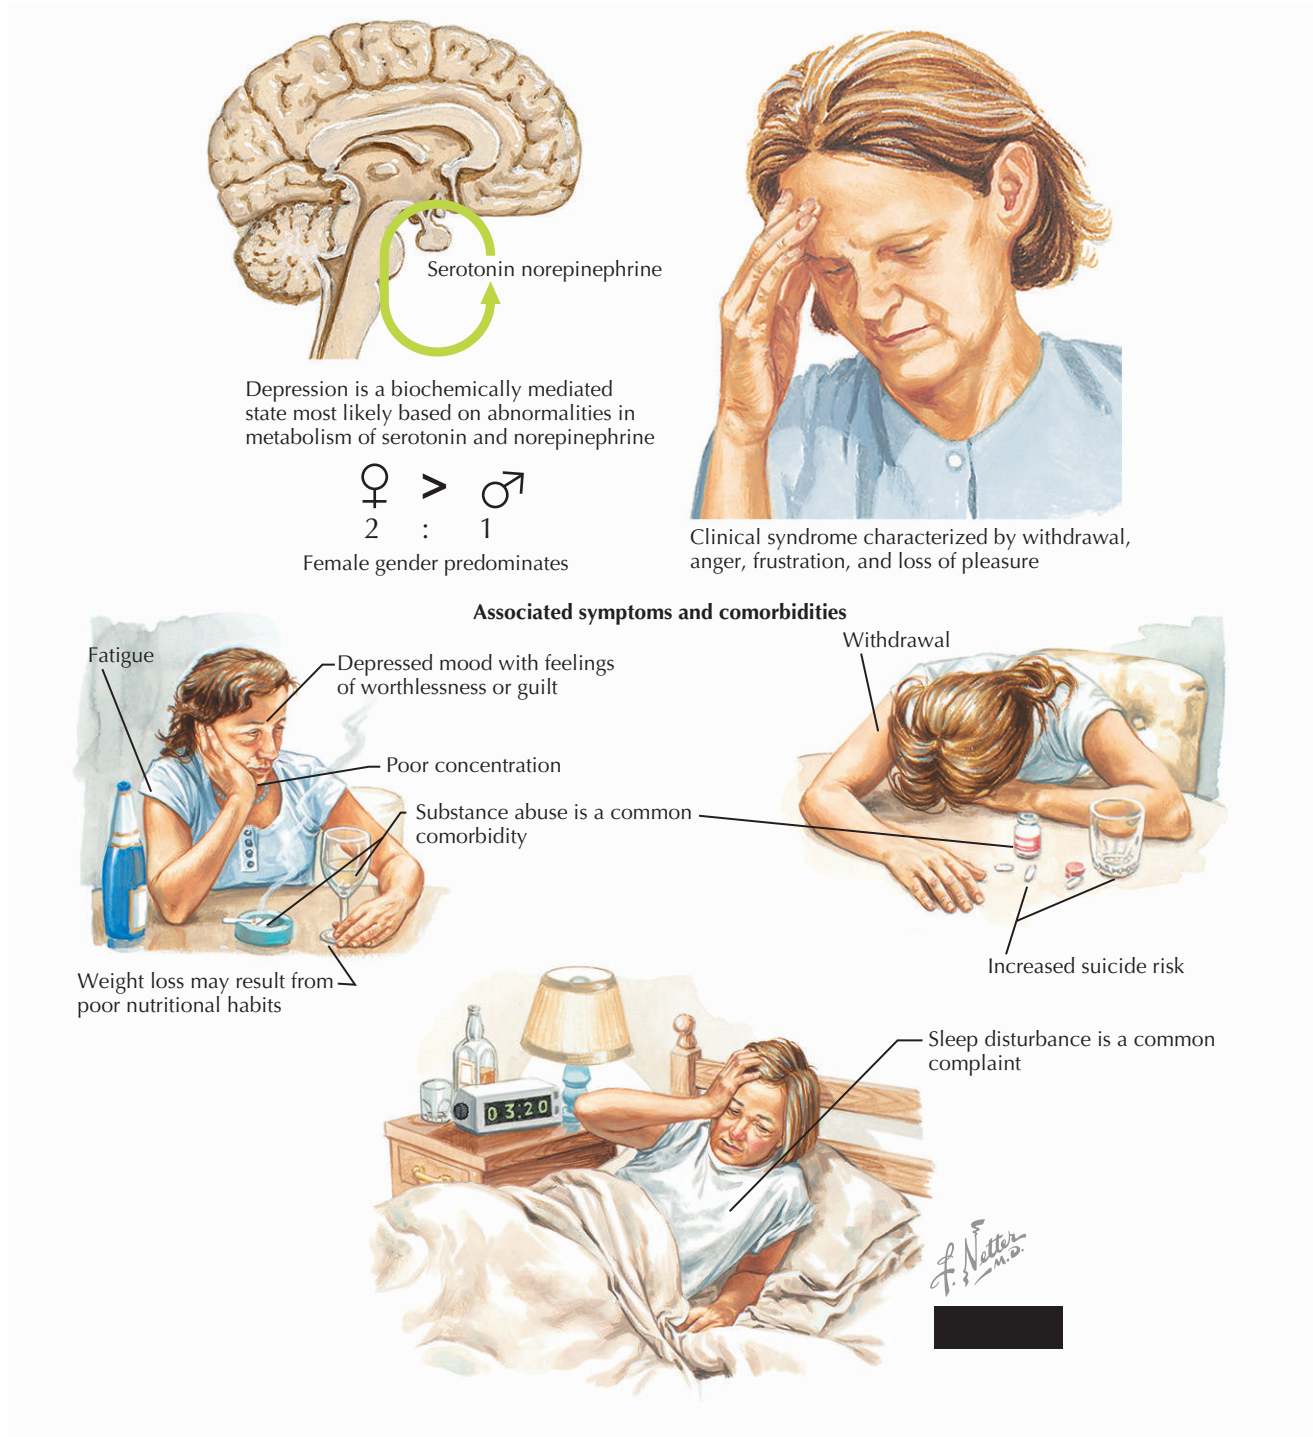

depression, and conversely, major depression increases the lifetime odds of having alcohol dependence. Treatment of depression that is comorbid with cocaine dependence requires both an antidepressant as well as a therapy that focuses on the addiction. Treatment of opiate dependence typically results in improvement in the comorbid depression. However, similar to antidepressant treatment of a depression that is comorbid with other drug addictions, treatment of depression in the setting of untreated opiate dependence yields mixed results.

Depression Secondary to Medical Illness

Depression secondary to a medical condition should be considered whenever depressive mood changes accompany a medical condition known to be associated with depression. A partial list includes hypothyroidism, Addison's or Cushing's disease, pancreatic cancer, AIDS, tuberculosis, multiple sclerosis, stroke, Alzheimer's disease, Parkinson's disease, and diabetes mellitus. Sometimes depression may be the first manifestation of undetected systemic illness, and for this reason, medical history and reasonable medical assessment should be part of the standard evaluation of all new cases of depression. Depression may also be induced by a variety of commonly used medications, including glucocorticoids and interferon. Evidence fails to support the belief that β -blockers commonly induce depression.

Diagnostic Approach

Consider depression not just in patients who present with depressed mood, but also in those who primarily complain of insomnia, anxiety, decreased energy, chronic pain, or cognitive changes. The diagnosis is established purely on the basis of history and observation of symptoms and signs consistent with the diagnostic criteria. Excellent self-administered screening tools such as the Zung, Beck, or PHQ-9 depression inventories are available. Information from family members or close associates is invaluable in substantiating the diagnosis when the onset of symptoms has been insidious. Diagnostic evaluation must include enumeration of the frequency and timing of prior episodes, and an exploration for past episodes of elevated mood. This information is necessary for later treatment planning, including decisions about the duration of treatment. Every evaluation must include queries about suicide risk. The simplest way to begin this inquiry is to ask, "Have you had thoughts of death or of harming yourself in any way?" Thoughts of dying or committing suicide are extremely common in depression. Most frequently, they remain at the thought level and can be managed on an outpatient basis. However, in a significant minority of patients, thoughts are accompanied by intent or specific suicidal plans, which require rapid psychiatric consultation or hospitalization. History of a suicide attempt and the presence of psychosis, substance use, or significant isolation raise the risk for suicide.

Figure 164-2 Depression (Unipolar).

Management and Therapy

The most important principle for the management of depression is to view it as a lifelong disorder that recurs at a rate of at least 50% following a single episode. The recurrence rate climbs with each subsequent episode, as does the rate of chronic residual symptoms between major episodes. Treatment planning must take into account patient education and duration of treatment. The second

most important principle is that, although all antidepressant agents have similar efficacy rates, there is significant variability in terms of response and tolerance among patients. Many patients try more than one antidepressant before finding one that works for them.

Initial medication treatment usually starts with a member of the serotonin-specific reuptake inhibitor (SSRI) class of antidepressants, which includes fluoxetine, sertraline, paroxetine, citalopram, and escitalopram. If there is a personal

or family history of preferential response to a particular antidepressant of any class, then this should be the first choice. A generic member of the older tricyclic class of antidepressants is an equally good choice if cost is an issue. Sixty to 70% of patients have at least partial response to the initial choice. Evidence-based algorithms exist to guide treatment when it is necessary to move beyond this step (see Texas Medication Algorithm Project website). The usual sequence is to (1) increase the dose every 1 to 2 weeks as tolerated; (2) add either lithium or tri-iodothyronine (25 to 50 mcg) as an augmenting agent; (3) switch to a different member of the same class or switch to a member of a different class (bupropion, venlafaxine, duloxetine, mirtazapine, tricyclic, monoamine oxidase inhibitor); (4) combine antidepressants (SSRI + bupropion or tricyclic; venlafaxine + mirtazapine); and (5) consider electroconvulsive therapy, which has the highest response rate of all somatic treatments for depression. Recently approved vagal nerve stimulation, which uses an implantable device to deliver deep brain stimulation through the vagus nerve, may induce remission in up to 30% of individuals who are completely refractory to all other forms of treatment.

Psychotherapy is equally as effective as medication in mild to moderate depression, but not in severe depression. Psychotherapies specifically designed for depression, cognitive behavioral therapy, and interpersonal psychotherapy in particular have been shown to have the highest effectiveness. A combination of psychotherapy plus medication provides the best coverage.

Optimum Treatment

Optimum treatment of depression requires a systematic approach using routine screening, algorithm-guided medication management targeting full symptom remission, and adequate duration of treatment.

Routine and universal screening for depression, followed by prompt psychoeducation and medication management, has been shown to be feasible and effective in decreasing morbidity in general medical settings and is a necessary starting point for successful management. Any of the brief self-administered tools mentioned earlier will work.

The goal of antidepressant therapy needs to be full remission rather than partial symptom reduction. With time and effort, this is feasible in at least 70% of depressed individuals. However, only 25% achieve full remission after the initial medication trial and 50% after the first two interventions. Therefore, reaching this end point requires routine monitoring of all symptoms at each evaluation (ideally using one of the symptom rating scales mentioned previously) and a systematic approach to advancing treatment if benchmarked improvement does not occur within a specified interval. The Texas Medication Algorithm Project provides an excellent detailed example of this process.

Optimally, antidepressant treatment should continue at least 6 to 12 months after a single episode to prevent

relapse. Evidence shows that indefinite maintenance treatment with antidepressants, psychotherapy, or both is safe and significantly decreases the future relapse rate. It should be strongly considered in individuals with more than one episode of depression or in those who experience chronic interepisode depressive symptoms.

Avoiding Treatment Errors

Reluctance to Treat

The U.S. Food and Drug Administration (FDA) black-box warnings about possible treatment-associated emergent suicide can be misinterpreted as a caution against starting an antidepressant. Evidence continues to emerge that the risk for not treating outweighs treatment-associated risks. The more important message in the FDA warnings is to monitor adequately once treatment is initiated (see below).

Failure to Recognize Depression as Part of Bipolar Disorder

Patients with bipolar depression may respond initially to antidepressants, but are unlikely to sustain their response, and frequently worsen over time owing to antidepressant-driven mood cycling. These individuals require mood stabilizers and are often best served by psychiatric consultation.

Inadequate Monitoring

Issues affecting safety and treatment adherence typically occur during the first 4 to 6 weeks on medication. Monitoring, which can be either in person or by phone, should occur no less than every 1 to 2 weeks during this period and should include assessment of medication tolerance and response (or worsening) and education about importance of daily compliance.

Future Directions

Further Delineation of Pathogenesis and Inheritance

One or more genes affecting catecholaminergic neurotransmission show promise for predicting risk for depression following stressful life events. With time, these findings may lead to clinically useful biologic markers for mood disorders. Research using functional brain imaging and molecular biology will significantly improve our understanding of the neural circuitry of depression and of what happens between the synapse and the cell nucleus during initiation, maintenance, and recovery from depression.

Development of Antidepressant Treatments with Novel Mechanisms of Action

There are many individuals who do not respond to available treatments, all of which tend to focus on synaptic activ-

ity. Examples of treatments under investigation include agents that block the exaggerated hypothalamic-pituitary-adrenal axis response in depression, transcranial magnetic stimulation, and other forms of deep brain stimulation.

Public Education and Stigma Reduction

Failure to seek treatment is the single most important impediment to reducing morbidity and mortality in depression. Public education about depression lags far behind health information efforts for other common illnesses. Investment of public resources in the development of organized, ongoing screening and health education programs for depression will have an impact on the burden of depression that is equal to if not greater than biologic advances.

orbidity survey replications (NCS-R). *JAMA* 289:3095-3105, 2003.

The most current national epidemiologic data show an annual prevalence of 6.6% and a lifetime prevalence of 16% for depression. Only 50% of annual cases receive treatment, and only 42% of these receive adequate treatment.

*Structured treatment in real-world settings, including primary care, can achieve results approaching that of highly selective efficacy studies. In the STAR*D study, which accepted psychiatric and medical comorbidity, 47% of patients responded to first-line treatment, and 28% reached remission.*

Grief

Introduction

The loss of a love object triggers a complex set of biologic, psychological, and social reactions. Definitions vary, but generally, grief refers to the psychological response, bereavement to the loss itself, and mourning to the social expression of grief. Social expressions differ widely among cultures and families, and grief can vary depending on the bereaved person's psychological makeup and the nature of the lost relationship. Grief can also be a psychological reaction to any loss. A person may grieve misspent youth and missed opportunities or the loss of any cherished object such as a pet or even an inanimate object. Grieving the loss of a loved person typically evokes more pronounced and clinically relevant responses, but other losses should not be dismissed. This chapter focuses on grief and pathologic variants of grief following a death.

Etiology and Pathogenesis

The risk for pathologic outcome in grief is increased by factors related to the loss and by factors related to the psychology of the grieving person. Sudden, unanticipated, and untimely deaths are more likely to be associated with adverse outcomes. If such losses are horrific (e.g., violent deaths, deaths in disaster or accidents), the bereaved person may suffer post-traumatic stress symptoms that interfere with grief. Other types of losses are more difficult to bear. The loss of a spouse or child, or the loss of a parent during childhood or adolescence, is a major life event that is often traumatic. Multiple losses, suicide, or murder-related deaths add to the complications of grief. Concurrent life crises and stresses, such as accidents, illness, separation from family, relationship difficulties, unemployment, or the consequences of trauma, may be so severe that the bereaved person is completely occupied with psychological survival and may not have the energy to withstand the process of grief.

Some individuals may be more vulnerable to pathologic grief. A perceived lack of social support worsens outcomes. A history of psychiatric disorder and a history of suicidal behavior specifically should alert the clinician to monitor closely for difficulty in the process of grief. The nature of the relationship that is lost can also contribute to pathology in grief. The loss of ambivalent or dependent relationships can be problematic. With ambivalence, acknowledgment of satisfaction with the death of the

person who is also beloved can provoke extreme guilt. The loss of either partner of a dependent relationship may require such an unusual degree of sudden development toward independence and autonomy that such persons may instead quickly establish new similar relationships before completing a process of grief.

Clinical Presentation

Normal grief can manifest in a myriad of ways. Initial responses to a death often include a sense of shocked disbelief and numbness. The bereaved person engages in searching behaviors that include seeing the lost loved one, hearing his or her voice, or feeling his or her touch (Fig. 165-1). Such hallucinatory experiences may last weeks or sometimes months and are not considered pathologic. Following the initial shock, a period of intense anguish and emotionality ensues. All conceivable emotions can be experienced with rapid fluctuation. Many of the neurovegetative symptoms of depression such as low energy, loss of appetite with weight loss, and insomnia can last for months. The final stage of grief includes a reorganization of the psychological life that may take years. Although most bereaved people await closure and a return to normal, some losses lead to psychological changes that last a lifetime.

Generally, experts agree that these stages of grief do occur, yet the individual variance is so wide that boundaries of normal grief can be hard to define. The time frame cannot be specified or predicted for any individual, and

Figure 165-1 Grief.

The bereaved person engages in “searching” behaviors that include seeing the lost loved one, hearing his or her voice, or feeling his or her touch

Anniversary reactions can reawaken earlier stages of grief, and they can also occur around significant holidays or other reminders of the loss.

Grief can lead to a major depressive episode. These conditions share symptoms such as decreased energy, appetite, and sleep. The presence of suicidal thoughts and a depletion of the self suggest major depression; simple withdrawal from the external world is more typical in grief.

attenuated experiences of any of the stages or nonlinear progression through them does not always signify pathology. Stage models provide a broad outline that does not account for the variables of psychological differences, personal history, or cultural expectations. Most people avoid pain and will attempt to suppress expressions of grief. What emerges is a compromise between this suppression and the underlying pain. Such partial expressions of the depth of the pain can be perceived not only as unwanted but also as “out of the blue.”

Anniversary reactions can reawaken earlier stages of grief, and they can occur not only at the anniversary of the loss but also around significant holidays or other reminders of the loss. When a bereaved person reaches the age at which a parent died, often there is some pause of grief. Such anniversary reactions can be unconscious to the person, who experiences only the symptoms without understanding their context.

Biologic changes can accompany grief. There is evidence to suggest that numerous physiologic changes occur, including impairment of immunity, increased adrenocortical activity, increased prolactin, and increased growth hormone. The clinical significance of such changes is not clear. Studies of relative risk for diagnosable morbidity following grief have been inconclusive. Several studies have demonstrated an increased relative risk for mortality in bereaved spouses, but the absolute risk remains low.

Differential Diagnosis

Grief has pathologic forms marked by abnormalities of time course or intensity. Absent grief or rigid denial occurs when expression of grief is much less than expected. Delayed grief is another abnormality of time course in which the expression of grief is somehow postponed or suspended. The grief may follow a typical course after the delay. Chronic grief can continue for years, remain extremely intense, and block personal growth and the establishment of new attachments. Pathologic grief characterized by such abnormalities of time course or intensity can border on normal grief. Pathologic grief is, thus, distinguished by the degree of functional impairment.

Grief can also lead to a major depressive episode, and grief and depression share some symptoms, including decreased energy, appetite, and sleep. Because of these shared symptoms, differentiating the two can be difficult. Symptoms characterized by a depletion of the self, such as the presence of undue guilt, suicidal thoughts, or feelings of worthlessness, suggest a major depression. Simple withdrawal from the external world is more typical of normal grief. Severe psychomotor retardation and hallucinations, other than brief contacts with the lost one, suggest a possible depressive episode complicating the grief. The number of depressive symptoms present at 1 month after the loss is a strong predictor of an unremitting depression.

In addition, sleep studies may distinguish depression from grief. Medications, alcohol, and illicit substances can be abused in the effort to avoid painful effects of grief. Substance abuse requires aggressive treatment to prevent its progression and the development of further consequences.

Grieving patients commonly seek medical advice for vague symptoms of somatic distress such as dull aching pains. Such somatic expressions of grief can be psychologically mediated or related to the biologic response to loss.

Management and Therapy

Most commonly, grief will run its own course with little need for intervention by a clinician. Inquiry about perceived supports and education to help the patient anticipate the process of grief are almost always justified. Sensitivity to the circumstances and psychological meaning of the particular loss will guide further management. Availability and sensitivity will facilitate uncomplicated grief. When a complication occurs or is anticipated, more specific measures can be taken. One intervention that may be indicated is a more involved level of bereavement counseling.

Optimum Treatment

The goal of bereavement counseling is to facilitate the grieving process or to convert pathologic grief to normal grief. Bereavement counseling has been established as being effective in a number of studies. Key elements include having the patient review (1) the period leading up to the death and the immediate afterward, including perceptions, rituals, and reactions; (2) the history of the lost relationship, including its good and bad aspects; (3) what has happened since the loss, including social responses and support, and other stressors; (4) the impact on and needs of other family members and their relationship to the bereaved person; and (5) relevant experience and coping, including earlier losses and personal styles. Such explorations are designed to assist the bereaved person in expressing grief and reassessing the lost relationship, two important aspects of the resolution process. If a grieving person is unwilling or unable to move forward from the loss, an exploration of the block he or she is experiencing, such as trauma, depression, or dependent needs, may be necessary. Some bereaved people need permission from a perceived authority to stop mourning after sufficient expression of grief.

Information, education, books, and videos about grief may help the bereaved anticipate their reactions. The opportunity to explore concrete memories, places, and objects associated with the deceased (e.g., by looking at and discussing photographs or visiting the gravesite) may help overcome resistance to grieving. Self-help associations for general bereavement or the specific form of loss (Sudden

Infant Death Association, Compassionate Friends [for loss of a child], Stillbirth and Neonatal Death Support Groups, and spousal support groups) can provide support, education, role models, and practical assistance. Writing about the loss (e.g., keeping a diary or journal) or giving testimony builds mastery and may be of value for some bereaved people. Referral to a psychiatrist with skills in this area is sometimes appropriate. Indications include severe, unremitting grief; a traumatic loss (especially if the bereaved develops symptoms of post-traumatic stress disorder); major depression or suicidal ideation; and children who have lost a parent or sibling, especially if a surviving parent is depressed.

Avoiding Treatment Errors

The role of any caregiver is to facilitate normal grief and not to intervene in any way that might interfere with grief such as giving ill-conceived advice or suggesting any religious or other prescriptive formulas for grieving. Nor should a clinician prevent the bereaved from undertaking adaptive tasks such as viewing the deceased or attending the funeral or memorial service.

Medication is not part of the management of normal or pathologic grief unless specific indications exist. If sedation is initiated, it should be prescribed for a few nights while support and counseling are also provided. Sedation can impair the memory of important events such as viewing the body, family gatherings, or funeral services that may provide the patient comfort in the future. If major depression develops, antidepressant medication is indicated.

Post-traumatic Stress Disorder

Introduction

Post-traumatic stress disorder (PTSD) occurs after an event in which an individual either has personally been subjected to risk for death or serious injury or has witnessed or been confronted with the same circumstances involving another person. In addition, PTSD usually occurs only if the individual's response to the event involves a sense of intense fear, helplessness, or horror. A wide range of events can produce the symptoms of PTSD, and several populations have been identified as having an increased incidence and prevalence of PTSD. Among these are war veterans, motor vehicle crash survivors, rape and incest survivors, and survivors of natural and human-made disasters.

There are three major symptom clusters of PTSD: (1) re-experiencing the traumatic event, (2) avoidance and emotional numbing, and (3) increased arousal. Re-experiencing phenomena such as flashbacks and nightmares are the hallmarks of PTSD. Almost anything can trigger flashbacks, even when its connection to the traumatic event goes unrecognized by the individual. For example, a rape survivor might not understand why she cannot stand the odor of lilacs until she recalls that there was a vase of the fresh cut flowers in the room where she was attacked.

Avoidance symptoms, including emotional numbing, are frequently viewed as attempts to control or protect against the negative affect and arousal associated with re-experiencing the event. For survivors, it can become extreme, as in cases in which the individual becomes agoraphobic and refuses to leave his or her home for years. Emotional numbing can include suppression of positive affective responses and an increased sensitivity to negative events and emotions. Increased arousal symptoms can include such things such as hypervigilance and an exaggerated startle reaction. Sleep disturbance, difficulty concentrating, and memory impairment are also commonly reported by individuals suffering from PTSD.

Symptoms of PTSD usually develop within 3 months of the event but occasionally emerge years afterward, and not every person who experiences a traumatic event will develop PTSD. The symptoms must last more than a month to be considered PTSD. There is a high degree of variability as to the course of PTSD. Some people recover within 3 months (acute PTSD), whereas others have symptoms that last much longer (chronic PTSD).

PTSD affects about 7.7 million American adults, but it can occur at any age, including childhood. Women are more likely to develop PTSD than men, and there is some evidence that susceptibility to the disorder may run in families. PTSD is often accompanied by depression, substance abuse, or one or more of the other anxiety disorders. Among men, the traumas most commonly associated with PTSD are combat exposure and witnessing someone being badly injured or killed. Among women, rape and sexual molestation are the traumas most commonly associated with PTSD.

Etiology and Pathogenesis

As with many psychiatric disorders, there is not one specific factor or set of factors involved in the etiology of PTSD. It is likely that a combination of psychological, biologic, and environmental factors contribute to its development. Learning theorists speculate that the major symptoms of PTSD are caused by classical conditioning to fear. For example, a patient with PTSD may experience increased anxiety or fear when traveling in a car, after having been involved in a traumatic car accident. Avoidance of motor vehicles only serves to reinforce the fear of cars, which is to say that when a car is not present, neither is the anxiety or fear.

From a biologic viewpoint, lasting changes in brain chemistry are often evident in patients diagnosed with PTSD. People with PTSD have heightened physiologic responses (e.g., an exaggerated startle reflex) to any physical stress, not just to reminders of the trauma. When the sympathetic nervous system is activated to prepare for an emergency, the locus coeruleus releases the catecholamine neurotransmitters norepinephrine and epinephrine. Many studies have shown that patients with PTSD may have characteristic catecholamine abnormalities. Some studies have found that a high norepinephrine-to-cortisol ratio is present in individuals with PTSD.

Clinical Presentation

PTSD develops after a traumatic event. A person who develops PTSD may have been the one who was harmed, the harm may have happened to a loved one, or the person may have witnessed a harmful event that happened to someone else.

PTSD was first brought to public attention in relation to war veterans, but it can result from a variety of traumatic events. Patients with PTSD can startle easily, become emotionally numb, lose interest in most things they used to enjoy, have trouble feeling affectionate, be irritable, become more aggressive, or even become violent toward others. They avoid situations that remind them of the trauma, and anniversaries of the incident are often very difficult. Most people with PTSD repeatedly relive the trauma in their thoughts during the day and in nightmares when they sleep (Fig. 166-1). Some patients experience flashbacks—intense, highly realistic memories of a trauma. Flashbacks may consist of images, sounds, smells, or feelings and are often triggered by ordinary occurrences, such as a door slamming or a car backfiring on the street. In some cases, the person with PTSD having a flashback may lose touch with reality and believe that the traumatic incident is happening all over again.

Differential Diagnosis

A diagnosis of PTSD cannot be made without a clear history of a traumatic event. Other conditions cause many

of the symptoms experienced in PTSD, and these conditions must be ruled out. Conditions such as substance abuse and depression develop as complications of PTSD. Ultimately, the distinguishing factor is the fact that the patient has experienced a severe trauma. Some of the conditions that must be ruled out include adjustment disorder, depression, panic disorder, and substance abuse or dependence disorder. Furthermore, malingers—in this case, people who falsely claim to be traumatized—sometimes feign PTSD symptoms to win money in a court case as compensation for emotional suffering.

Acute stress disorder (ASD) is similar to PTSD in that it occurs after exposure to a traumatic event. Symptoms of ASD appear within 4 weeks of the trauma and last from 2 days to 4 weeks. As with PTSD, they include re-experiencing, avoidance, and increased arousal. However, fewer symptoms are required in each category to make a diagnosis. ASD is distinguished from PTSD by having more dissociative symptoms; that is, patients describe feeling “as if they’re in a daze,” or have temporary amnesia about the trauma. ASD may progress to PTSD but is more responsive to treatment, emphasizing the need for early recognition and intervention.

Diagnostic Approach

Diagnosing PTSD in an office visit can be challenging. The diagnosis is frequently missed because patients do not typically volunteer information about traumatic events they may have experienced or readily disclose symptoms associated with PTSD. Although direct questioning is necessary, making the diagnosis requires more than checking off a list of symptoms.

To ensure that the diagnosis is not missed, a brief trauma history should be included in all evaluations for anxiety or depression. Traumatic events of adulthood can be asked about directly, for example, “Have you ever been physically attacked or assaulted? Have you ever been in a severe accident? Have you ever been in combat or a disaster?” A positive response should alert the clinician to inquire further about the relationship between the event and any current symptoms. Traumatic childhood experiences require reassuring statements of normality to put the patient at ease: “Many people continue to think about frightening aspects of their childhood. Do you?”

The mnemonic DREAMS can help elicit pertinent details after the trauma history has been obtained (Box 166-1). With each event, the examiner should determine if the person appears emotionally *detached* (called *alexithymia*), either from the event or in relationships with others. It may also manifest as a general numbing of emotional responsiveness. The individual *re-experiences* the event in the form of nightmares, recollections, or flashbacks. The event involved substantial emotional distress, with threatened death or loss of physical integrity, and feelings of helplessness or disabling fear. The person avoids

Figure 166-1 Post-traumatic Stress Disorder.

Individuals with PTSD may relive traumatic events in their thoughts during the day and in nightmares when they sleep.

Box 166-1 DREAMS: A Mnemonic for Screening Patients with Post-traumatic Stress Disorder

Detachment
Re-experiencing
Emotional distress
Avoidance
Month's duration of symptoms
Sympathetic hyper-reactivity or hypervigilance

places, activities, or people that remind him or her of the event. The symptoms need to have been present longer than one *month*, and the individual should experience sympathetic hyperactivity or hypervigilance, which may include insomnia, irritability, and difficulty concentrating. As with all psychiatric interviews, assessing imminent danger of the patient to self or others is essential.

More formal means of assessing traumatic events and PTSD with tests and diagnostic interviews are also available. Selection of tests and diagnostic instruments should include an examination by the clinician of the relevant data on their psychometric properties, such as rates of

false-positive and false-negative results, sensitivity, and specificity.

It is standard practice in clinical research settings to use structured diagnostic interviews to ensure that PTSD symptoms are reviewed in detail. The use of structured diagnostic interviews in the clinical setting is less common, with perhaps the exception of clinical forensic practice.

Several self-report measures have been developed as a time- and cost-efficient method for assessing PTSD symptoms. These measures are widely used because of their ease of administration, but are also useful as adjuncts to the structured diagnostic interviews. They are often used as screening measures for PTSD, but specific cutoff scores on some instruments can be used to derive a diagnosis of PTSD.

Research on biologically based measures of PTSD has grown tremendously during the past 15 years. Studies have shown that PTSD alters a variety of physiologic functions and may also affect structural regions of the brain. Findings in this area point to the capacity of psychophysiological indices to identify and classify cases of PTSD on the basis of reactivity to audio-, audiovisual-, and imagery-based cues. Measures have included heart rate, blood pressure,

skin conductance, and electromyography. Psychophysiological assessment is costly in terms of time, patient burden, and cost. It is unlikely that this form of assessment will be widely adopted by clinicians because of the costs, expertise required, and success of other, more economical measures such as the diagnostic interviews and self-report measures that are currently available.

Management and Therapy

Optimum Treatment

Treatment of PTSD typically begins with a detailed evaluation and the development of a treatment plan that meets the unique needs of the patient. Generally, PTSD-specific treatment is started when the patient is not in crisis. Crises that need to be addressed before the initiation of PTSD-specific treatment include: problems such as the patient is currently being exposed to trauma, for example, ongoing domestic violence, abuse, or homelessness; severe depression or suicidal ideation, extreme panic or disorganized thinking; or the need of alcohol or drug detoxification. The important components of treatment for PTSD include (1) educating trauma survivors and their families about the likely causes of PTSD, how PTSD affects survivors and their loved ones, and other problems that commonly occur with PTSD symptoms; (2) exposure to the traumatic event through imagery, which allows the survivor to re-experience the event in a safe, controlled environment, while also carefully examining his or her reactions and beliefs in relation to that event; (3) having the patient examine and resolve strong feelings such as anger, shame, or guilt, which are common among survivors of trauma; and (4) teaching the patient to cope with post-traumatic memories, reminders, reactions, and feelings without becoming overwhelmed or emotionally numb. Trauma-related memories usually do not go away entirely as a result of therapy but become manageable with the mastery of new coping skills. The steps outlined here represent only a portion of the several therapeutic approaches commonly used to treat PTSD.

Cognitive-behavioral therapy (CBT) involves working on thoughts (cognitions) and how those cognitions influence emotions and behaviors. Exposure therapy is one form of CBT that is unique to trauma treatment. It uses careful, repeated, detailed imagining of the trauma (exposure) in a safe, controlled context to help the survivor face and gain control of the fear and distress that were overwhelming during the trauma. In some cases, trauma memories or reminders can be confronted all at once, an approach referred to as *flooding*. For other individuals or traumas, it is preferable to work up to the most severe trauma gradually by using relaxation techniques and by starting with less upsetting life stresses, or by taking the trauma one piece at a time. This approach is called *systematic desensitization*.

Along with exposure, CBT for trauma includes learning skills for coping with anxiety (such as breathing retraining

or relaxation training), and negative thoughts (cognitive restructuring), anger management training, preparing for stress reactions (stress inoculation training), coping with future trauma-specific symptoms, coping with urges to use alcohol or drugs when trauma symptoms occur, and communicating and relating effectively with people (social skills training or couples therapy).

Pharmacotherapy can reduce the anxiety, depression, and insomnia often experienced with PTSD, and in some cases, pharmacotherapy may help relieve the distress and emotional numbness caused by trauma-related memories. Several kinds of antidepressant drugs have been shown to contribute to patient improvement in most (but not all) clinical trials, and it is possible that other classes of drugs will be useful based on preliminary studies. At this time, however, the only drug approved by the U.S. Food and Drug Administration for the specific treatment of PTSD is sertraline (Zoloft).

Eye movement desensitization and reprocessing (EMDR) involves elements of exposure therapy and CBT combined with techniques (eye movements, hand taps, or sounds) that create an alternation of attention back and forth across the person's midline. Although the theory and research are still evolving for this form of treatment, there is some evidence that the therapeutic element unique to EMDR, attentional alternation, may facilitate the accessing and processing of traumatic material.

Group treatment is often an ideal therapeutic setting because trauma survivors are able to share traumatic material within the safety, cohesion, and empathy provided by other survivors. As group members achieve greater understanding and resolution of their trauma, they often feel more confident and able to trust. As they discuss and share how they cope with trauma-related shame, guilt, rage, fear, doubt, and self-condemnation, they prepare themselves to focus on the present rather than the past. Telling one's story (the "trauma narrative") and directly facing the grief, anxiety, and guilt related to trauma enable many survivors to cope with their symptoms and memories and other aspects of their lives.

Brief psychodynamic psychotherapy focuses on the emotional conflicts caused by the traumatic event, particularly as they relate to early life experiences. Through the retelling of the traumatic event to a calm, empathic, compassionate, and nonjudgmental therapist, the survivor achieves a greater sense of self-esteem, develops effective ways of thinking and coping, and learns to deal more successfully with intense emotions. The therapist can help the survivor identify current life situations that set off traumatic memories and worsen PTSD symptoms as well as help identify coping mechanisms.

Avoiding Treatment Errors

The first step in effectively treating PTSD is an accurate diagnosis. Not all patients will spontaneously disclose that

they have experienced a traumatic event, especially one that they may perceive as particularly stigmatizing such as childhood trauma, sexual assault, or domestic violence. Additionally, many patients with a history of trauma and PTSD present with somatic complaints, depression, anxiety, or substance abuse that is comorbid with their trauma symptoms. It is important that clinicians routinely screen patients for a history of trauma and assess the individual for symptoms of PTSD if a traumatic event is present in the individual's history. Once a diagnosis of PTSD has been established, the second step in effectively treating PTSD is to assess the patient's symptoms and level of functional impairment to see if pharmacotherapy is indicated or to refer the patient for trauma-focused therapy.

Future Directions

The primary prevention of PTSD is vital and should include support and advocacy of community and national efforts to prevent violence and curb its sequelae. Gun control and educational efforts to prevent rape, child abuse, and domestic violence are primary preventive strategies that may reduce the incidence of PTSD.

Biologic and treatment outcome research has been largely restricted to combat veterans. Similar types of studies need to be conducted on survivors of other types of trauma such as natural disasters, sexual assault, and industrial accidents. Future trauma studies are needed to clarify whether the subjective, behavioral, and biologic responses to different types of trauma are the same as the responses to combat-related trauma. Other issues that merit further study include investigation of whether there are gender-specific factors that may promote a different trauma response in women than men, how PTSD is expressed differently in people from different cultures and nationalities, and whether there are other psychiatric syndromes resulting from traumatic exposure that may

have a unique cluster of symptoms distinguishable from PTSD.

These guidelines are intended to inform the clinician about what are considered to be the best practices in the treatment of individuals with a diagnosis of PTSD.

Obsessive-Compulsive Disorder

Introduction

Obsessive-compulsive disorder (OCD) is a well-defined, often debilitating illness characterized by obsessions, compulsions, or both. First described 150 years ago, the conceptualization of OCD has undergone profound changes over the past 2 decades. Once considered a rare psychogenic syndrome with treatment based on the exploration of early childhood conflict, OCD is now understood as a prominent, neuropsychiatric disease with abnormal brain circuitry and neurotransmitter dysfunction. Unfortunately, OCD continues to be a hidden, often unrecognized illness with an average 5- to 10-year lag from onset of symptoms to appropriate diagnosis and treatment. Because effective treatment is highly specific and nonspecific treatments are ineffective, many are left to suffer needlessly.

OCD affects 2% to 3% of the U.S. population, and cross-national studies have found a remarkably similar prevalence across diverse geographic and cultural sites. Men and women are equally likely to be affected. Age of onset is typically during late adolescence or early adulthood, although childhood onset is not uncommon, with as many as one third of patients recalling the emergence of symptoms before age 15 years. Males tend to have an earlier age of onset than females.

Etiology and Pathogenesis

Remarkable advances have been made in our understanding of the genetic and neurologic underpinnings of OCD. The observation that the tricyclic antidepressant, clomipramine, a serotonin reuptake inhibitor (SRI), is effective in treating patients with OCD, whereas antidepressants with primarily noradrenergic reuptake activity (e.g., desipramine) are not, led to the hypothesis that serotonin plays a major role in the mediation of OCD. Results of neuroendocrine, metabolite, and platelet-binding studies also suggest dysregulation of serotonin function in OCD.

Studies using modern neuroimaging techniques strongly implicate basal ganglia circuitry in the mediation of OCD symptoms. Corticostriatal pathways involve both serotonergic and dopaminergic neurons. Several structural studies have found decreased basal ganglia volumes in OCD patients compared with those in healthy controls. Functional studies using positron emission tomography have shown increased resting activity in the frontal lobes, basal ganglia, and cingulum of patients with OCD, with

normalization of these findings following successful pharmacologic or behavioral intervention. Neuropsychological and neurosurgical studies are also consistent with the importance of the basal ganglia in OCD.

Family and twin studies indicate a genetic contribution to the etiology of OCD. There is increased risk for OCD in first-degree relatives of affected patients, as well as increased concordance in monozygotic compared with dizygotic twins.

Clinical Presentation

The clinical description of OCD has changed little over the past 150 years. The core clinical symptoms are obsessions or compulsions that either are time consuming or cause functional impairment or distress, and are not due to another psychiatric or medical illness (Box 167-1).

Obsessions are persistent thoughts, images, or impulses that are experienced as intrusive, distressing, and inappropriate. Most studies have found that the most common

Figure 167-1 Obsessive-Compulsive Disorder.

Box 167-1 DSM-IV Criteria for Obsessive Compulsive Disorder

Either obsessions or compulsions
 Symptoms cause marked distress
 Not simply excessive worries about real life problems
 Attempts to ignore, suppress, neutralize
 Recognition that thoughts, impulses, and images are product of one's own mind
 Behaviors or mental acts are aimed at preventing or reducing distress or preventing some dreaded event; however, they either are not connected in a realistic way with what they are meant to neutralize or prevent, or are clearly excessive
 Symptoms recognized as excessive at some point (*does not apply to children*)
 Obsessions or compulsions result in one of the following:

- Cause marked distress
- Are time consuming (take more than an hour a day)
- Significantly interfere with the person's normal routine, occupational or academic functioning, or usual social activities or relationships

Content not restricted to another Axis I disorder
 Not due to the direct effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition

obsessional theme in both adults and children is that of contamination, typified by fear of dirt, germs, toxins, environmental hazards, or bodily secretions (Fig. 167-1). Patients may fear spreading disease or contracting an illness, and such worries are often associated with elaborate and time-consuming washing or bathing compulsions. Other obsessions include pathologic doubt, whereby one worries that his or her actions may cause harm or disastrous consequences; somatic obsessions; sexual or aggressive thoughts and images; and need for symmetry, order, or exactness.

Compulsions are repetitive behaviors or mental acts that an individual feels driven to perform to reduce anxiety or to prevent some dreaded event or outcome, even though the event may be totally unrelated to the behavior. Common compulsions are checking, washing (often associated with contamination obsessions), counting, needing to ask or confess, repeating, hoarding, and ordering or arranging. In clinical samples, the presence of pure obsessions or compulsions is rare. Often patients who appear to have only obsessions also have covert reassurance rituals or mental compulsions, such as repeating or praying rituals.

Traditionally, the obsessions and compulsions in OCD have been characterized as *ego dystonic* (i.e., patients typically view their thoughts and behaviors as senseless and

excessive). However, more recent studies and field trials have reported a subset of patients who at times lack insight and display conviction about the reasonableness of their obsessions and necessity of their rituals. It is more likely that insight in OCD may span a spectrum from good to delusional thinking.

Several studies have found that about two thirds of OCD patients have a lifetime diagnosis of a comorbid psychiatric disorder. Major depression is common (50% to 67%), as are other anxiety disorders, including social anxiety disorder, specific phobia, panic disorder, and generalized anxiety disorder (GAD). OCD rarely occurs with mania. Some patients with schizophrenia have coexisting obsessions and compulsions, and concurrent OCD may be associated with a poorer outcome of schizophrenia.

There is a high degree of bidirectional overlap between tic disorders and OCD. Almost 25% of patients with tic disorders meet full criteria for OCD, and conversely, 20% of OCD patients have a lifetime history of multiple tics, with 5% to 10% having a lifetime history of Tourette's syndrome (TS). Patients with tics and obsessive-compulsive symptoms have an earlier average age of onset and strong family histories of OCD and TS. Psychostimulants (e.g., methylphenidate or dextroamphetamine) may exacerbate both tics and obsessive-compulsive symptoms in susceptible individuals.

Recent research has focused on the concept of an obsessive-compulsive spectrum, based on the observation that a series of possibly related disorders are similar in phenomenology, associated features (age of onset, clinical course, neurobiology), familial transmission, and clinical response to specific pharmacologic and behavioral interventions. These include eating disorders, certain somatoform disorders (hypochondriasis, body dysmorphic disorder), and disorders of impulse control (trichotillomania, pathologic gambling).

Differential Diagnosis

There are a number of medical disorders that can produce syndromes resembling OCD, including diseases of the basal ganglia such as Huntington's disease, certain tumors, postencephalitic conditions, and traumatic brain injury. Because OCD characteristically presents in the teens and 20s, new onset of symptoms in an older individual should raise questions considering the possibility of neurologic conditions.

Swedo and colleagues observed a high prevalence of obsessions and compulsions in children in whom Sydenham's chorea developed. Sydenham's chorea is a neurologic variant of rheumatic fever following a group A β -hemolytic streptococci infection. Because there is evidence that Sydenham's chorea may be an autoimmune response involving antibodies to the basal ganglia, this association has led to intriguing work on this phenomenon that has come to be called *pediatric autoimmune neuropsychi-*

atric disorder associated with *Streptococcus* and treatment with immunologic interventions, such as plasmapheresis or intravenous immunoglobulin therapy. This syndrome tends to present more acutely, in contrast to the more insidious onset in other cases of childhood OCD.

The clinician must also rule out other psychiatric conditions in which obsessive-compulsive behavior might be found. Major depressive disorder is frequently comorbid with OCD and may be characterized by obsessive ruminations. The two conditions may be differentiated by the course of illness. Obsessive symptoms associated with depression are only present during the depressive episode, whereas true OCD symptoms persist independently of a depressive episode. Additionally, depressed patients do not see their thoughts as absurd or senseless. It can also be difficult to distinguish OCD from the worry and anxious apprehension seen in GAD. In patients with GAD, the content of the anxious thoughts is realistic, although the worry is excessive. OCD is often confused with obsessive-compulsive personality disorder (OCPD). Although patients with OCD may display perfectionism and indecisiveness, they are no more likely than healthy controls to exhibit the features characteristic of OCPD, such as rigidity, restricted ability to express warmth, or excessive devotion to work.

Psychotic symptoms may sometimes result in obsessions and compulsions that are difficult to distinguish from OCD with poor insight. In most instances, however, patients with OCD will be able to acknowledge the unreasonable nature of their symptoms. Additionally, psychotic disorders, such as schizophrenia, are characterized by other symptoms that are not present in OCD, such as hallucinations, disorganized speech, or flattened affect.

Diagnostic Approach

The failure to properly diagnose OCD is most likely due, in part, to the shame and humiliation that many patients feel about the symptoms and the fear that they will be seen as crazy. Adults and children can be very secretive about their symptoms, and often OCD is not apparent until secondary symptoms (e.g., dermatologic problems from excessive washing and cleaning) reveal themselves or until families complain. However, lack of suspicion on the part of clinicians, as well as failure to ask appropriate screening questions, also play a role in the failure to recognize this disorder. The primary method of establishing a diagnosis is a clinical interview with specific questions designed to elicit a history of intrusive thoughts or behavioral rituals.

Because OCD typically presents in adolescence or early adulthood, screening questions should be asked of any patient in this age group who presents with anxiety, depression, or secondary symptoms, or whose family complains of odd rituals and preoccupations. Sample questions might include, "Do you experience thoughts or images that you find disturbing but cannot seem to keep out of your head?"

Table 167-1 Comparison of Antidepressant Treatment of Depression versus Obsessive-Compulsive Disorder

	Depression	Obsessive-Compulsive Disorder
Drug	Drugs with different profiles of monoamine uptake effective	Only serotonergic drugs effective
Time to response	Adequate trial usually 4-6 weeks for treatment response	Trial of 8-12 weeks for response
Treatment goal	Remission	Symptom reduction
Relapse rate	Variable upon discontinuation of medication (30%-50% within 2 months)	Higher relapse rate upon medication discontinuation (90% within 2 months)

and “Are there actions you feel you must do over and over even though you don’t want to?” A patient-administered diagnostic instrument, as well as relevant information about OCD is available on the Obsessive Compulsive Foundation website.

Management and Therapy

Pharmacotherapeutic advances have revolutionized the treatment of OCD. Serotonin reuptake inhibitors (SRIs), including the tricyclic antidepressant clomipramine and the selective serotonin reuptake inhibitors (SSRIs), are the first-line treatment for OCD. Treatment of OCD is specific; antidepressants other than SRIs are ineffective. Additionally, the therapeutic lag time is longer (8 to 12 weeks), and higher doses are often needed for patients with OCD compared with those with other conditions. Failure to recognize these differences in appropriate treatment of OCD versus depression can result in major treatment errors and therapeutic response failures (Table 167-1).

A case report in 1967 provided the first hint that clomipramine might be effective for OCD. Its efficacy was later confirmed by multicenter placebo-controlled trials. Clomipramine also has norepinephrine and dopamine reuptake properties and is associated with the adverse effects typical of tricyclic antidepressant agents, including anticholinergic, antihistaminergic, α -adrenergic side effects; quinidine-like cardiac properties; sexual dysfunction; increased risk for seizures; and lethality in overdose. SSRIs are better tolerated than clomipramine and are also effective in treating obsessive-compulsive spectrum disorders. Fluvoxamine, sertraline, fluoxetine, and paroxetine have been shown to be effective in large, multicenter, placebo-controlled trials. There is also evidence that citalopram and escitalopram are effective. SRIs may effectively treat comorbid mood and anxiety disorders (Table 167-2).

A review of studies suggests that 65% to 70% of OCD patients have a clinically significant response to initial SRI treatment and that as many as 90% of patients respond with sequential trials. Thus, patients who do not respond to one SRI may respond to a different one. Generally, treatment provides a 30% to 60% relief of symptoms but does not induce a full remission. Symptoms tend to re-

Table 167-2 First-Line Pharmacologic Treatment for Obsessive-Compulsive Disorder

Drug (Serotonin Reuptake Inhibitor)	Usual Dose Range (mg)	Average Daily Dose (mg)
Clomipramine	100-300	200
Fluoxetine	20-80	50
Sertraline	75-225	150
Paroxetine	20-60	50
Fluvoxamine	100-300 (divided)	200
Citalopram	20-60	—
Escitalopram	10-40	—

emerge upon discontinuation of therapy, thus requiring long-term treatment for most patients. Long-term data suggest that efficacy is maintained and may even increase over time.

Because as many as 40% to 60% of patients do not have an adequate response to SRI treatment, augmentation strategies are important in managing OCD. A number of pharmacologic agents, including a second SRI, lithium, buspirone, clonazepam, and trazodone, have been used to augment SRIs, but data confirming their usefulness are limited. Dopamine antagonists, such as haloperidol, have been found to be helpful, particularly in patients with comorbid tic disorders or poor insight. More recently, the combination of an SRI and the atypical antipsychotic risperidone seems to hold some promise. Electroconvulsive therapy has not been shown to be effective. Neurosurgery, particularly cingulotomy, has been effective in treating severe, refractory OCD, and deep brain stimulation is being studied.

Cognitive Behavioral Therapy

Behavioral therapy has consistently been shown to be helpful in reducing the symptoms of OCD, and studies have shown techniques are based on exposure and response prevention. Patients are increasingly exposed to the feared situation or avoided stimuli and prevented from performing the associated rituals. Compulsions are more amenable to behavioral treatment than obsessions. Cognitive therapy

may be particularly useful for pathologic doubt, aggressive obsessions, and scrupulosity. Because traditional psychodynamic psychotherapy is not effective for OCD, patients should be referred to a mental health professional trained in these techniques.

Optimum Treatment

Treatment of OCD should always include cognitive behavioral therapy, and mild to moderate cases may respond to this modality alone. A combination of pharmacotherapy and behavioral therapy is considered the standard of care for more severe or disabling cases and is associated with earlier response and reduced risk for relapse.

Avoiding Treatment Errors

Misdiagnosis accounts for many of the treatment errors made in the management of OCD. A mistaken diagnosis of psychosis may result in unnecessary and potentially harmful treatment with antipsychotic drugs. Treatment of major depression without recognition of comorbid OCD may result in ineffective drug choice, as well as inadequate dosing and duration of treatment. Failure to include a behavioral therapy component to treatment may deprive the patient of an optimal chance of recovery.

Future Directions

As our understanding of the brain continues to advance, the exact nature of the pathogenesis and etiology of OCD should become more apparent, enabling more precise detection and treatment. More work should be done identifying subtypes of OCD as well as exploring alternative and adjunctive treatment for patients with treatment resis-

tance. Exciting developments clarifying this important disorder will certainly continue over the coming years.

Swedo's characterization of the OCD-like symptoms associated with Sydenham's chorea is fascinating and sheds light on the neurobiology of OCD.

Schizophrenia

Introduction

Schizophrenia describes a heterogeneous group of chronic relapsing psychotic disorders with a lifetime incidence of about 1% worldwide. Schizophrenia is a disease that often significantly affects the ability of an individual to function in a number of different ways. The overt clinical symptoms typically present in late adolescence or early adulthood, at a time when one is establishing independence from family, beginning higher education or employment, and establishing adult relationships. Males have an earlier onset, more severe symptoms, poorer treatment response, and a more chronic course. Childhood-onset schizophrenia is a rare, more severe form of the adult-onset illness. About 10% of new-onset psychosis occurs after the age of 40 to 45 years, designated as late-life schizophrenia.

Schizophrenia is, at its core, a disorder of altered reality perception, characterized by hallucinations and delusions (Fig. 168-1). However, its onset, presentation, clinical course, and presumably its causes are remarkably heterogeneous. The course is characterized by acute episodes of psychotic symptoms with intervening periods of relative stability that have a varying degree of residual symptoms and functional impairment. The chronic course is variable. In some individuals, symptoms are minimal between acute psychotic episodes, and there is little functional impairment. At the opposite extreme, hallucinations and delusions persist, and there is profound functional impairment.

Etiology and Pathogenesis

There is clearly a genetic component to schizophrenia. The incidence in the first-degree relatives of an affected individual is about 10%. The concordance rate in monozygotic twins is about 45%. The search for genes that confer risk for schizophrenia has been somewhat disappointing because a contribution of any single gene to risk for schizophrenia is small. Regions on several chromosomes have been identified, and it is most likely that schizophrenia is a polygenic disorder with multiple susceptibility genes.

Environmental factors contribute to the risk for schizophrenia in an individual. Prenatal exposure to maternal infection, perinatal hypoxia, and other obstetric complications increase risk. Birth in an urban area and late winter or early spring birth are more frequent in people in whom schizophrenia develops, perhaps a result of toxic, nutritional, or infectious exposures.

Structural neuroimaging studies find subtle abnormalities of the brain, including mild enlargement of the lateral

and third ventricles and gray matter reductions in the frontal and temporal lobes, as well as reductions in the volume of the hippocampus. There is evidence that white matter is also abnormal. Functional imaging studies such as positron emission tomography (PET), magnetic resonance imaging (MRI), and magnetic resonance spectroscopy reveal abnormalities in frontal cortex and temporal structures, including the hippocampus. Abnormalities in the cerebellum, thalamus, and striatum have also been described.

Postmortem studies reveal subtle abnormalities as well, including changes in neuron number, alteration of various synaptic protein densities, and reduced density of dendritic spines. Abnormalities in several neurotransmitter systems have been implicated by postmortem, PET, and preclinical studies as well as by the mechanism of action of antipsychotic medications. The dopamine, glutamate, and serotonin systems are all of importance in schizophrenia.

Currently, schizophrenia is conceptualized with a two-hit model, in which genetic risk factors interact with perinatal environmental risk factors to cause subtle abnormalities

Figure 168-1 Schizophrenia.

Schizophrenia is a heterogeneous disorder with a wide range of symptomatology. This patient demonstrates the flat affect that is common in schizophrenia. She appears to be responding to internal stimulation—perhaps attending to auditory hallucinations. Alternatively, she may have significant negative symptoms, including anhedonia, amotivation, and poverty of speech. Finally, she may have parkinsonism secondary to antipsychotic medication.

in brain structure and connectivity between neurons. Age-dependent neurodevelopmental events during adolescence such as synaptic pruning and myelination unmask abnormal functional circuits in the brain and give rise to clinical symptoms.

Clinical Presentation

There are three main domains of symptoms associated with schizophrenia: (1) positive symptoms, (2) negative symptoms, and (3) cognitive dysfunction. Positive symptoms are the classic symptoms of psychosis and include delusions and hallucinations. Delusions, false beliefs that are held with conviction despite evidence to the contrary, are present in more than 90% of patients. Delusions can take many forms; paranoid, persecutory, and religious are common. Hallucinations, perceptual disturbances that can occur in any sensory modality, are present in about 50% of patients. Of these, auditory and visual hallucinations are the most common.

Negative symptoms are abnormalities of volition and include restricted or flat affect, anhedonia, poverty of speech, apathy, amotivation, and asociality. About 25% of patients with schizophrenia have the deficit syndrome, or primary negative symptoms, which may be a true subtype of schizophrenia. In other patients, negative symptoms, although common, are secondary to the positive symptoms

(i.e., a paranoid person would be asocial and amotivated), depression, anxiety, demoralization, an understimulating environment, or side effects of the medication used to treat psychosis.

Patients typically have cognitive dysfunction, which is increasingly recognized as a major reason for functional impairment. A variety of neurocognitive functions including attention, memory, and executive function are impaired. Patients often present with disorganized thinking and speech, as a result of cognitive dysfunction, as well as positive and negative symptoms.

Differential Diagnosis

The differential diagnosis of psychosis (Box 168-1) is long and begins with substance abuse (amphetamines, cocaine, phencyclidine, marijuana, hallucinogens) or withdrawal (alcohol, sedative-hypnotic). Psychosis is often seen in a hospital setting in the form of delirium resulting from a variety of causes. Medical conditions include acute intermittent porphyria, Cushing's syndrome, hypocalcemia and hypercalcemia, hypoglycemia, hypothyroidism and hyperthyroidism, hepatic encephalopathy, and paraneoplastic syndromes. Neurologic conditions include partial complex seizures, brain tumors, multiple sclerosis, degenerative disorders (Alzheimer's, Pick's, Huntington's disease), infections (HIV, neurosyphilis, herpes simplex), lupus cerebritis,

 Thiamine
 Vitamin B₁₂

Psychiatric Conditions

Bipolar disorder
 Major depression

stroke, and Wilson's disease. Nutritional deficiencies of folate, niacin, thiamine, and vitamin B₁₂ can present with psychosis. Many prescribed medications, heavy metals, and other toxic agents can cause psychotic symptoms. Psychotic symptoms are present in other psychiatric disorders, including mania, severe depression, brief psychotic disorder, delusional disorder, and schizoaffective disorder.

Diagnostic Approach

The diagnosis is a clinical one based on symptoms present during an interview and by history (Box 168-2). Diagnostic criteria for schizophrenia include the presence of two of the following for 1 month: delusions, hallucinations, disorganized speech, grossly disorganized or catatonic behavior, and negative symptoms. In addition, significant social and occupational impairment and duration of symptoms of at least 6 months are needed to make a diagnosis of schizophrenia. Symptoms that meet criteria for schizophrenia but have not lasted as long as 6 months are designated as *schizophreniform disorder*. Patients often believe that their psychotic experiences are real and do not

Box 168-2 Diagnostic and Statistical manuals of Mental Disorders, Fourth Edition (DSM-IV) Criteria for Schizophrenia

- A. Characteristic symptoms
 Two or more present for a month or more:
 1. Delusions
 2. Hallucinations
 3. Disorganized speech
 4. Grossly disorganized or catatonic behavior
 5. Negative symptoms
- B. Social and occupational dysfunction
 For a significant portion of the time since onset, one or more major areas of functioning such as work, interpersonal relations, or self-care are marked below the level achieved before onset.
- C. Duration: continuous signs of the disturbance persist for at least 6 months.
- D. Schizoaffective disorder and mood disorders have been ruled out.
- E. Substance and general medical condition have been ruled out.
- F. Relationship to a pervasive developmental disorder
 If there is a history of autism or another pervasive developmental disorder, the additional diagnosis of schizophrenia is made only if prominent delusions or hallucinations are also present for at least 1 month.

recognize that they are ill. Acutely psychotic patients are frequently disorganized, responding to internal stimuli, and unable to attend to questions. Therefore, it is necessary to get collaborative history from a friend or family member.

New-onset psychosis requires a careful workup, including a physical and neurologic examination to rule out medical and neurologic causes and substance abuse. Basic laboratory tests include a drug screen; complete blood count; and blood chemistries, including calcium, thyroid function tests, HIV, VDRL, and measurement of vitamin B₁₂ and folate levels. Additional laboratory work including ceruloplasmin, heavy metals, and autoantibody titers, should be pursued based on relevant history, physical examination, and clinical suspicion. Neuroimaging (computed tomography, MRI) is typically done in the workup to rule out a brain tumor and other central nervous system abnormalities.

Management and Therapy

Hospitalization is indicated when the patient is disorganized and is unable to care for himself or herself or unable to participate in treatment as an outpatient. Suicidal ideation is common. As many as 50% attempt suicide, and 10% are successful. Less frequently, patients with schizophrenia harbor homicidal thoughts based on their delusions. The presence of suicidal and homicidal ideation should be carefully assessed. Hospitalization is indicated when the patient is a danger to himself or herself or to others.

The mainstay of treatment is antipsychotic medications. There are a number of antipsychotic medications, now designated as the older *typical* antipsychotics or the newer *atypical* antipsychotics. Although antipsychotics have different receptor-binding profiles, all have dopamine D₂ receptor antagonist properties that are thought to underlie their antipsychotic action. All antipsychotics are equally efficacious in the treatment of psychosis; choice is based on side-effect profile, prior treatment response, and physician or patient preference. Clozapine has been shown to be more effective than other antipsychotics in patients with treatment-resistant schizophrenia (those who have failed two other antipsychotic trials of adequate dose and duration). Cognitive dysfunction and disorganization may make it difficult for a patient to consistently take medication. In these situations, long-acting injectable antipsychotics can be given every 2 to 4 weeks.

Antipsychotic side effects represent a significant challenge in the management of schizophrenia. Acute extrapyramidal syndromes such as parkinsonism, dystonias, akathisia, and acute dyskinesia are most common. Tardive dyskinesia is a long-term effect consisting of involuntary choreoathetoid movements of the mouth, hands, or trunk. Neuroleptic malignant syndrome, a rare but potentially fatal syndrome, is characterized by fever, muscular rigidity, and mental status changes and can also include autonomic instability, leukocytosis, and elevated creatinine kinase. Other side effects include sedation, orthostatic hypotension, electrocardiogram changes (especially prolongation of the Q-T interval), agranulocytosis, hyperprolactinemia, and sexual dysfunction. Many of the newer atypical antipsychotics are associated with development of the metabolic syndrome, including significant weight gain; elevation of glucose, cholesterol, and triglycerides; and development of type 2 diabetes mellitus.

Optimum Treatment

Schizophrenia is a chronic, complex disorder that is best treated by a team of professionals who work together to address all aspects of the illness. Patients with schizophrenia frequently have comorbid psychiatric disorders that need to be recognized and treated to improve the course of schizophrenia and the patient's overall functioning. The most common are substance abuse, depression, and obsessive-compulsive disorder.

Although medication is the foundation of treatment, other psychosocial treatment modalities play an important role in helping the patient deal with the impact of schizophrenia on his or her life. Supportive, psychoeducational, and cognitive-behavioral therapies, as well as family psychoeducation and intensive community-based outreach programs, all improve outcome and level of functioning in patients. Rehabilitative strategies are used to help patients compensate for deficits in cognitive and social functioning.

Avoiding Treatment Errors

The diagnosis of schizophrenia can be made only after other organic causes of psychosis are ruled out. Psychosis also occurs in severe depression and bipolar illness; these and other psychiatric conditions should be considered when making the diagnosis. It often takes several weeks for antipsychotic treatment to achieve its full benefit, so the temptation to escalate the dose of an antipsychotic prematurely should be avoided. All antipsychotics can have severe and life-threatening side effects; the treating physician should be aware of and carefully monitor for the presence of side effects of the prescribed antipsychotic. Many of the newer atypical antipsychotics are associated with the metabolic syndrome, which can cause significant long-term morbidity and mortality; weight, serum glucose, cholesterol, and triglycerides should be routinely monitored.

Management of Medical Illness

Medical illness is common in patients with schizophrenia, and the recognition and treatment of medical illness presents a challenge to clinicians. Individuals with schizophrenia have high rates of morbidity and mortality related to a variety of medical conditions, including cardiovascular disease, infections, endocrine disorders, and cancer. This high rate of morbidity and mortality is probably related to the side effects of antipsychotic medications (especially the newer atypical antipsychotics), high rates of smoking, low physical activity, poor nutrition, and high levels of chronic stress.

Psychiatrists and other physicians fail to diagnose medical conditions in one third to one half of patients with schizophrenia and a comorbid medical disorder. Psychotic symptoms and cognitive dysfunction, as well as elevated pain thresholds associated with schizophrenia, interfere with symptom recognition, symptom reporting, and seeking help on the part of the patient. From the physician's perspective, a frightening, unhygienic patient with imaginary voices and delusions may be assumed to have imaginary medical problems. Physicians must be alert to high rates of unreported and unrecognized medical illness in patients with schizophrenia. Once a medical illness is diagnosed, it is important to anticipate how the positive and negative symptoms and cognitive dysfunction of schizophrenia might affect a patient's ability to participate in treatment.

Future Directions

There is a clear need for improved pharmacologic treatment of schizophrenia. Only 35% to 45% of patients with schizophrenia have their positive symptoms well controlled by antipsychotic medication, and an estimated 33% are considered to be treatment resistant. In addition, available antipsychotics have potentially serious side effects. Medi-

cations that treat negative symptoms and cognitive dysfunction have the potential to improve functional outcome. There is new interest in recognizing and treating schizophrenia before the onset of gross psychotic symptoms with the hope of preventing the progression of the illness and improving long-term outcome. Continuing advances in understanding brain development and functioning from basic neuroscience studies will ultimately improve our ability to define the causes and pathogenesis of schizophrenia and should lead to improved preventive and therapeutic efforts.

Phase 2 of the CATIE study evaluates treatment for patients with a poor response to the initial trial of antipsychotics.

Emotional and Behavioral Problems among Adolescents and Young Adults

Introduction

Emotional and behavioral problems among adolescents and young adults are associated with substantial morbidity, mortality, and health care costs. Young people experiencing these problems are more likely to participate in behaviors leading to negative outcomes such as injuries, sexually transmitted infections, and unwanted pregnancy. Frequently such problems herald the onset of psychiatric disorders including major depression, bipolar affective disorder (BPAD), and schizophrenia that will require lifelong treatment. Emotional and behavior problems may complicate management of chronic illness in youth by influencing choices about adherence to treatment plans. In all these situations, individuals' life trajectories may be affected by the establishment of maladaptive patterns of behavior and negative influences on major life decisions about education, work, and family. Finally, adolescents and young adults with emotional and behavioral problems are at increased risk for suicide and homicide, the second and third leading causes of death in this age group.

Etiology and Pathogenesis

A broad spectrum of emotional and behavioral problems are seen among adolescents and young adults. The etiology of most problems appears to be multifactorial, with genetic, biologic, social, and developmental factors contributing to varying degrees.

Clinical Presentation

Many adolescents and young adults with emotional and behavioral problems first present in medical rather than mental health care settings. Common presentations include the following:

- Physical symptoms directly related to underlying mental health problems
- Mental status changes that raise questions about underlying medical versus mental illness

- Negative health outcomes of behaviors precipitated by underlying mental health problems
- Worrisome symptoms elicited during routine health care evaluation, which should include a psychosocial history asking about family and peer relationships, school and vocation, alcohol and other drug use, sexual behaviors, emotional health, and body image

Youth experiencing emotional or behavioral problems that are seriously affecting their life and functioning are usually not “just going through a phase” of normal development, and evaluation must include a physical examination and assessment for psychiatric disorders.

Depressive Disorders

The prevalence of major depressive disorder (MDD) in adolescence is estimated at 4% to 8% with a male-to-female ratio of 1 : 2. Symptoms include the following:

- At least 2 weeks of marked change in mood or loss of interest and pleasure
- Significant changes in patterns of appetite, weight, sleep, activity, concentration, energy level, or motivation

Symptoms must impair relationships or performance of activities. Comorbid psychiatric conditions are common, including anxiety disorders, learning problems, attention-deficit/hyperactivity disorder (ADHD) and substance abuse. Adolescents tend to display more irritability and behavioral problems and fewer neurovegetative symptoms than adults with MDD. Hallucinations are also more frequent. Clinical variants include atypical depression with increased sleep and weight gain, seasonal affective disorder, and dysthymia with chronic changes in mood and motivation but few neurovegetative symptoms. About 25% of youth with major depression will attempt suicide within 5 years.

Anxiety Disorders

There are several different anxiety disorders seen in youth, with estimated prevalence ranging from 0.3% to 4.6%. These include panic disorder (0.6% prevalence), post-traumatic stress disorder (PTSD) (about 1%), generalized anxiety disorder (4.6%), obsessive-compulsive disorder (1.9%), and various phobias. Distribution by gender varies by disorder and age of onset.

In each of these disorders, there are unwanted, disturbing thoughts or worries that negatively affect the youth's functioning. Panic disorder is characterized by the presence of panic attacks with at least four somatic symptoms, including palpitations, dyspnea, nausea, dizziness, sweating, paresthesias, and gastrointestinal discomfort. Early onset of panic disorder is associated with greater morbidity. Youth with PTSD often have experienced recurrent traumas and may have difficulty identifying a clear precipitant.

Bipolar Affective Disorder

The overall prevalence of BPAD is 2%, with one third of adults reporting onset during adolescence. There are no significant gender differences. The diagnosis requires the presence of at least one episode with manic symptoms including the following:

- Significantly elevated, expansive, or irritable mood associated with functional impairment
- Significant distractibility, pressured speech, racing thoughts, grandiosity, agitation, and decreased need for sleep

Mixed manic and depressed episodes are common. Youth tend to have more frequent, but shorter, episodes with more severe psychotic symptoms than adults. Youth with bipolar disorder are at even greater risk for suicide than those with major depression. They are also likely to be involved in dangerous sexual and physical activities with numerous health risks.

Substance Use Disorders

Substance use is very common among adolescents and young adults, especially the use of alcohol. To be considered a problem, substance use must produce dysfunction in one or more domains of a patient's life and cause clinically significant levels of distress or impairment. The most common features among adolescents are impairment in psychosocial and academic functioning. Substance use disorders are often associated with other psychiatric disorders and significantly increase the risk for suicide in those disorders.

Eating Disorders

Estimates of the lifetime prevalence of anorexia nervosa range from 0.5% to 3.7% and of bulimia nervosa range from 1.1% to 4.2%. Eating disorders are more common in females (male-to-female ratio of 1:6 to 1:10), and onset usually occurs during adolescence and young adulthood.

Symptoms of anorexia nervosa include the following:

- Refusal to maintain weight at or above a minimally normal weight or failure to gain weight during a period of expected growth
- Intense fears of gaining weight
- Disturbance in body image
- Absence of at least three spontaneous menstrual cycles in postmenarchal females

Symptoms of bulimia nervosa include the following:

- Recurrent episodes of binge eating characterized by eating large amounts of food in a short period and inability to control eating
- Recurrent inappropriate compensatory behavior to prevent weight gain (e.g., self-induced vomiting, misuse of medications, fasting, or excessive exercise)
- Binge eating and inappropriate compensatory behaviors have both occurred at least twice a week for 3 months
- Self-evaluation is unduly influenced by body shape and weight

Patients with anorexia nervosa often present to medical settings with weight loss or amenorrhea. Patients with either disorder may present with complications of severe electrolyte disturbances. Occasionally patients present with constipation or esophageal tears. Rates of comorbid psychiatric diagnosis among patients with eating disorders are high (50% to 75%). Mortality rates vary according to age of onset, length of disease, and presence of purging behaviors. Death is typically from cardiac arrhythmia or suicide. In general, younger adolescents have the best and adults have the worst outcomes.

Schizophrenia Spectrum Disorders

Schizophrenia affects 1% of the adult population. Sixty percent of those affected have symptoms during adoles-

cence. Although equal numbers of males and females are affected, males typically have earlier onset with more severe symptoms. At least two of the following symptoms are required for diagnosis:

- Delusions
- Hallucinations
- Disorganized or illogical speech
- Catatonia or grossly disorganized behavior
- Negative symptoms (social withdrawal, apathy, and poverty of speech)

Frank symptoms are often preceded by transient hallucinations or delusions, social isolation, or deterioration in social and academic functioning. Substance use may trigger symptoms in biologically vulnerable individuals or may reflect efforts to self-medicate. Youth tend to have less systematized delusions and more complex hallucinations than adults. The main variant is schizoaffective disorder with intermittent affective symptoms but persistent psychotic symptoms. One in ten individuals with schizophrenia commits suicide.

Attention-Deficit/Hyperactivity Disorder

The estimated prevalence of ADHD is 5% in the school-age population with male-to-female ratios ranging from 4:1 to 9:1. As many as 80% have symptoms persisting into adolescence and 65% into adulthood. Infrequently ADHD is diagnosed in adolescents and young adults, although there should be a history of attentional difficulties in childhood.

Symptoms may be predominately inattention, predominately hyperactivity with impulsiveness, or a combination of both. Symptoms typically are present in situations that are unstructured, boring, or require sustained mental effort. Adolescents often complain of restlessness rather than hyperactivity. Other psychiatric illnesses such as major depression and schizophrenia may also reduce attention.

Differential Diagnosis

When evaluating emotional and behavioral disorders in adolescents and young adults, it is important to recognize that the same symptoms may occur in different disorders. For instance, striking changes in appetite and weight may be seen in anorexia nervosa, major depression, schizophrenia, and substance abuse. Generally the diagnosis is dependent on the constellation of symptoms observed and their developmental course. It is also essential to consider non-psychiatric etiologies of the symptoms such as medical illness or reactions to medications.

Diagnostic Approach

The evaluation and management of adolescents and young adults should be conducted in a developmentally

appropriate manner. Issues to consider include chronological age, cognitive development, psychosocial development, and parental relationships. Youth often provide more accurate reports about their affective state, anxieties, and cognitive processes than their parents, but may have difficulty recognizing behavioral, functional, and social problems. Legal, ethical, and professional guidelines have been developed for managing confidentiality when providing health care to minor adolescents.

The general approach to diagnosis of emotional and behavioral problems in youth includes the following:

- Complete history and physical examination, including a detailed neurologic examination
- Gathering additional information from family and other sources (e.g., school personnel)
- Judicious use of laboratory tests to exclude primary medical conditions
- Consultation with or referral to a mental health professional as needed

All adolescents and young adults with emotional and behavioral problems should be assessed for risk for suicide. Factors that place youth at highest risk for suicide include male gender, previous suicide attempt, substance abuse, MDD, agitation, psychosis, and family history of suicide.

Management and Therapy

Optimum Treatment

The American Academy of Child and Adolescent Psychiatry publishes Practice Parameters guiding the treatment of adolescents with emotional and behavioral disorders.

General management strategies encourage the adolescent or young adult to take an active role in treatment. Health care providers and families should provide support and guidance. Treatment often includes the following:

- Individual cognitive, behavioral, and supportive therapy
- Family therapy and education
- Psychopharmacology

Cognitive therapy has been demonstrated to be particularly effective in the treatment of anxiety disorders and milder cases of depression. Behavior therapy is often essential for the treatment of eating disorders, substance abuse disorders, ADHD, and BPAD. Education about the illnesses and their treatments are essential in all disorders.

Medication treatments are effective in adolescents. Serotonin reuptake inhibitors are typically the first line of treatment for major depression and anxiety disorders and may also be useful in the treatment of some eating disorders. Some of the newer antidepressants may be alternatives. Tricyclic medications have been established to be ineffective antidepressants in youth. Antidepressants are associated with increased suicidal thoughts and behavior in about 4% of treated youth (particularly during the early phases of treatment) regardless of diagnosis.

Concerns about the safety of antidepressants in adolescents need to be weighed against clear risks for inadequately treated depression.

Mood stabilizers, including lithium, valproic acid, carbamazepine, and many newer antiepileptic agents, are the cornerstone of treatment for BPAD. Each of these agents can have significant systemic side effects, including renal, liver, and hematologic changes. Increasingly, newer antipsychotics are being used for first-line treatment of BPAD without psychotic features. Antipsychotic medication is essential for youth with psychotic symptoms, whether associated with depression, BPAD, or schizophrenia. The newer antipsychotics have relatively few extrapyramidal side effects but often result in considerable weight gain and increased risk for diabetes and lipid abnormalities. Some antipsychotics, particularly risperidone, cause prolactin elevations that may lead to amenorrhea and increased risk for osteopenia in females.

Management of patients who are at high risk for suicide includes measures to ensure their acute safety and treatment for associated emotional disorders. Those at highest risk may need to be hospitalized. Those who do not require hospitalization need to have adequate supervision and support from a responsible adult and a safe home environment. It is essential that firearms be removed from the home and that access is limited to medications.

All adolescents and young adults with emotional and behavioral problems should continue receiving routine health care to monitor for possible health consequences of psychotropic medications and to assess emerging health needs.

Avoiding Treatment Errors

It is particularly important to monitor adolescents' clinical response to medication because the emergence of symptoms of lifelong psychopathology often occurs during this stage of development and definitive diagnoses may not yet be clear. For example, an adolescent who will eventually be diagnosed as having BPAD may first present as an adolescent with clinical signs and symptoms of MDD; treatment with antidepressants may precipitate the first manic episode.

Future Directions

Adolescents and young adults with psychiatric disorders are much less likely to be identified and treated than older adults. Better identification depends on improving com-

munity education about major mental illnesses in youth, recognition in schools, and diagnosis by primary care physicians. Future research needs to focus on prevention, early intervention, and treatment of emotional and behavioral disorders specifically in adolescent and young adult populations. Focus on mental health issues in this age group has the potential to substantially reduce morbidity, mortality, health care costs, and the individual and societal burden of psychiatric illness among youth and across the life cycle.

Alcohol and Substance Dependence and Abuse

Introduction

Humans have used psychoactive substances for thousands of years. Nature has provided most of our psychoactive drugs, including ethanol, morphine, cocaine, and marijuana. However, human ingenuity has enabled us to also develop synthetic molecules with potent psychoactive properties, such as fentanyl, oxycodone, and methamphetamine. Although most cultures accept the use of some psychoactive drugs, which drugs are used and the patterns of use differ across cultures. For example, alcohol consumption is common in the United States, with 60% to 70% of the U.S. population reporting use.

Psychoactive substances can produce medical harm in many ways, but the two principal causes of harm are direct effects of the substance (e.g., cocaine-induced arrhythmia) and behavioral consequences of seeking and using the substance (e.g., missing work recovering from alcohol or activities related to procuring psychoactive substances). Most psychoactive substances share a unique ability to produce addiction in vulnerable individuals. Addiction, or substance use dependence, represents the most severe form of dysfunctional use of psychoactive substances. Addiction is characterized by a compulsive need to use the drug, loss of control over the use of the drug, continued use despite negative consequences, and—particularly for alcohol, opiates, and the sedative-hypnotics—development of physical dependence.

Unhealthy substance use, including addiction, is common. At least 15% of outpatients, 25% to 40% of inpatients, and more than 50% of some specialty unit patients (e.g., psychiatry, burn unit) have a substance abuse problem. Alcohol and tobacco use causes most of these encounters; however, the use and abuse of other drugs is substantial. Concurrent use of two or more psychoactive drugs is common. In some cases, this can lead to unique problems. For example, the metabolic production of cocaethylene after alcohol and cocaine consumption can produce serious arrhythmias and necrotizing vasculitis. Physicians need to understand the consequences of the use of alcohol and drugs of abuse and develop an open-minded approach that considers these agents as potential contributors in every patient encounter.

Etiology and Pathogenesis

Alcoholism, as a disease syndrome, was described independently in 1785 by the American physician Dr. Benjamin Rush and the British physician Dr. Thomas Trotter. Although considerable societal stigma remains, many studies have demonstrated the therapeutic importance of regarding alcohol and drug abuse through a disease concept with both genetic and environmental components. Adoption and twin studies have revealed that genetic factors contribute about 50% to the etiology of substance

use disorders. No single gene is dominant, and multiple genes are being identified, many affecting neurobiologic function.

Significant advances have occurred in understanding the neurobiologic actions of addictive drugs and how these contribute to the disease process. Two components have emerged from the many studies on addiction and the development of the compulsive use pattern that characterizes addiction. First, positive reinforcement occurs from all addictive drugs—these drugs activate the classic dopamine reward pathways from midbrain to nucleus accumbens and

prefrontal cortex. Thus, drugs take on behavioral significance for an individual, and the sensitivity to this effect is likely genetically influenced. Second, over time, alcohol and other drugs produce neuroadaptation such that when the drug is stopped, acute and protracted withdrawal can occur. Acute withdrawal is well understood (see later). Protracted withdrawal, a relatively new concept, lasts for months. Although the symptom profile of protracted withdrawal is still being defined, it likely includes insomnia, stress sensitivity, anxiety, decreased ability to experience pleasure, and other symptoms. These are negatively reinforcing and are significant factors in relapse to use.

Alcoholism and drug addiction are progressive and, not uncommonly, fatal illnesses. Individuals may have cycles of treatment and relapse, never receive treatment, or achieve significant improvement with, or even without, treatment.

Clinical Presentation

The clinical presentation of alcoholism is extremely varied. In a general medical practice or hospital setting, the medical or traumatic consequences of alcoholism are the most common reasons an individual with an alcohol problem comes to a physician's attention. Alcohol has toxic effects on most organ systems, and individuals may present with any of a number of end-stage medical problems (e.g., cirrhosis, pancreatitis), behavioral problems, including depression and insomnia, and a number of less severe medical problems that are exacerbated by alcohol or drug use (Fig. 170-1). Patients in surgical and medical units frequently go into alcohol withdrawal after admission with symptoms of autonomic activation, tremor, confusion, fever, seizures, agitation, and hallucinations. Withdrawal delirium is one of the most common reasons for psychiatry consultations. At the less severe end of the spectrum, alcohol use is known to increase the risk for common medical problems such as essential hypertension, hypertriglyceridemia, and gout. A connection between alcohol use and presenting physical symptoms is commonly not offered. Therefore, physicians should always consider the possible role of alcohol and other drugs of abuse in their clinical evaluation of patients who are acutely ill and hospitalized or who are outpatients with less severe problems.

The clinical presentation of drugs of abuse is also quite varied and can include the following:

- Stimulants: tachycardia, increased blood pressure, ischemia of brain or heart, delusions, grandiose behavior
- Opioids: bradycardia, decreased respiratory rate, miotic pupils, decreased consciousness
- Sedative-hypnotic drugs: bradycardia, hypotension, decreased respiratory rate, decreased consciousness, ataxia
- Hallucinogens: hallucinations, disorientation, anxiety, psychosis

These general findings on presentation are as useful as a more comprehensive list of presenting signs and

symptoms, given the very large number of agents and their association with numerous diseases. There are a number of additional red flags for substance abuse that reflect the physical and social effects of addiction, infection related to intravenous drug abuse, clinical syndromes resulting from accelerated atherothrombosis (from cocaine and other stimulants), and laboratory or physical findings resulting from alcohol or drug-induced end-organ damage. These include the following:

Historical factors: violence, trauma, hematemesis, acute mental status changes, acute psychosis, previous drug abuse, homelessness, criminal behavior, financial deterioration, job loss, seeking a specific controlled substance

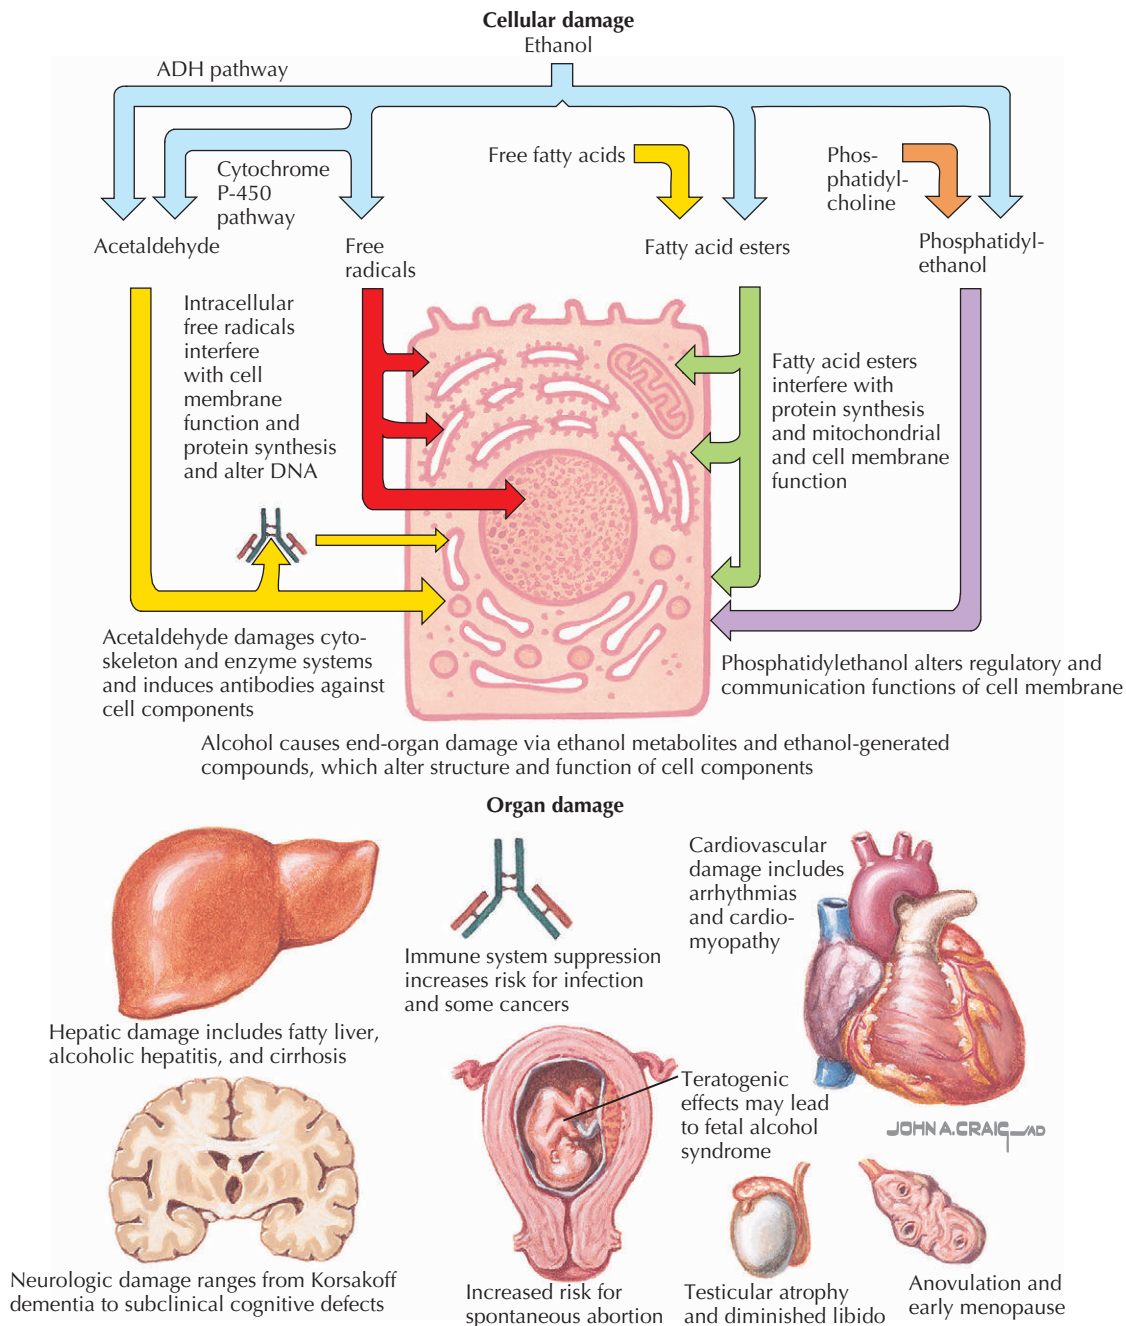

Physical findings: increased or decreased pulse, respirations or blood pressure; poor hygiene; odor of alcohol; jaundice, splinter hemorrhages, needle tracks or spider hemangiomas; miosis or mydriasis; perforated nasal septum; new heart murmur; ataxia, hyperreflexia; combativeness, decreased consciousness; findings inconsistent with the stated level of pain

Diagnostic test results: positive drug screen; ethanol level >0.10 g/dL; elevated liver enzymes; elevated mean corpuscular volume; positive cardiac enzymes in a young person; electrocardiograms showing rapid rhythms; evidence of myocardial infarction (MI) in a young person; computed tomography or magnetic resonance imaging evidence of stroke in a young person

Differential Diagnosis

The differential diagnosis of alcohol use and other drug disorders can be conceptualized as separating the consequences of unhealthy alcohol or drug use from true alcohol or drug addiction, wherein loss of control and compulsive use commonly lead to severe consequences. The diagnosis of alcohol dependence (alcoholism), or drug dependence, as defined by the *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition, includes a maladaptive pattern of substance use, leading to clinically significant impairment or distress, as manifested by three or more of the following, occurring in the same 12-month period (Fig. 170-2):

- Tolerance as evidenced by requiring more alcohol (or drug) to achieve intoxication or less of an effect with continued use of the same quantity of alcohol (or drug)
- Withdrawal symptoms when alcohol (or drug) is stopped
- Alcohol (or drug) taken in greater quantities or for a longer time than intended
- Persistent desire or unsuccessful efforts to reduce use
- A great deal of time spent in using and recovering from alcohol (or drug)
- Important activities given up or reduced because of alcohol (or drug) use
- Alcohol (or drug) use continued despite adverse consequences

Figure 170-1 Effects of Alcohol on End Organs.

Alcohol and drugs of abuse may be the underlying cause of disease in patients not previously known to be abusers. Because known drug abusers are often malnourished, have underlying organ damage, and experience events such as falls or tracheal aspiration while intoxicated, it is common for them to develop other mental and physical illnesses. For these reasons, drug abuse should be a part of the differential diagnoses for most common medical and psychiatric diagnoses.

Some general considerations for drug-related problems are (1) when the working diagnoses are ruled out, think

about drugs; (2) when young patients suffer ischemia (e.g., transient ischemic attacks or MI), consider cocaine or the combination of cocaine and alcohol; (3) when treating a substance abuser (e.g., delirium in a withdrawal syndrome) without getting the expected response, look for a complication (e.g., subdural hematoma); (4) toxic manifestations of one drug (e.g., agitation, tachycardia in cocaine intoxication) mimic the withdrawal symptoms of another (e.g., agitation, tachycardia in barbiturate withdrawal); and (5) drug use is associated with perinatal problems (e.g., premature labor, placental abruption with cocaine abuse) and

Figure 170-2 Alcohol Dependence.

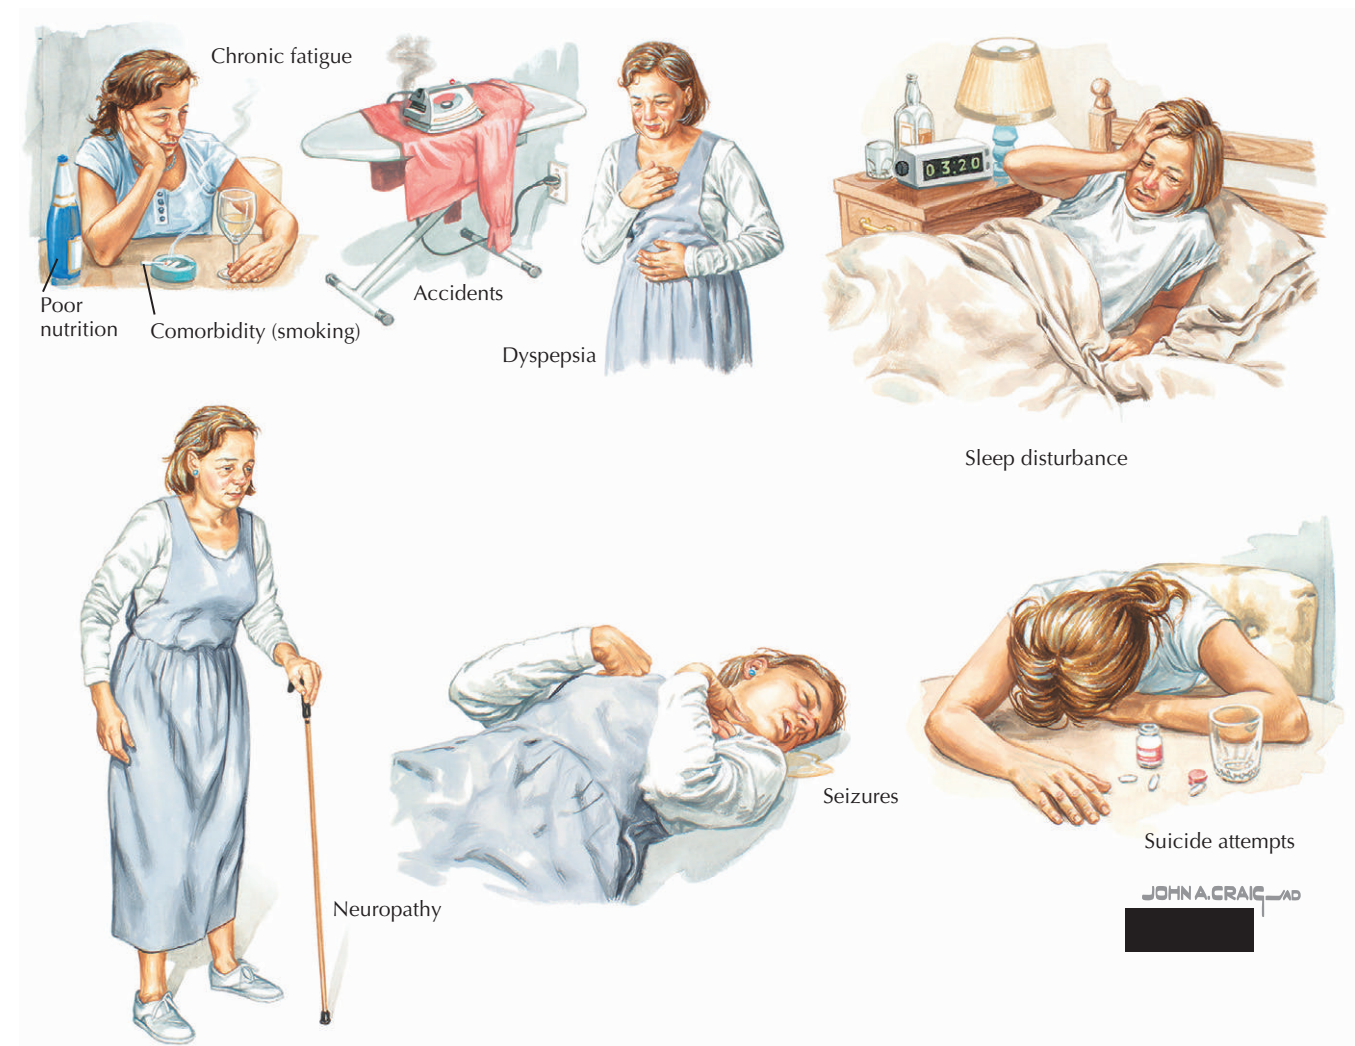

newborn complications (e.g., HIV, opiate withdrawal in infants of heroin-addicted mothers).

Diagnostic Approach

The diagnosis of alcohol and drug use disorders depends on the documentation of signs and symptoms (see previous criteria and Fig. 170-3). Because the diagnosis is based primarily on the history, it is important to gather data on alcohol and drug use patterns and related problems from the patient, as well as from collateral sources of information such as a spouse. In a nonjudgmental fashion, ask the patient about the type, amount, and frequency of substances used. After determining use, its consequences should be explored, including physical symptoms, relationship and employment problems, and emotional and psychological issues.

Screening tests have been developed, including the CAGE (4 questions) and the Alcohol Use Disorders Identification Test (AUDIT, 10 questions), which are easy to administer and provide good sensitivity for detection of alcohol problems (Box 170-1). The AUDIT-C, the first three questions of the AUDIT, focuses just on consumption—how often do you have a drink, how many drinks on a typical day, how often have you had six or more drinks on one occasion—and has shown very good sensitivity and specificity as a simple screening tool. The higher the score on the AUDIT-C, the greater the likelihood that the individual has alcohol-related problems.

Laboratory tests for alcoholism have suffered from a lack of specificity. For example, γ -glutamyl transpeptidase is a reasonably sensitive test of recent heavy alcohol use but is not specific for alcohol use. Recently, carbohydrate-

Figure 170-3 Signs Suggestive of Alcohol Abuse.

deficient transferrin has emerged as a test with improved specificity for heavy alcohol use, and it may be useful when heavy drinking is suspected.

Blood testing for drugs is quantitatively accurate and necessary for managing critical problems but has the diagnostic disadvantage of a relatively narrow window of positivity. Urine drug screens are qualitatively accurate and offer a longer window of positivity (e.g., 48 to 72 hours for cocaine users, 2 to 4 weeks for regular marijuana users). Hair testing is helpful in documenting remote use and use over time. However, hair testing is not quantitatively accurate or readily available, and is expensive.

Laboratory testing may be necessary to make diagnoses; properly manage patients' medical conditions; monitor patients in addiction treatment; screen job applicants; and monitor federal personnel involved in the Departments of Transportation (e.g., pilots, truck drivers) and Defense (e.g., the Army). The federal screening panel includes amphetamines, cannabinoids, cocaine, opioids, and phenylcyclidine. Laboratories are regulated by strict criteria;

certified medical review officers interpret positive results, taking patient histories into account.

Legal and ethical dilemmas of laboratory drug testing include the following:

- *Informed consent.* Ideally, patients should understand the ramifications of getting tested for drug use. Yet, some patients are unconscious on presentation and cannot give consent. Others are minors living in states where parents can demand tests even though the child refuses. Some refusals may be ignored, especially when a patient is intoxicated and not competent to refuse. Inevitably, drug tests sometimes are performed without patient consent.
- *Criminal and civil justice.* For a drug test to be admissible in a criminal court, the following must happen: (1) a chain of custody must be established from the time the sample is collected until the results are introduced into evidence; and (2) the methodology required by the state's courts must be used.

Box 170-1 CAGE and AUDIT Questions

CAGE: One positive answer on the CAGE should raise suspicion; two positive answers on the CAGE is highly predictive of alcohol dependence.

Cut

1. Ever felt you ought to cut down on your drinking?
Annoyed
2. Have people annoyed you by criticizing your drinking?
Guilt
3. Ever felt bad or guilty about your drinking?
Eye Opener
4. Ever had an eye opener to steady nerves in the morning?

AUDIT: A score of 8 or greater on the AUDIT indicates that additional screening should be conducted for alcohol problems. (points in parentheses)

1. How often do you have a drink containing alcohol?
Never (0)
Monthly or less (1)
2-4 times a month (2)
2-3 times a week (3)
4 or more times a week (4)
2. How many drinks containing alcohol do you have a typical day when you are drinking?
1-2 (0)
3-4 (1)
5-6 (2)
7-9 (3)
10 or more (4)
3. How often do you have 6 or more drinks on one occasion?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
4. How often during the last year have you found you were not able to stop drinking once you had started?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
6. How often during last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?
Never (0)
Less than monthly (1)
Monthly (2)
Weekly (3)
Daily or almost daily (4)
9. Have you or someone else been injured as a result of your drinking?
No (0)
Yes, but not in the last year (2)
Yes, during the last year (4)
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?
No (0)
Yes, but not in the last year (2)
Yes, during the last year (4)

Cage test from Ewing JA: *Detecting alcoholism. The CAGE questionnaire.* JAMA 252(14):1905-1907, 1984.

Audit test from Babor TF, de la Fuente JR, Saunders J, Grant M: *AUDIT: The Alcohol Use Disorders Identification Test. Guidelines for use in primary health care.* Geneva, World Health Organization, 1992.

- **Medicolegal liability.** There is legal risk for physicians treating drug abusers without definitive diagnoses. If a patient suffers a bad outcome from a medical condition caused by use of illicit drugs (defined in most states as the fault of the user), but drug use testing was never considered or performed, the treating physician may be held responsible.

Management and Therapy

The treatment of alcoholism and drug use disorders should involve a long-term management approach similar to the treatment of diabetes or hypertension. O'Brien and McLellan have articulated this perspective of a harm-

reduction model viewing substance use disorders as a chronic disease. In this model, the clinician is aware that there will be ups and downs in the course of treatment but that over time many patients will have significant reductions in their use of the substance and fewer substance-related problems.

Optimum Treatment

Alcohol

The initial step in alcoholism treatment is for the clinician to identify alcohol as a problem for the patient and attempt to work collaboratively with the patient on ways to modify drinking behavior. Most patients do not understand the

nature of addiction, nor are they fully aware of the health-related consequences of heavy alcohol use. In these circumstances, patient education is valuable.

The decision whether to medically detoxify a patient depends on the risk for serious withdrawal (i.e., seizures, delirium tremens [DTs]). Factors that increase the likelihood of serious withdrawal include history of seizures or DTs, concomitant medical illness, old age, and to some extent, quantity and frequency of alcohol consumption. Patients who do not have risk factors can be monitored for signs of significant withdrawal. The Clinical Institute Withdrawal Assessment of Alcohol Scale Revised is a useful instrument to quantify withdrawal severity. Patients with risk factors or significant withdrawal symptoms require medical detoxification, and this should be completed in a residential medical setting unless an established outpatient detoxification program is available. Benzodiazepines have been recommended as the treatment of choice for alcohol withdrawal and are highly effective in reducing withdrawal symptoms and in reducing the risk for seizures or DTs. However, DTs develop in some patients despite benzodiazepine treatment. Thiamine should be given parenterally to prevent the development of Wernicke's encephalopathy (confusion, ataxia, ophthalmoplegia) or permanent memory impairment (Korsakoff's syndrome).

Detoxification has been referred to as the first step in alcoholism treatment. Many approaches have been tried to help the alcoholic or alcohol abuser to change his or her drinking behavior, ranging from long-term residential care to brief outpatient visits. To date, no clear algorithms are available to guide the clinician on what specific form of treatment should be recommended for a given patient. However, patients with milder forms of alcohol problems may show improvement in a primary care setting with very brief interventions that provide education, feedback, and encouragement to alter drinking patterns. Patients with more severe alcohol problems usually require more specialized treatment that may include a period of residential care, intensive outpatient treatment, encouragement to attend Alcoholics Anonymous (AA), and medication. The strategies employed in these settings include motivational therapy, cognitive-behavioral relapse prevention therapy, and engagement in the 12 steps of AA. An important element in working with the alcoholic patient is to provide care over time and to avoid therapeutic nihilism. In fact, outcome studies suggest that 50% or so of alcoholics will have at least a 50% reduction in alcohol use 6 months after treatment.

The question of abstinence versus reduced use commonly comes up in early discussions of treatment. For some drugs, such as cocaine and heroin, there is no question that abstinence is the necessary path. For alcohol, the picture can be less clear. For patients with alcoholism and severe consequences, abstinence is the appropriate objective. For patients with unhealthy alcohol use and resistance to abstinence, it is appropriate for the clinician to work

with the patient to reduce use and evaluate the role alcohol plays in the patient's life. Maintaining a therapeutic relationship is more important than demanding a patient endorse lifelong abstinence. Over time, many patients will move toward abstinence.

Medication management of alcoholism is in the midst of significant change that should enhance treatment. For years, the only medication to treat alcoholism was disulfiram, an inhibitor of aldehyde dehydrogenase. Disulfiram produces an aversive reaction (ranging from flushing and headache to profuse vomiting, tachycardia, chest pain, confusion, and other symptoms) when alcohol is consumed and provides a psychological deterrent to alcohol consumption. Its efficacy is related to compliance, and it is particularly valuable in highly motivated patients or with supervised administration. In the United States, disulfiram is usually given as 250 mg/day once a patient is detoxified from alcohol.

Naltrexone represents a newer class of medications for the treatment of alcoholism that do not act by aversive deterrence. Naltrexone is an opioid antagonist that has been shown to reduce the risk for relapse to heavy drinking and, possibly, enhance the likelihood of abstinence. Naltrexone is thought to work by counteracting the "high" experienced after drinking alcohol so that patients are less likely to lose control. Naltrexone is usually started after several days of sobriety and continued for at least several months in combination with psychosocial treatment. In 2006, the U.S. Food and Drug Administration approved a long-acting injectable formulation of naltrexone that is administered once per month. This formulation has been shown to reduce heavy drinking frequency and, in patients with a period of abstinence before injection, to enhance abstinence.

Acamprosate, another relatively new agent, is thought to attenuate overactive *N*-methyl-D-aspartate activity in the brain that may occur after alcohol withdrawal. Acamprosate has been shown to significantly reduce the frequency of drinking and enhance the likelihood of abstinence.

Because of the added value provided by medications and the overall positive risk-to-benefit ratio, clinicians should strongly consider the use of medications along with psychosocial therapy in the treatment of alcoholism.

These broad treatment concepts are also applicable to the management of other drugs of abuse. However, there are specific issues with different classes of drugs about which physicians should be aware.

Opiates

Opiates produce a classic physical withdrawal syndrome that can include diarrhea, nausea, restlessness, piloerection, mydriasis, rhinorrhea, tachycardia, hypertension, fever, insomnia, and drug craving. Serious medical consequences to opiate withdrawal are rare; however, relapse to opiate use is high. Pharmacologic management of opiate withdrawal involves the use of either an opiate agonist such

as methadone, a partial opioid agonist such as buprenorphine, or an α_2 -noradrenergic agonist such as clonidine. Once opiate withdrawal is complete, patients need to be engaged in psychosocial treatment. Some patients may need longer-term agonist treatment with either methadone or buprenorphine in order to achieve stabilization. Buprenorphine may be prescribed by specially licensed physicians in their office, whereas methadone must be provided by a certified clinic. The advantage to agonist therapy is that it has been shown to significantly reduce HIV conversion, legal problems, and use of illegal opiates.

Benzodiazepines and Barbiturates

Benzodiazepine and barbiturate withdrawal can be severe and life threatening. Withdrawal symptoms can include agitation, anxiety, insomnia, tremor, tinnitus, nausea, delirium, hallucinations, tachycardia, hypertension, fever, and in severe cases, seizures and death. The onset of withdrawal is rapid for short-acting drugs such as alprazolam but can be delayed until up to 7 to 10 days for long-acting drugs such as clonazepam or diazepam. Management of withdrawal is usually done with a long-acting benzodiazepine or phenobarbital. No medications are approved for long-term management of benzodiazepine or barbiturate addiction.

Cocaine and Stimulants

Cocaine or stimulant withdrawal is not life threatening and, by itself, is not an indication for hospitalization. Withdrawal symptoms include depression, oversleeping, tiredness, increased appetite, increased dreaming, and drug craving. After withdrawal, patients should be engaged in counseling and encouraged to attend 12-step meetings. No medications are approved for treatment of cocaine or stimulant addiction.

Cannabinoids

Cannabinoid withdrawal in a heavy user does occur and can include irritability, strange dreams, anxiety, and decreased appetite. There are no treatments for cannabinoid withdrawal. The discovery of antagonists for brain cannabinoid receptors (e.g., rimonabant) is of theoretical interest for treatment of cannabinoid dependence, but no large-scale clinical trial data are available.

General Issues

Most clinicians have recovering patients in their practices. Physicians should follow certain principles in the treatment of these patients: use appropriate, nonpharmacologic therapies when possible; be wary of treating anxiety, insomnia, pain, and allergies with sedative-hypnotic drugs or opioids, which may provoke relapse; treat depression and anxiety with drugs that are not addictive (e.g., selective serotonin reuptake inhibitors, buspirone). When an analgesic is needed, the physician and the patient should contract specifically for pain relief. Finally, it is very important

for physicians to offer ongoing support for the patient's recovery.

Avoiding Treatment Errors

The first error to avoid is failure to identify substance misuse as an important factor in a patient's health problems. It is important to be aware that more than one substance is often used by patients. For this reason, it is important to gather additional history and use toxicology screens to enhance the accuracy of the diagnosis. Identification of multiple drug use is important for detoxification and long-term management.

The clinician should remain flexible with regard to the level of care that a patient may need. If a patient is failing less intense outpatient treatment, consider more intense outpatient treatment or residential care.

Compliance with medication use is a common problem. Monitor for compliance by using collateral information and talking to the patient. For patients who have problems with compliance, consider a long-acting formulation where available, such as intramuscular naltrexone.

Future Directions

The development of the disease concept of addictive disorders has been a significant advance for understanding and treating alcohol and drug use disorders. The past 30 years have seen a much more sophisticated description of the biologic and psychosocial forces that lead to addiction. However, far too many individuals remain undiagnosed and untreated. Science will continue to provide new and unexpected insights into the genetic and pathophysiologic basis of addiction, and undoubtedly more effective medications will emerge. Yet, for the benefits of science to be translated to the care of patients, health care providers, policy makers, and the general public will need to realize that the treatment of addiction is not only effective but the most efficient manner in which to use society's scarce resources. Clinicians will be key players in the effort to reduce the stigma of substance use disorders through education and to advocate for adequate resources for treatment.

Urticaria

Introduction

Urticaria is often a source of great frustration to patients and physicians alike. Although the list of reported associations is extensive, many patients have idiopathic urticaria with no obvious cause defined after an extensive evaluation. Also, urticaria is not infrequently recalcitrant to treatment, leading to therapeutic trials of many agents.

Etiology and Pathogenesis

Urticaria results from fluid transudation from tiny cutaneous blood vessels, often with mast cells and histamine acting as mediators. It is subclassified into immunologic and non-immunologic categories. Physical urticaria is nonimmunologic; urticaria associated with food, drugs, or insect stings is often immunologic. The most common allergic mechanism is the type I hypersensitivity state mediated by immunoglobulin E (IgE). Type III (immune complex) reactions can also induce urticaria with activation of classic or alternative complement cascades, as in serum sickness. In non-immunologic urticaria, physical factors or substances cause nonspecific histamine release from mast cells. Genetic factors may predispose individuals to urticaria as evidenced by the hereditary syndromes in Box 171-1. Angioedema is similar to urticaria but involves deeper dermal and subcutaneous tissues. The plasma kinin-generating system may play an important role in types of angioedema. Recent reports have identified autoimmune chronic urticaria as the etiology in about 30% of patients with chronic idiopathic urticaria. In this condition, an anti-IgE antibody of the IgG (immunoglobulin G) class or anti-FcεRIa (Fc-epsilon-RI receptor antibody) cross-links adjacent mast cell receptors or IgE molecules. Many disorders and substances are reported, but not necessarily proven, to be associated with urticaria or angioedema (Boxes 171-1 and 171-2). In chronic urticaria, an etiologic diagnosis is established in less than 20% of patients.

Clinical Presentation

Intensely itching wheals with smooth, elevated, usually white centers and surrounding erythema characterize

urticaria (Fig. 171-1). The lesions range in size from pinpoint to several centimeters and are circular, annular, or serpiginous in shape (Fig. 171-2). Typically, lesions appear in widely distributed crops over the body surface. Variations in presentation of the physical urticarias are given in Table 171-1. Chronic urticaria and physical urticaria can coexist. Contact urticaria is most prominent where the inciting substance has contacted the skin. Adrenergic urticaria presents with a halo of white skin around a small papule and is associated with stress. A single wheal tends to last less than 24 hours. Usually no constitutional symptoms are present; however, nausea, vomiting, abdominal cramping, headache, salivation, wheezing, and syncope may accompany urticaria.

Angioedema presents as an area of painful swelling, often initially around the eyelids, lips, or on a limb, that can persist for several days. In hereditary angioedema, an autosomal dominant condition, episodes of nonpruritic swelling occur either spontaneously or after minor trauma. Erythema may develop before the swelling occurs, but typically urticaria is absent. Laryngeal edema, which is often life threatening, and gastrointestinal involvement can complicate the clinical presentation.

Differential Diagnosis

If individual lesions last more than 24 hours, have a violaceous hue, show hyperpigmentation, are painful and nonblanching, or are associated with signs and symptoms of a rheumatologic disease, a biopsy is indicated to rule out urticarial vasculitis. In urticaria pigmentosum or mastocytosis, patients can develop pruritic urticarial-type wheals

Box 171-1 Disorders Associated with Urticaria or Angioedema

Acquired angioedema	Hereditary disorders and syndromes
Adrenergic urticaria	Arthritis, hives, angioedema
Atopy	C3b inactivator deficiency
Autoimmune anti-IgE or anti-FcεRI	Cold-induced autoinflammatory syndrome
Bacterial infections	Erythropoietic protoporphyria
Dental abscess	Familial cold urticaria
Genitourinary infection	Hereditary angioedema
<i>Helicobacter pylori</i>	Muckle-Wells syndrome (urticaria, deafness, amyloidosis)
Mycoplasmal infection	Schnitzler's syndrome
Sinus infection	Malignancy
Streptococcal infections	Carcinoma
Endocrine disorders	Leukemia
Hyperthyroidism	Lymphoma
Progesterone	Myeloma
Fungal infections	Polycythemia vera
Candida	Rheumatologic disorders
Dermatophytosis	Necrotizing vasculitis
Hematologic disorders	Polymyositis
Iron deficiency anemia	Rheumatoid arthritis
Paraproteinemia	Rheumatic fever
Infestation and parasites	Sjögren's syndrome
Amebiasis	Still's disease
Ascaris	Systemic lupus erythematosus
Filariasis	Viral infections
Giardiasis	Coxsackie virus
Hookworm	ECHO virus
Malaria	Cytomegalovirus
Scabies	Epstein-Barr virus
Schistosomiasis	Hepatitis B and C viruses
Strongyloides	HIV
Trichomonas	Mononucleosis

Box 171-2 Substances Associated with Urticaria or Angioedema

Blood products	Foods
Contactants	Berries
Animal dander and saliva	Cheese
Arthropods	Chocolate
Foods	Eggs
Latex	Fish
Marine forms	Gluten
Medications (topical)	Milk
Plants	Nuts
Textiles	Shellfish
Toiletry items	Tomatoes
Drugs*	Food additives
Anesthetics	Sulfites
Angiotensin-converting enzyme inhibitors	Tartrazine
Antiepileptic agents	Implants
Aspirin	Amalgam fillings
Bromides	Intrauterine devices
Cephalosporins	Orthodontic bands
Chloroquine	Platinum
Dextran	Tantalum staples
Diuretics	Insect and arthropod stings and bites
Isoniazid	Inhalants
Nonsteroidal anti-inflammatory drugs	Animal dander
Opioids	Cigarette smoke
Penicillins	Dusts
Polymyxin B	Flour
Quinidine	Mold
Sulfa drugs	Pollen
Radiographic contrast media	
Vancomycin	

* Almost any prescription or over-the-counter medication can cause urticaria.

Table 171-1 Physical Urticaria		
Type of Urticaria	Clinical Appearance	Method to Test for Presence
Aquagenic	Small punctate pruritic wheals in a follicular pattern on an erythematous background	Wet compresses at 35° to 36° C for 30 minutes
Cholinergic	Small (2-3 mm), very pruritic papules on a large erythematous background (Fig. 171-3)	Use methacholine skin test or immerse in hot bath of 42° C, raising body temperature 0.7° C
Cold	Wheal assumes the shape of the stimulus with surrounding erythema	Wheal and flare within 10 to 15 minutes at the site of application of an ice cube, maintained for 5 minutes
Dermatographism	Linear cutaneous wheal greater than 3 mm long, surrounded by a flare	Stroke skin on back firmly with tongue blade or dermatographometer
Delayed pressure	Raised, painful, erythematous, deep-seated swellings that develop in areas 4 to 8 hours after pressure exposure	Use 15 pounds of weight slung over the shoulder for 15 minutes with the patient walking during the test
Local heat	Erythema, pruritus, urticaria	Apply warm compress to forearm
Solar	Urticaria in exposed areas (Fig. 171-4)	Expose skin to defined wavelengths of light
Vibration-induced angioedema	Pruritus, erythema, and local swelling in the area confined to application of a vibratory stimulus	Gently apply lab vortex to forearm for 4 minutes

Figure 171-1 Urticaria.

Figure 171-2 Annular and Serpiginous Urticaria.

Figure 171-3 Cholinergic Urticaria.

Figure 171-4 Solar Urticaria.

at the sites of the mast cell infiltrates in the skin. The skin lesions, however, are often persistent red-brown papules or macules that can urticate with stroking (the Darier sign). Pruritic urticarial papules and plaques of pregnancy, typically seen in the third trimester, are characterized by pruritic erythematous papules and urticarial plaques with onset typically in the striae distensae of the abdomen. In papular urticaria, a hypersensitivity syndrome, lesions are more persistent, typically on the lower extremities, and thought to be caused by insect bites. Erythema multiforme and the urticarial phase of bullous pemphigoid are often also considered in the differential diagnosis. Serum sickness occurs 8 to 10 days after administration of a foreign protein; fever, lymphadenopathy, arthralgias or arthritis, splenomegaly, and nephritis may develop in addition to urticaria. Laboratory findings include leukopenia, hypocomplementemia, and albuminuria.

Diagnostic Approach

A thorough history and review of systems are key, with emphasis on timing of attacks, provoking factors, and associated signs and symptoms (Box 171-3). The timing of urticaria in comparison with a list of exposures is helpful in determining an underlying cause. Often a diary of food intake and exposures will help determine any associations. Almost any medication may cause urticaria, so trials off medication are often necessary. To exclude urticarial

vasculitis, characterized by urticarial lesions lasting longer than 24 hours, a wheal should be circled and observed. A skin biopsy, done at the edge of a wheal, will clarify the diagnosis. If a particular allergen is suspected, scratch, intradermal, or radioallergosorbent testing is helpful. Aeroallergens, dermatophytes, foods, and candida can be tested. Allergy to aeroallergens warrants consideration if there is a history of rhinitis or asthma.

Urticaria is defined as chronic if it persists for 6 weeks or longer. The laboratory workup for chronic urticaria includes a white blood cell count, differential count, and sedimentation rate. Other tests to consider include a thyroid-stimulating hormone level and thyroid microsomal (peroxidase) and thyroglobulin antibodies. In the case of chronic urticaria, testing for *Helicobacter pylori* infection could also be considered. Additional tests, based on history and physical examination, may include urinalysis and urine culture, liver function tests, hepatitis B and C serologies, antinuclear antibody, complement levels, serum IgE, streptococcal throat culture, monospot, stool for parasites, vaginal smears for *Candida* and *Trichomonas* species, and chest radiograph. If serum sickness is suspected, urinalysis, CBC and sedimentation rate are indicated. The autologous serum skin test is the only in vivo method to test for functional autoantibodies to FcεRIa or IgE. In vitro testing for functional autoantibodies is not widely available.

In hereditary angioedema, C4 levels, which remain depressed between attacks, are a reliable screening test, but hereditary angioedema must be confirmed by C1 inhibitor level and function. An IgE-mediated allergic or drug reaction or a parasitic infection is high on the differential list if eosinophilia or elevated IgE is present. An elevated erythrocyte sedimentation rate suggests a systemic disease or urticarial vasculitis. Testing for physical urticaria is done as described in Table 171-1. In cold urticaria, laboratory testing may include cryoglobulins, cryofibrinogens, VDRL, cold hemolysis, and α_1 -antitrypsin. Adrenergic urticaria is diagnosed by intracutaneous injection of noradrenaline.

Management and Therapy

General Management

General recommendations for allergen avoidance and assistance by the patient in determining possible causes are important (Box 171-4). Ideally, the cause of the urticaria is determined and eliminated. In physical urticaria, the associated physical factor should be avoided. Because aspirin and nonsteroidal anti-inflammatory medications can function as histamine releasers and cause exacerbation of urticaria, they should be discontinued. Patients with physical urticaria, such as cold urticaria, should be warned that intense exposure to the inciting agent (such as diving into a cold pool) can result in massive angioedema and anaphylaxis.

Box 171-3 Diagnosis

- Obtain a thorough history and physical exam and tailor evaluation based on individual clues.
- Perform a physical exam to look for urticaria and angioedema. Check for dermatographism.
- Consider examination for the physical urticaria in atypical cases.
- If individual lesions last more than 24 hours, have a violaceous hue, show hyperpigmentation, are painful or nonblanching, or are associated with signs and symptoms of a rheumatologic disease, a biopsy is indicated to rule out urticarial vasculitis.
- If urticaria is chronic:
 - Consider obtaining a white blood cell count, differential count, and sedimentation rate.
 - Consider also obtaining thyroid-stimulating hormone level and thyroid microsomal (peroxidase) and thyroglobulin antibodies.
 - Consider testing for *Helicobacter pylori* infection.
 - Overall, tailor diagnostic testing to the individual history and examination.
- Obtain complement studies if isolated angioedema is present or if hypocomplementemic vasculitis is being considered.
- A C4 level can be used as a screen for C1 esterase inhibitor deficiency, which may be associated with a family history of angioedema.

Box 171-4 General Management Recommendations

- Urticaria accompanied by asthma, laryngeal edema, or circulatory collapse is treated as a medical emergency.
- Adrenaline emergency packs should be prescribed for patients with a history of severe urticaria or angioedema.
- Advise patients to avoid aspirin and nonsteroidal anti-inflammatory medications.
- Advise patients to avoid foods known for being allergens such as nuts, peanuts, and shellfish.
- Ask patients to keep a food and hive diary.
- For chronic urticaria, consider an elimination diet.

Box 171-5 Antihistamines Used for Urticaria

- Cetirizine, 10 mg once daily
- Chlorpheniramine, 4 mg every 4-6 hours
- Cyproheptadine, 2-4 mg every 6-8 hours
- Desloratadine, 5 mg once daily
- Diphenhydramine, 25-50 mg every 6 hours
- Doxepin, 10-25 mg every 12-24 hours
- Fexofenadine, 120-180 mg daily
- Hydroxyzine, 25-50 mg every 6 hours
- Loratadine, 10 mg once daily

Drug Therapy

Acute urticaria is usually treated with antihistamines and, if severe, with corticosteroids. An acute episode of urticaria, accompanied by asthma, laryngeal edema, or circulatory collapse, is treated as a medical emergency with epinephrine, systemic corticosteroids, oxygen, intravenous fluids, or even airway intubation. The prescription of adrenaline emergency packs is critical for patients with a history of severe urticaria or angioedema.

H₁ blockers are often the first-line treatment (Box 171-5). Treatment with the tricyclic antidepressant doxepin takes advantage of its combination of H₁ and H₂ blockade. Alternatively, the addition of an H₂ blocker like ranitidine (150 mg orally every 12 hours) or cimetidine (300 mg orally every 8 hours) to an H₁ blocker offers some advantages.

For chronic urticaria, it is best to avoid prescribing corticosteroids whenever possible. Other treatments that may have value include mycophenolate mofetil, antileukotrienes, cyclosporine-attenuated anabolic steroids, nifedipine, dapson, sulfasalazine, colchicine, methotrexate, hydroxychloroquine, cyclosporine, ultraviolet B, and psoralen plus ultraviolet light of A wavelength. Some clinicians use estrogen therapy for autoimmune progesterone urticaria. In patients with autoimmune thyroiditis, urticaria has been reported to respond to thyroxine, even when the patient is euthyroid.

Cyproheptadine is effective for cold urticaria in some patients. In physical urticaria, induction of tolerance is sometimes possible. Adrenergic urticaria responds to β -blocker therapy.

Acute treatment and short- and long-term prophylaxis of hereditary angioedema are important, and the treatment must be tailored to the severity. Agents, available in the United States, that have shown some efficacy are fresh-frozen plasma, attenuated androgens, and epsilon aminocaproic acid.

Avoiding Treatment Errors

The diagnostic workup for chronic urticaria is important in an attempt to identify and eliminate any underlying causes; however, the testing must be carefully tailored to the patient's history and physical exam findings. In chronic urticaria, the use of long-term corticosteroids should be avoided whenever possible.

Optimum Treatment

Nonsedating H₁ blockers are often preferred in chronic urticaria. It is not unusual for H₁ blockers to be used at increased dosages, for two H₁ blockers to be given in combination, or both. H₂ blockers added to the regimen may improve control. A variety of corticosteroid-sparing immunosuppressive agents have been studied for their use in urticaria and may be helpful for certain patients.

Future Directions

Further study of autoimmune chronic urticaria and development of a reliable commercial test of functional autoantibodies implicated in this process seem important for better classification of these patients. Also, whether proposed disease associations such as chronic urticaria and *H. pylori* are real or merely coincidental remains to be determined. Latex allergy is important as a cause of urticaria and anaphylaxis. The future should bring better control of the use of latex in our environment and better preventive measures to avoid sensitization of individuals.

New antihistamines are undergoing testing and may result in improved treatments. Recently, two distinct mast cell populations have been identified, and their homeostasis between inhibition and activation is under study. Research is likely to lead to drugs directed against these specific subtypes. Better classification of patients with autoimmune urticaria may allow improved diagnosis and appropriate treatment of this entity with immunosuppressive agents. Several promising drugs to treat hereditary angioedema, including drugs to replace the C1 inhibitor protein and others to decrease bradykinin-mediated vascular permeability, are undergoing testing in the United States.

Eczema and Other Common Dermatoses

Introduction

Eczema is a term broadly applied to many inflammatory skin conditions or dermatoses, characterized by the presence of pruritus, erythema, scaling, macules, papules, plaques, or vesicles. Evaluation of the patient with eczema or dermatitis should include a thorough history focusing on onset (acute versus chronic), inciting and exacerbating factors, associated medical conditions, and family history of similar or related diseases. On physical examination, attention is paid to individual lesion morphology, pattern, and distribution. A potassium hydroxide preparation of skin scrapings is often helpful in differentiating superficial fungal infection from other causes of scaling dermatitides. Punch biopsy can also be helpful in identifying specific dermatoses. A complete description of each of the clinical entities that can cause eczematous dermatitis is beyond the scope of this chapter, but many excellent resources are available for in-depth study of this reaction pattern.

ATOPIC DERMATITIS

Etiology and Pathogenesis

Atopic dermatitis is an immune-mediated disease. Most patients have a personal or family history of atopic disease (allergic rhinitis, asthma, and atopic dermatitis). In affected areas, a predominance of T-helper type 2 cells produce interleukins that cause elevated immunoglobulin E and eosinophil levels. Controversy exists on the role of potential food and other environmental allergens in the pathogenesis of atopic dermatitis.

Clinical Presentation

The major feature of atopic dermatitis is pruritus. In adults, chronic flexural involvement with lichenified erythematous plaques is common (Fig. 172-1). The plaques are distributed symmetrically on the face, neck, and antecubital and popliteal fossae. However, significant involvement of the dorsal hands and feet can occur. Exacerbations typically occur during dry weather and episodes of stress. Even during periods of relative remission, individuals usually have dry and sensitive skin. Secondary bacterial or viral infections involving the affected areas should always be considered during acute exacerbations that are unresponsive to previously effective therapy.

Differential Diagnosis

The intense pruritus and symmetric distribution distinguish atopic dermatitis from other scaling eruptions. Seborrheic dermatitis, irritant dermatitis, and contact dermatitis should be considered.

Diagnostic Approach

Bacterial and viral cultures can dictate therapy in secondarily infected plaques. Skin biopsies are rarely necessary.

Management and Therapy

Optimum Treatment

Affected skin has an impaired barrier to transcutaneous water loss. Therefore, efforts to improve and maintain skin hydration are helpful. Daily bathing can be useful in rehydration if a gentle soap (Cetaphil, Dove) is used sparingly and moisturizers are applied after bathing. Immediate (within 3 minutes) application of thicker moisturizers like petrolatum, Eucerin, and Aquaphor is effective during winter months, whereas lighter products (Cetaphil cream) are better tolerated in warmer weather. Recent U.S. Food and Drug Administration–approved topical emollients are claimed to repair barrier function by including ceramides. Regardless of the vehicle, emollients should be applied twice daily, following application of topical steroids, if indicated.

Figure 172-1 Atopic Dermatitis.
Lichenified plaques of the antecubital fossa are typical.

Oral antihistamines can be quite effective in controlling episodes of pruritus. Awareness of possible sedation with the use of these products is important.

Topical corticosteroids are the mainstay of treatment. The location and thickness of the plaque should guide the choice of an agent. Corticosteroids are best used in pulsed applications such that a particular agent significantly improves the area in 1 week. Topical pulsing avoids the chronic use of topical steroids and reduces the risk for steroid atrophy and striae. Low-potency steroids can be used intermittently on the face and neck. Potent and ultra-potent steroids are occasionally necessary for thickened, lichenified plaques on the extremities. With all topical corticosteroids, ointments are more potent than creams, which are more potent than lotions.

Crusted and weeping lesions frequently demonstrate secondary bacterial infection. Topical soaks or compresses with aluminum acetate (Domeboro) are indicated for these lesions, followed by steroid application. Oral antibiotics (antistaphylococcal, antistreptococcal) may be necessary for multiple areas of infection. Given the increasing rates of community-acquired oxacillin-resistant *Staphylococcus aureus* infections, a low threshold for surface culture to provide directed antibiotic therapy is recommended.

Other Therapies

Conclusive safety data remain elusive for topical calcineurin inhibitors, such as tacrolimus (Protopic) and pimecrolimus (Elidel). Reported malignancies after use of topical

immunomodulators are not typical of calcineurin inhibitors used systemically, and these malignancies likely existed before use of the topical medication. The current recommendation is to use these preparations as second-line therapy in patients 2 years of age or older. Long-term studies and clinical experience will better address potential side effects of this class of medication. When topical agents fail, the next step is systemic therapy, such as phototherapy, azathioprine, or cyclosporine.

CONTACT DERMATITIS

(Refer to Chapter 173 for a more complete review.)

Etiology and Pathogenesis

Contact dermatitis may develop secondary to an allergic or an irritant response. Allergic contact dermatitis represents a cell-mediated immune response to haptens, small molecules that modify endogenous macromolecules in the skin. Re-exposure to antigen results in repeated bouts of cutaneous inflammation as a result of the generation of antigen-specific memory T cells. In contrast, irritant contact dermatitis represents a response to a non-immune-mediated injury to the skin from prolonged or repeated exposures to noxious substances. Soaps, detergents, and organic solvents are typical agents that cause irritant contact dermatitis.

Clinical Presentation

Acute contact dermatitis is a very pruritic eruption characterized by erythema, papules, vesicles, and bullae corresponding to the pattern and exposure of the contactant (Fig. 172-2). An acute vesicular eruption in a geometric pattern is essentially pathognomonic for acute contact dermatitis. Chronic contact dermatitis presents as lichenified, scaling, erythematous, hyperpigmented or hypopigmented papules, plaques, or both.

Differential Diagnosis

Contact dermatitis should be distinguished from other eczematous processes, including atopic dermatitis, nummular eczema, seborrheic dermatitis, and lichen simplex chronicus.

Diagnostic Approach

The onset, distribution, and pattern of the reaction are helpful in identifying responsible contactants. Biopsy is rarely indicated.

Management and Therapy

Optimum Treatment

Identification and removal of the offending agent is necessary. Frequently this requires eliciting an extensive history to determine the relationship of the patient's exposures to

Figure 172-2 Contact Dermatitis.

Linear distribution of erythematous papules and vesicles characterizes contact dermatitis to poison ivy.

the onset, exacerbations, and ameliorations of the dermatitis. For example, eyelid dermatitis is often an allergic contact dermatitis to nail polish (transferred when the patient rubs the eyelids), and ear lobe involvement is often caused by nickel in earrings. Patch testing may be helpful in identifying potential allergic contactants. High-potency topical corticosteroids, emollients, and antihistamines will generally be sufficient to resolve the condition once the exposure has been identified and eliminated. For vigorous, generalized, acute contact dermatitis, such as can be seen in response to poison ivy, systemic corticosteroids may be indicated. Prednisone (40 to 60 mg by mouth daily) tapered over 2 to 3 weeks prevents flares experienced with shorter-duration oral corticosteroid dose packs.

SEBORRHEIC DERMATITIS**Etiology and Pathogenesis**

The etiology of seborrheic dermatitis is uncertain. Individuals appear to have an exuberant response to increased numbers of *Malassezia furfur* in lesional skin; however, the exact role of this organism in the pathogenesis is unclear.

Clinical Presentation

Seborrheic dermatitis is a chronic inflammatory disease with periods of remissions and exacerbations. It is characterized by greasy scale overlying erythematous patches involving the eyebrows, nasal bridge, and nasolabial folds. Extension to the forehead and postauricular areas is often seen (Fig. 172-3). On the scalp, diffuse dry scale (dandruff) is common. Intertriginous areas (axillae and groin) can have sharply demarcated erythematous patches with yel-

Figure 172-3 Seborrheic Dermatitis.

Erythema and greasy yellow scale of the forehead, eyebrows, nasal bridge, and nasolabial folds.

lowish, greasy, or waxy scale. Progression to exfoliative erythroderma is a rare event.

Differential Diagnosis

In some patients, seborrheic dermatitis can be difficult to distinguish from psoriasis. Intertrigo, candidal infection, and atopic dermatitis should also be considered.

Diagnostic Approach

Cultures of intertriginous lesions will differentiate candidal intertrigo.

Management and Therapy**Optimum Treatment**

Generally, seborrheic dermatitis is more responsive to treatment than psoriasis. Treatment for 3 to 5 days is

usually adequate to control flares. Shampooing with zinc pyrithione (Head and Shoulders, DHS Zinc), selenium sulfide 1% or 2.5% (Selsun Blue), salicylic acid (T/Sal), or ketoconazole 1% or 2% can decrease scalp scale. Facial and intertriginous areas typically respond to periodic application of 1% or 2.5% hydrocortisone, 1% or 2% ketoconazole cream, or sulfur-based products (sulfacetamide lotion, 5% or 10%). Resistant cases may need brief application (twice daily for 5 to 7 days) of medium-potency corticosteroids (fluocinolone .01% or .025%) and should be evaluated for possible secondary bacterial or fungal infections.

STASIS DERMATITIS

Etiology and Pathogenesis

Poor venous return leads to edema, which affects the diffusion barrier of oxygen and nutrients to the epidermis. These chronic changes result in inflammation.

Clinical Presentation

Typically, stasis dermatitis occurs on the lower extremities of elderly patients as a bilateral, pruritic, erythematous, scaling macular and sometimes papular eruption. Chronic stasis dermatitis can result in pigment deposition from hemosiderin and from postinflammatory hyperpigmentation. Pitting edema is present. Chronic stasis dermatitis can progress to ulceration.

Differential Diagnosis

Potassium hydroxide preparation of skin scrapings aids in differentiating stasis dermatitis from dermatophytosis. Cellulitis is usually unilateral, acute in onset, and associated with constitutional symptoms and leukocytosis.

Diagnostic Approach

Usually, the clinical presentation is quite characteristic. When ulceration is present, other causes of ulcer formation should be considered, including arteriolar disease, vasculitis, infection, malignancy, and pyoderma gangrenosum. If warranted by clinical suspicion, biopsy may be helpful in excluding nonstasis entities.

Management and Therapy

Optimum Treatment

Decreasing lower extremity edema by leg elevation, daily compression stockings, and medical management of underlying cardiovascular disease is essential. Low- to mid-potency topical corticosteroids reduce cutaneous inflammation and pruritus. Frequent emollients aid in preventing exacerbations after the inflammation has resolved. Stasis ulcers respond well to Unna boots, a medicated compression dressing.

DERMATOPHYTOSIS

Etiology and Pathogenesis

The superficial mycoses of the skin, hair, and nails are caused by fungi that can be classified in three genera: *Epidermophyton*, *Microsporum*, and *Trichophyton*. The fungi are transmitted from multiple sources, including soil (geophilic), animals (zoophilic), and humans (anthropophilic). Genetic susceptibility and immunosuppression promote dermatophytosis. Once infected, the incubation period can be as little as 2 to 4 days before skin lesions are evident.

Clinical Presentation

Tinea faciei and corporis present similarly with annular, erythematous, scaling patches and plaques (Fig. 172-4). The borders are described as active, with more erythema and elevation, whereas the centers tend to be clear and flat. Tinea pedis can be quite inflammatory with weeping and vesiculation or noninflammatory with dry, scaling, minimally erythematous patches. Onychomycosis presents as a thickened nail plate with subungual debris. The plate will often separate from the underlying nail bed.

Tinea capitis is unusual in individuals after adolescence. Inflammatory lesions can develop into boggy, indurated, erythematous plaques called *kerions*. Noninflammatory lesions present with scaling papules and patches with broken-off hairs. Pruritus and occipital lymphadenopathy are common findings with tinea capitis.

Differential Diagnosis

Tinea faciei can be confused with lupus erythematosus, seborrheic dermatitis, contact dermatitis, and atopic dermatitis. Onychomycosis must be distinguished from psoriasis, atopic or contact dermatitis, lichen planus, chronic paronychia, and trachyonychia. Tinea capitis should be

Figure 172-4 Tinea Faciei.

Serpiginous bordered, erythematous plaque with central clearing.

differentiated from pediculosis, atopic dermatitis, seborrheic dermatitis, psoriasis, and bacterial infection.

Diagnostic Approach

The performance of a potassium hydroxide preparation of the scale, hair, or nail from affected lesions is essential in the diagnosis of dermatophytosis. Cultures can also be obtained from affected areas and placed on Mycosel or dermatophyte test medium culture. Alternatively, skin scrapings or brushings may be submitted for a dermatophyte screen, which will also provide speciation. In cases in which nail clippings fail to identify a fungal etiology, nail plates can be clipped and fixed in formalin for histologic evaluation with periodic acid–Schiff staining. Rarely, skin biopsies are needed to diagnose dermatophytosis. Wood lamp illumination of the scalp is no longer helpful in the diagnosis of tinea capitis because the more common fungi do not fluoresce.

Management and Therapy

Optimum Treatment

Multiple antifungal preparations are available for topical and oral dosing. Consideration of the extent and location of the infection dictates the route. Localized tinea faciei, corporis, pedis, and cruris can be treated effectively with topical agents (clotrimazole, miconazole, econazole, oxiconazole, ketoconazole, terbinafine, naftifine, ciclopirox, and butenafine) twice daily for 1 week after the eruption resolves. Extensive skin disease is more effectively treated with oral therapy (terbinafine, itraconazole, or fluconazole). Regular use of antifungal powders can be useful in preventing recurrences of tinea cruris and pedis. Erosive tinea pedis may be secondarily infected with gram-negative organisms; therefore, topical or oral antibacterial therapy should be considered as an adjunct to antifungal therapy.

Involvement of hair or nails requires systemic therapy. Griseofulvin is still the drug of choice for childhood tinea capitis at 20 to 25 mg/kg/day (micronized) or 15 to 20 mg/kg/day (ultramicrozoned) for 8 to 12 weeks. As more literature and experience are available, the newer allylamines (terbinafine) and triazoles (itraconazole, fluconazole) may replace griseofulvin with easier dosing and shorter treatment duration. Onychomycosis requires 3 to 4 months of therapy (terbinafine or itraconazole). Most insurance companies will not approve the course of therapy for onychomycosis until diagnosis is confirmed through culture or potassium hydroxide examination. Rare cases of hepatic failure have been reported with several of the oral antifungal agents. Patients should be screened for underlying hepatic disease before the use of these systemic medications. Recurrences are not unusual; preventative measures (antifungal cream or powder) may be helpful after a course of oral therapy. Combining systemic antifungal medications with topical antifungal medications may result in slightly higher mycologic and clinical cure rates.

Avoiding Treatment Errors

It is essential to distinguish noninfectious inflammatory dermatoses such as atopic dermatitis and contact dermatitis from tinea. Physicians treating these disorders should have a low threshold for performing a potassium hydroxide preparation and be comfortable interpreting the results.

Future Directions

Corticosteroids have been the therapeutic mainstay for treatment of eczema and dermatitis; however, chronic use results in dermal atrophy and tachyphylaxis. Extensive investigations by numerous researchers have led to a more precise understanding of the molecular and cellular events that are required to generate cutaneous inflammation. Using this information, nonsteroidal drugs are being developed that target specific components of the immune response. For example, bioengineered macromolecules that modify immune cell responses by disrupting antigen presentation and cytokine secretion profile will likely broaden the therapeutic armamentarium available to treat particularly recalcitrant eczema and dermatitis.

Allergic Contact Dermatitis

Introduction

Allergic contact dermatitis (ACD) is a common skin disorder characterized by pruritic erythematous papules and vesicles that develop after repeated contact with an allergen. ACD accounts for 20% of occupational contact dermatitis and is the second most frequent dermatologic diagnosis. Worldwide, the most common contact allergen is nickel.

Etiology and Pathogenesis

ACD occurs from exposure to environmental allergens, usually small-molecule substances. These allergens bind to class II molecules on the antigen-presenting cells of the skin, primarily Langerhans cells, and are subsequently presented to effector T lymphocytes in the lymph nodes. Initial sensitization may take 7 to 14 days for a specific antigen. Once sensitization has occurred, the antigen may elicit a clinical response within hours to days through a delayed-type hypersensitivity reaction. However, individuals can also become sensitized by low levels of chronic exposure to certain antigens over years, such as cement workers chronically exposed to low levels of chromium.

ACD is more common in women, presumably because of allergens in jewelry, especially nickel. ACD can affect all ages, and allergen exposure also varies with age. The top four allergens in the United States are nickel sulfate, neomycin sulfate, balsam of Peru, and fragrance mix.

Clinical Presentation

Acute ACD may manifest as very pruritic erythematous papules and vesicles days after exposure to the sensitizing agent. Chronic ACD presents as lichenified plaques with scale over a longer period of time. In areas of thin skin such as the eyelids, penis, and scrotum, edematous lesions may appear.

The location of the lesions provides important diagnostic clues (Fig. 173-1). Classic ACD caused by the plant

allergen urushiol in poison ivy and poison oak is characterized by linear streaks of vesicles that are usually seen on the extremities. Patients who present with well-demarcated hand dermatitis on the dorsal aspect may be reacting to chemicals in rubber gloves. Sensitization to nail products, ophthalmologic preparations, and airborne allergens may manifest as eyelid dermatitis. Topical preparations such as benzocaine lead to perianal ACD in susceptible patients. ACD to hair dyes containing paraphenyldiamine often presents with lesions on the adjacent face and ears. ACD over the dorsal feet is often a reaction to rubber accelerators or potassium dichromate in tanned leather. Table 173-1 shows important contact allergens, sources of contact, and usual ACD sites.

A widespread autosensitization eruption may develop from local sites of contact to the offending agent and lead to erythroderma.

Differential Diagnosis

The differential diagnosis of ACD includes irritant contact dermatitis, atopic dermatitis, nummular eczema, dyshidrotic eczema, and even tinea corporis. When scale is present, a potassium hydroxide (KOH) prep should be performed to rule out dermatophytosis. In contrast to ACD, tinea pedis usually involves the interdigital spaces and is associated with onychomycosis. Psoriasis of the palms and soles can be confused with ACD but usually has accompanying nail changes and psoriatic plaques elsewhere. In the setting of ACD-induced autosensitization

Figure 173-1 Allergic Contact Dermatitis.**Table 173-1** Contact Allergens, Sources, and Locations

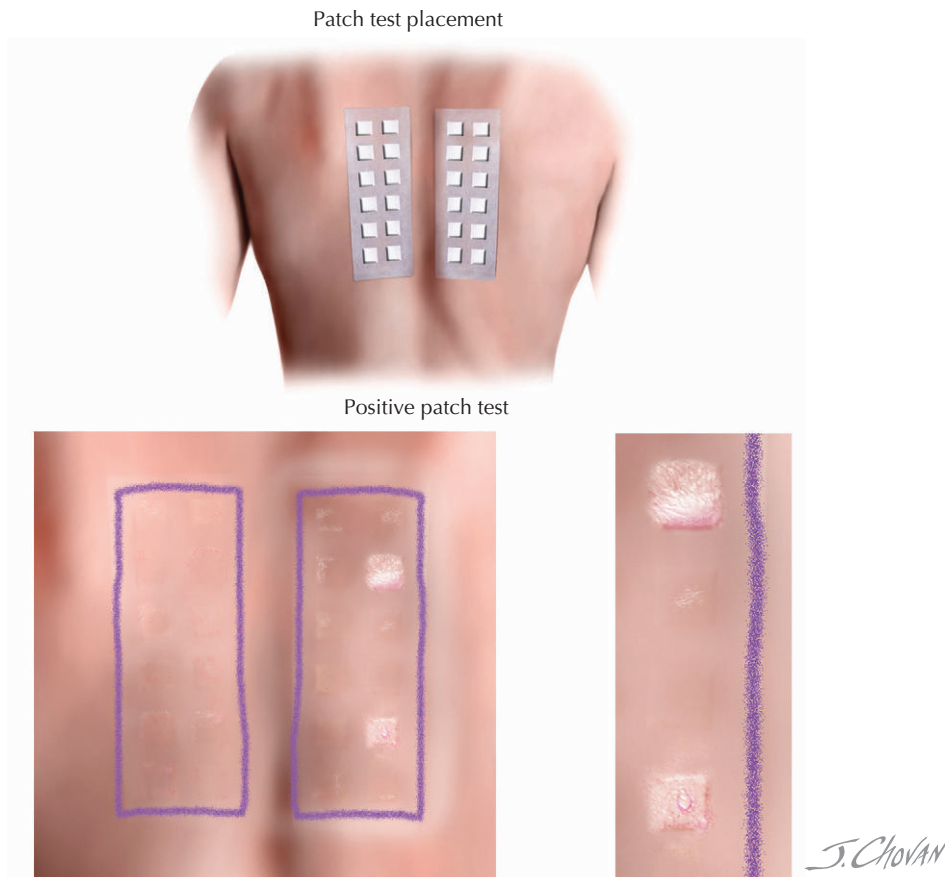

Allergen	Source	Location
Nickel sulfate	Jewelry, clothing snaps	Earlobes, neck, umbilicus
Neomycin sulfate	Topical antibiotic	Wounds
Balsam of Peru	Fragrance, adhesives	Neck
Chromates	Leather and cement	Dorsal feet from leather boots
Paraphenylenediamine	Hair dye	Adjacent face and ears
Toluene sulfonamide	Nail lacquer	Eyelids

with erythroderma, other causes to consider include cutaneous T-cell lymphoma. A skin biopsy provides very useful information: in ACD, microscopy demonstrates epidermal spongiosis and a superficial, perivascular, lymphohistiocytic dermal infiltrate.

Diagnostic Approach

When ACD is suspected, a thorough exploration of the patient's work exposures and hobbies is essential. When occupational exposure is likely, asking whether the condition improves away from the workplace is key. A review of personal care products is also very important. The critical role of a detailed history cannot be overemphasized.

Patch testing remains the gold standard in the diagnosis of ACD. U.S. Food and Drug Administration–approved ready-to-use-skin patch tests are used for the diagnosis of contact dermatitis by most dermatologists. The TRUE (Allerderm) and TROLAB (Hermal) patch test kits are two commonly used commercial products that allow testing for many allergens simultaneously. Some dermatologists and allergy clinics prefer customized skin patch tests (Fig. 173-2). There are also specific allergen panels when occupational exposure is suspected, including a hair-dressing tray or a florist tray. Chemicals that patients bring in should not be used because the substances may cause severe skin damage and all ingredients may not be known.

Figure 173-2. Patch Test.

When a specific allergen is suspected, the patient should be considered for confirmatory patch testing. The most common site for application is the upper back. The patient should not have a sunburn or other significant rash in the test area and should not have used topical corticosteroids on the patch test site for at least 1 week and oral corticosteroids at a dose greater than 15 mg for 1 month before patch testing. Both topical and systemic steroids decrease the patient's ability to produce a positive response.

Once patch testing is planned, the TRUE test strips are applied to the upper back and then reinforced with paper tape. The patient should keep the area dry for at least 48 hours and refrain from activities that cause excessive sweating. Whether oral antihistamines will affect the test results remains controversial. After 48 to 72 hours, the patient should return, the outline of the tests marked, and the patches removed for the first reading. After the initial reading, the patient should ideally return for a second reading 5 to 7 days after the initial patch test placement. The second reading is necessary because some allergens, including gold and disperse blue dye, take a longer time to induce a response.

The patch test is graded by the International Grading System (Box 173-1) and should be interpreted in the context of the patient's current exposures. For example, the clinical significance of a positive reaction to thimerosal

Box 173-1 International Grading System

- ±, Doubtful reaction, faint macular erythema
- +, Weak, nonvesicular reaction with erythema, infiltration, and papules
- ++, Strong, vesicular reaction with erythema, infiltration, and papules
- +++, Spreading bullous reaction
- , Negative reaction
- IR, Irritant reaction

may be minimal because many people are sensitized in their childhood through routine vaccinations. When interpreting the patch test, clinical correlation is recommended. False-positive reactions may occur secondary to *excited skin syndrome*. True allergic reactions tend to itch more than irritant ones. The second reading is particularly important in elderly patients, who may take longer to react. False-negative reactions occur because of a low concentration of the suspected substance, failure to perform a later reading, wet patches, or the influence of corticosteroids.

Management and Therapy

Once the diagnosis of ACD is made, the mainstay of therapy is allergen avoidance. With the TRUE patch test,

information sheets on substances that test positive are provided to the patient. Unfortunately, some allergens are not listed on the label of the offending product. Patients and physicians should also be aware of cross-reacting substances, such as poison ivy and mangos.

For a few allergens, a test kit is available to determine product content. For example, in patients allergic to nickel, the dimethylglyoxime test is commercially available so that patients can test products before purchasing them to determine whether they contain nickel. The feasibility and usefulness of a nickel-free diet are debatable. The elimination of nickel from the diet is very difficult, and little information is available on dietary recommendations for individuals with a true nickel allergy. Canned foods and acidic foods prepared in stainless steel cookware can contain nickel, as can a variety of uncooked foods, such as leafy green vegetables.

Optimum Treatment

In addition to antigen avoidance, therapy should focus on symptomatic care. Patients with ACD to poison ivy manifested by an acute vesicular eruption benefit from using a drying agent such as Burow solution 2 to 3 times per day and from lukewarm oatmeal baths. Patients with lesions that are more chronic in nature should use an emollient such as petrolatum. When significant pruritus is present, oral antihistamines are helpful, such as hydroxyzine, 10 to 25 mg every 6 to 8 hours, plus a longer-acting agent such as cetirizine, 10 mg every 24 hours. Do not use topical antihistamines because they can produce an additional ACD. The presence of superinfected lesions with crusting is an indication for oral antibiotics. Patients should also be advised to cleanse with gentle agents like Cetaphil.

Topical glucocorticoids are indicated in most cases of ACD. For thicker skin areas, including the hands and feet, and for severe cases, a class 1 steroid such as clobetasol ointment can be used twice a day for 3 weeks. A class VI to VII steroid such as hydrocortisone valerate should be used twice a day on thinner skin such as the face and intertriginous regions. For lesions on other body areas, a medium-potency steroid such as triamcinolone 0.1% ointment twice a day will often suffice. In general, ointments are better vehicles to use than creams or gel formulations because they contain fewer ingredients and therefore fewer possible allergens. For ACD inside the oral cavity, a mid-potency steroid gel is better suited. For suspected cases occurring on the scalp, mid- to high-potency steroids are available in solution formulations.

Involvement of greater than 25% of the body surface area by allergic contact dermatitis warrants a course of oral glucocorticoids. Prednisone, 40 to 60 mg daily tapered over a 2-week period, is usually sufficient. If steroid therapy is contraindicated, patients should be referred to a dermatologist for possible narrow-band ultraviolet B treatment

or immunosuppressive medications. The complete clearing of ACD lesions may take as long as 6 weeks.

Avoiding Treatment Errors

One pitfall in the treatment of ACD is the failure to use the appropriate strength of topical glucocorticoid for a given body region. For instance, a 2.5% hydrocortisone ointment will likely not be strong enough to treat an ACD of the hands caused by mercaptobenzothiazole found in rubber gloves. Patients also need to use the topical steroid often and for a long enough period of time. They need to be reminded that results are not apparent overnight. Another common pitfall is the failure to identify the responsible allergen. The result is repeated patient exposure to the antigen during the treatment period with little apparent benefit. A thorough history and significant investigative work are important in avoiding treatment errors.

Future Directions

ACD is a subspecialty of dermatology in which the marriage of history and physical exam is extremely important. Although patch testing remains the gold standard for diagnosis, there are many allergens not contained in currently available commercial patch test kits. There are more than 3700 potential environmental allergens. Future editions of patch tests will most likely contain more allergens to help guide therapy and allow avoidance of the offending agent. Tolerance induction is also an exciting area of research in this area.

Psoriasis

Introduction

Psoriasis is a chronic, relapsing disorder of the skin characterized by sharply demarcated, red plaques with silvery scale in a characteristic distribution. It occurs in 1% to 3% of the population. The lesions are usually distinctive, allowing diagnosis based on physical findings alone. A seronegative destructive arthritis can be seen in association with the skin disease and is more common in patients whose psoriasis begins in childhood.

Etiology and Pathogenesis

Increasing research into the molecular mechanisms of psoriasis has led to an increased understanding of disease pathogenesis. Evidence of a genetic predisposition includes an increased incidence in relatives and children of affected patients and a high rate of concordance in monozygotic twins. To date, six psoriasis susceptibility loci (Psor1-6) have been described. The genes mapped to these regions encode proteins involved in inflammation and epithelial differentiation. For example, Psor1 encodes the major histocompatibility complex, which is involved in antigen presentation. Psor2 has been mapped to the RunX1 transcription factor binding site that regulates transcription of two genes whose protein products regulate association of cytoskeletal proteins and transmembrane proteins. The genes for S100A8 and S100A9, two chemotactic proteins, have been mapped to Psor4. Psor6 has recently been mapped to JunB, a component of the activator protein-1 (AP-1) transcription factor. The polygenic nature of psoriasis may explain its variable presentation.

Psoriasis is currently believed to represent an aberrant immune response in which cytokines and chemokines secreted by inflammatory cells stimulate the keratinocytes to proliferate and differentiate in a pattern suggestive of wound repair. The increased proliferation and altered differentiation manifest histologically as thickened epidermis and parakeratosis, corresponding to the thickened skin plaques with adherent silvery scale observed clinically. Therapies targeting components of this inflam-

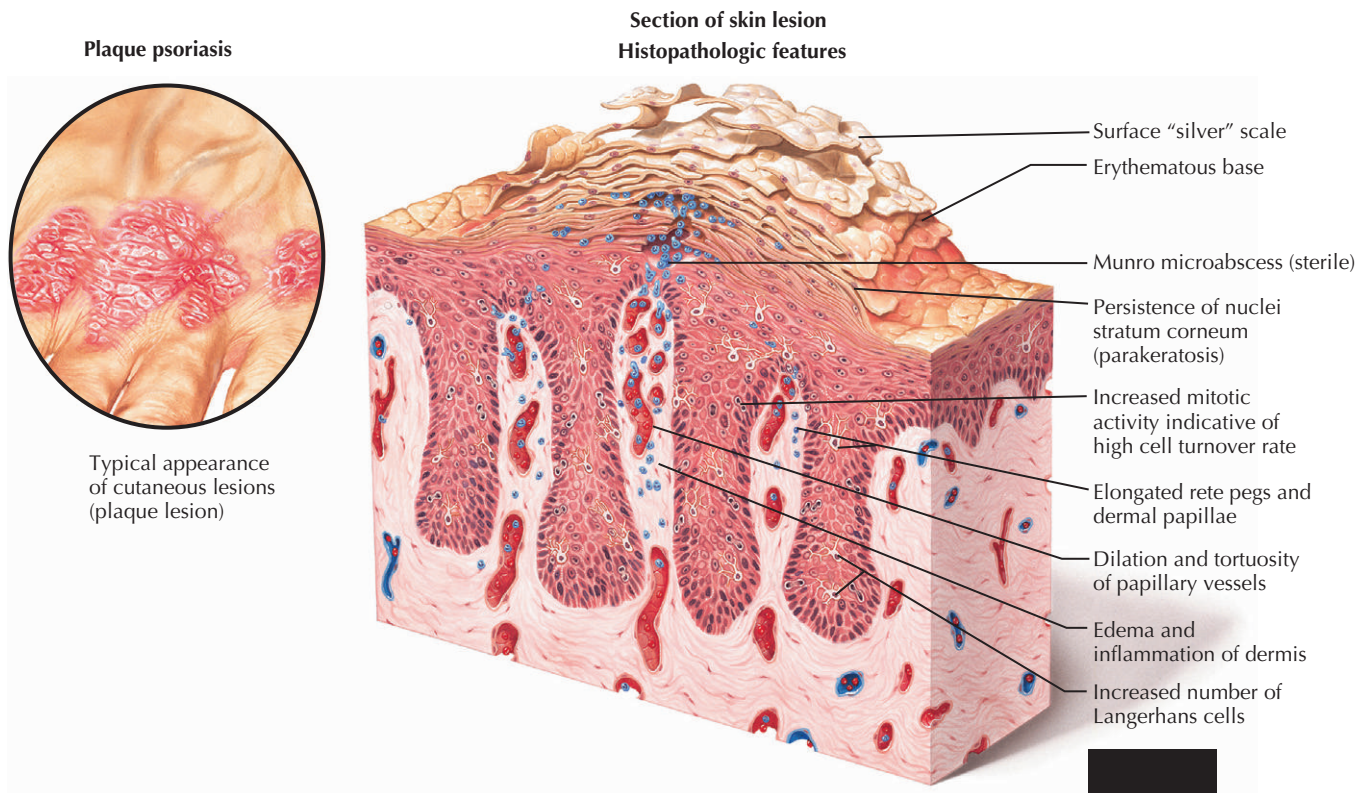

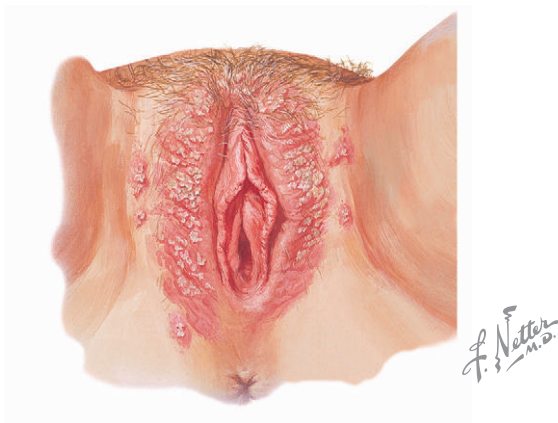

matory cascade, including such drugs as cyclosporine or the newer biologics, are very effective in treating psoriasis.

Clinical Presentation

Psoriasis affects men and women equally. It usually begins in the third decade but can develop at any age. It is clinically distinctive. Psoriasis begins as red, scaly papules that coalesce to form sharply demarcated plaques with adherent silvery white scale (Fig. 174-1). The extent of scaling varies with the body part involved and treatment. Scaling can be quite thick in the scalp and minimal in intertriginous areas and treated sites (Fig. 174-2). The plaques are deep red underneath the scale.

Psoriasis has a predilection for certain cutaneous sites, including elbows, knees, gluteal cleft, scalp, fingernails, and toenails (Fig. 174-3). Nail involvement most commonly appears as pits in the surface of the nail plate; less commonly, oil stains (brown discoloration), onychodystrophy, and onycholysis occur (Fig. 174-4). It has a tendency to spread to sites of skin trauma (Koebner's phenomenon). Lesions may be asymptomatic or extremely pruritic. Most disease is limited to the sites listed previously, but there are many other clinical presentations of psoriasis (Box 174-1).

Psoriatic arthritis follows the onset of the cutaneous manifestations most commonly but may occur at any time. It usually presents as asymmetric arthritis involving one or more joints of the fingers and toes. The affected digit is

Figure 174-1 Psoriasis.**Figure 174-2 Psoriasis in the Genital Area.**

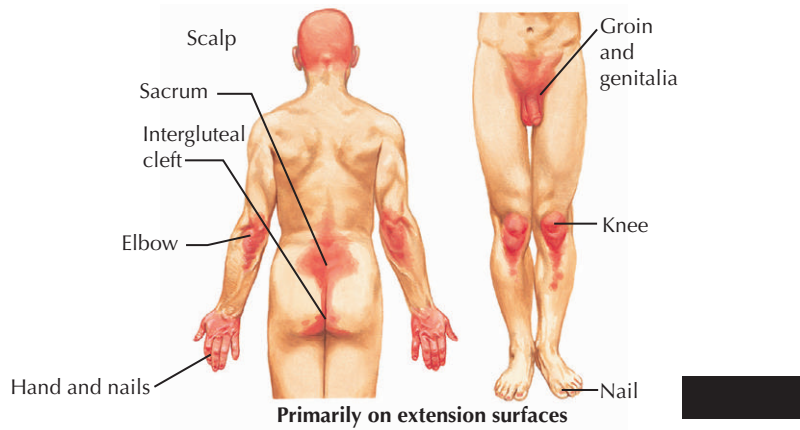

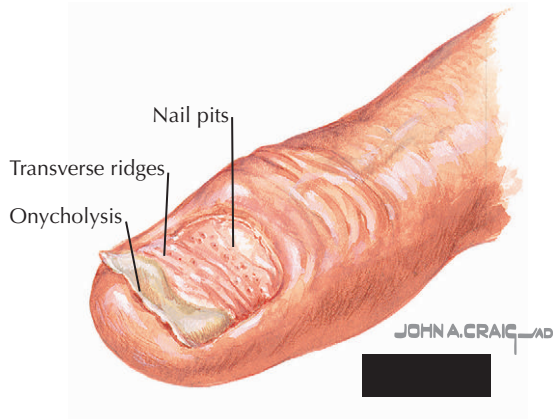

acutely hot and swollen and eventually develops soft tissue swelling producing the so-called sausage digit. There is a 5% incidence of psoriatic arthritis in the psoriatic population; men and women are affected equally. The usual age of presentation is between 20 and 40 years. About 80% of patients have nail involvement. Psoriatic arthritis can be progressive and deforming. Rheumatoid factor and anti-nuclear antibody test results are usually negative.

Box 174-1 Clinical Presentations of Psoriasis

Chronic plaque psoriasis
Guttate psoriasis—acute eruptive psoriasis following streptococcal pharyngitis
Pustular psoriasis
Erythrodermic psoriasis
Psoriasis of the palms and soles
Inverse psoriasis (flexural areas)

Differential Diagnosis

The differential diagnosis often depends on the morphology of the psoriatic lesions. Classic plaque psoriasis is quite distinctive but may occasionally be difficult to distinguish from nummular eczema, mycosis fungoides, atopic dermatitis, or tinea corporis. Guttate psoriasis should be differentiated from secondary syphilis, pityriasis lichenoides et varioliformis, and pityriasis rosea. Scalp psoriasis can be confused with seborrheic dermatitis or eczema. One distinguishing characteristic of scalp psoriasis is its tendency to move onto the forehead. Inverse psoriasis resembles seborrheic dermatitis, tinea, or candidal infection.

Figure 174-3 Psoriasis: Typical Distribution.**Figure 174-4 Psoriatic Nail Involvement.**

Diagnostic Approach

Classic plaque psoriasis is usually diagnosed clinically. Guttate psoriasis is differentiated from secondary syphilis through serologic testing. Pityriasis rosea is excluded by history and histologic examination. When tinea or candida is suspected, potassium hydroxide preparation of scale is helpful. In difficult cases, a punch biopsy can be done for histologic examination. HIV type 1 should be considered in patients with a particularly explosive onset of widespread psoriasis, including assessment of risk factors for HIV infection. HIV testing should be offered to all these patients.

Management and Therapy

Optimum Treatment

Management of psoriasis is determined by several factors:

Amount of body surface area involved: Generally, patients with less than 10% body surface area involvement can

be treated topically; greater than 10% body surface area involvement requires treatment with ultraviolet (UV) light or systemic therapy.

Area of involvement: Select topical medications based on where they will be applied. Potency is guided by the characteristics of the skin being treated. Some topical preparations (calcipotriene and tazarotene) can irritate the face or intertriginous areas. Systemic therapy is also guided by the distribution of lesions. For example, UV light therapy is not a good choice for intertriginous or scalp psoriasis.

Degree of plaque inflammation: Inflammatory, red plaques are irritated and worsened by certain topical therapies, including tar, anthralin, and calcipotriene.

Patient health and mental status: Some patients are unable or unwilling to follow a complicated regimen that includes multiple topical medications. Other patients may not be candidates for systemic therapy. It is important to tailor treatment to the individual needs of the patient.

Topical Therapy Options

Topical steroids offer the advantage of quick response with rapid improvement in inflammation and itching. Tolerance develops fairly quickly, and patients who did very well initially will note decreasing efficacy over time. This often leads to overuse of the preparation in an attempt to recapture the initial dramatic improvement. Patients should be educated regarding this aspect of steroid use. The specific steroid preparation needs to be tailored to the area where it will be applied and the thickness of the psoriatic plaque. Treat the face and intertriginous areas with a class V to VII steroid cream or ointment (Table 174-1). The extremities and trunk can be treated with class IV to I steroid creams or ointments depending on the thickness of the plaques. Hands and feet have thick skin and usually require a class I or II steroid ointment. Ointments have better absorption, making them more effective, but are less well

Table 174-1 Steroid Potency in Psoriasis

Group	Potency	Medication
I	Super high	Clobetasol propionate 0.05% (cream, ointment, scalp solution)
II	High	Fluocinonide 0.05% (cream, ointment, scalp solution)
III	Intermediate	Betamethasone dipropionate 0.05% (cream)
III	Intermediate	Betamethasone-17-valerate 0.1% (ointment)
IV	Intermediate	Fluocinolone acetonide 0.025% (ointment, scalp solution)
V	Low-intermediate	Hydrocortisone butyrate 0.1% (cream)
VI	Low	Desonide 0.05% (cream, lotion)
VII	Very low	Hydrocortisone 1, 2.5% (cream, ointment)

tolerated. Scalp psoriasis can be treated with a class IV to I steroid solution. Most topical steroids are designed for twice-a-day use. Class I steroids can induce atrophy and striae very quickly and cause adrenal axis suppression if applied to a large body surface area. Most practitioners use a class I steroid for 2 weeks, alternating with a 1-week rest period. As patients improve, they can taper the frequency of steroid use. Long-term steroid use should be discouraged. Application twice a week for maintenance is acceptable. Systemic steroids should not be used for psoriasis. Although they rapidly control the disease, withdrawal produces a rebound effect and potential conversion to pustular psoriasis, which requires hospitalization.

Vitamin D analogues including calcipotriene ointment, cream, and solution inhibit the proliferation of keratinocytes and normalize their maturation. These drugs can be effective as single agents, but better results are achieved when they are used along with a potent topical steroid. A typical regimen begins with once-a-day application of calcipotriene and of a class I steroid, which is continued until the plaques begin to thin, usually 2 to 3 weeks. Subsequently, calcipotriene is applied twice a day Monday through Friday, and the class I steroid is applied twice a day on the weekend. This phase can be continued for several weeks or even months. The goal is to use calcipotriene once or twice a day for maintenance as a single agent. Calcipotriene benefits include reduced time to clearance, decreased steroid use, less tolerance to steroids, and prolonged improvement. The most common side effect is irritation at the site of application. It should not be used on the face and intertriginous areas. There have been no reported effects on bone or calcium metabolism if less than 100 g/week is used. Acidic substances such as salicylic acid should be avoided because they inactivate calcipotriene.

Tazarotene (0.05% or 0.1% gel) is a retinoid developed specifically for use in psoriasis. It can be irritating and should only be used in noninflamed stable plaque psoriasis. Topical steroids can be used to help decrease inflammation. Tazarotene is rated pregnancy category X and should not be used in pregnant women. Use in intertriginous sites should be avoided. The advantages of tazarotene are that it is a once-daily dosage that can be used on the scalp, it decreases steroid use, and it often provides a prolonged response.

Psoriatic plaques frequently develop thick, adherent scale that limits the absorption and efficacy of topical medications, particularly on the scalp. Keratolytics including salicylic acid, urea, and lactic acid are available to remove the scale. A lotion or cream containing one of these agents can be applied to psoriatic plaques either concomitantly with other topical medications or separately. The scalp responds well to a lotion or solution containing a keratolytic applied under a shower cap overnight followed by a shampoo in the morning and the application of corticosteroid solution. Improvement within 1 to 2 weeks is typical, allowing for the discontinuation of the keratolytic. Patients should then be instructed to restart keratolytics whenever scale starts to build up.

Systemic Therapies

Systemic therapies should be considered in patients who fail topical medications, those with more than 10% total body surface involvement or palmar plantar involvement, or those with associated arthritis. Narrow-band UV-B phototherapy can rapidly clear patients with extensive skin disease; however, joint disease is not responsive to phototherapy. Care must be taken during administration of these treatments to avoid burning the patient. Additionally, UV-B phototherapy is associated with an increased risk for photodamage and photoaging and skin cancers. This risk appears to be cumulative, and patients who have received phototherapy should be monitored for the development of skin cancer.

Oral medications, including antimetabolites, systemic retinoids, and immunosuppressive agents are very effective at treating psoriasis. These agents should be used with caution and by those experienced with their toxicities and side effects. Methotrexate is an antimetabolite that inhibits dihydrofolate reductase. It is effective in treating both the skin and joint manifestations of psoriasis. Methotrexate can suppress the bone marrow, and patients should be regularly monitored. Additionally, methotrexate can cause hepatotoxicity. Serologic liver function tests and periodic liver biopsies are used to monitor for the hepatotoxic effects of methotrexate. Rare adverse effects, including pulmonary fibrosis, have been reported. Typical doses of methotrexate used for psoriasis are 7.5 to 25 mg weekly.

Supplementation with folate can be helpful in reducing methotrexate-associated gastrointestinal distress and may also lower the risk for cardiovascular disease that has recently been reported to be increased in psoriasis patients. Methotrexate is renally excreted and should be used with caution in patients with renal insufficiency. Nonsteroidal anti-inflammatory agents can decrease renal excretion of methotrexate, and patients should be cautioned on the concomitant use of these medications.

Acitretin is a systemic retinoid used for psoriasis. Because of the potent teratogenic effects, this medication should not be used in women of child-bearing potential. Systemic retinoids are particularly effective for pustular psoriasis but have efficacy in large-plaque psoriasis as well. Side effects, such as dryness, alopecia, and arthralgias, can often be limiting. Regular serologic monitoring includes fasting triglycerides, liver enzymes, and complete blood counts because of the potential for systemic retinoids to cause hypertriglyceridemia, hepatic inflammation, and rarely leukopenia.

Cyclosporine is very effective at treating psoriasis; however, systemic toxicities such as bone marrow suppression and nephrotoxicity limit its chronic use. In our practice, we typically limit the use of this potent immunosuppressive medication to the short-term treatment of acute exacerbations and psoriatic flares. To minimize nephrotoxicity, dosing should not exceed 5 mg/kg/day. Monitoring should include measurement of blood pressure, a complete blood count, liver function panels, renal function (blood urea nitrogen and creatinine), serum electrolytes, uric acid and magnesium.

Biologic agents represent a relatively new class of drugs that have added significantly to the therapeutic armamentarium. These agents are recombinant proteins produced in biologic expression systems and subsequently purified to homogeneity. The limiting factor tends to be the cost, typically being between \$12,000 and 25,000 per year depending on the agent and the dosing regimen. Several drugs are currently approved for the treatment of psoriasis and psoriatic arthritis, including the tumor necrosis factor- α blocking agents etanercept, adalimumab, and infliximab. Efalizumab, a monoclonal antibody directed against the CD11a subunit of LFA-1 (lymphocyte function-associated antigen), disrupts antigen presentation and the ability of lymphocytes to bind to vascular endothelium and keratinocytes. It is self-administered as weekly subcutaneous injections.

Special Considerations

Patients with scalp psoriasis should use medicated shampoos in addition to the agents discussed previously. Formulations with additives such as salicylic acid, zinc pyrithione, selenium sulfide, or coal tar can be helpful. Psoriasis in intertriginous sites is frequently superinfected with candida. The addition of a topical antifungal with yeast coverage is helpful in these patients.

There is a correlation between the severity of psoriasis and the degree of stress the patient is experiencing. Minimizing stress can also improve psoriasis.

Certain drugs, including lithium, β -blocking drugs, antimalarials, and systemic steroids can exacerbate psoriasis and should be avoided.

If the patient has greater than 10% body surface area involvement or remains unresponsive to topical therapy, consider referral to a dermatologist. Dermatologists use UV light, methotrexate, acitretin, cyclosporine, and a variety of other systemic medications to control severe, widespread psoriasis.

Avoiding Treatment Errors

Physicians may underestimate the time and inconvenience associated with use of topical therapies for patients with significant body surface area involvement. Patients may not necessarily admit to not using their topical medications; in this case, the physician assumes that the patient requires more potent medications. Treatment needs to be individualized to the patient with consideration of the patient's lifestyle in order to be optimally effective.

Future Directions

Decades of investigation into the detailed mechanisms of psoriatic inflammation have been translated into new mechanism-based therapies. Additional molecules are currently being investigated and developed to treat patients with psoriasis and psoriatic arthritis. These medicines will continue to improve our ability to care for patients suffering from this very common skin disease.

Bullous Skin Disease

Introduction

Blisters are classified by etiology or location; intraepidermal, dermal-epidermal junction, or subepidermal. Primary causes of blistering include inherited defects in cell adhesion proteins or diseases in which cell adhesion proteins are the target antigens for autoimmune responses. Autoimmune bullous skin disease typically presents in adults and tends to persist in the absence of clinical intervention. Secondary causes include infectious, traumatic, and inflammatory processes. Blistering as a secondary event is often acute in onset, is transient, and resolves with treatment of the underlying disease.

The clinical manifestations of bullous genodermatoses are apparent at birth or shortly thereafter, and similarly affected family members may be identified. Laboratory examination is critical to making a correct diagnosis and should include biopsy for (1) routine histology to determine the plane of cleavage within the skin and the presence or absence and nature of the inflammatory infiltrate, and (2) direct immunofluorescence to identify the nature and location of immunoreactants in the skin. Additional diagnostic studies include indirect immunofluorescent studies, Western blot analysis, immunoprecipitation, enzyme-linked immunosorbent assay, and immunoelectron microscopy (Box 175-1).

BULLOUS PEMPHIGOID

Etiology and Pathogenesis

Bullous pemphigoid (BP) is an autoimmune disease in which immunoglobulin G (IgG) autoantibodies target the basal keratinocyte hemidesmosome proteins BP180 (BP antigen 2) and BP230 (BP antigen 1). Passive transfer of BP180 IgG to neonatal mice causes subepidermal blister formation, demonstrating that the antibodies are pathogenic (Fig. 175-1).

Clinical Presentation

BP typically affects adults in the fifth to sixth decades of life with tense bullae on either a noninflammatory or an erythematous base (Fig. 175-2). BP may be localized or widespread. An urticarial phase may precede the development of frank blisters by 2 to 4 weeks. BP may resolve spontaneously within 2 to 6 years.

Differential Diagnosis

BP can be distinguished from other bullous dermatoses, particularly epidermolysis bullosa acquisita (EBA), by

immunofluorescent studies on salt split skin (see Fig. 175-1).

Diagnostic Approach

Punch biopsy should be performed for routine histologic studies and direct immunofluorescence. Histologic analysis of BP demonstrates a subepidermal blister with an eosinophilic infiltrate. Direct immunofluorescence demonstrates linear staining of the basement membrane with IgG and C3. In BP, immunoreactants localize to the blister roof on salt split skin. About 80% of patients with active disease demonstrate immunoreactants by indirect immunofluorescence.

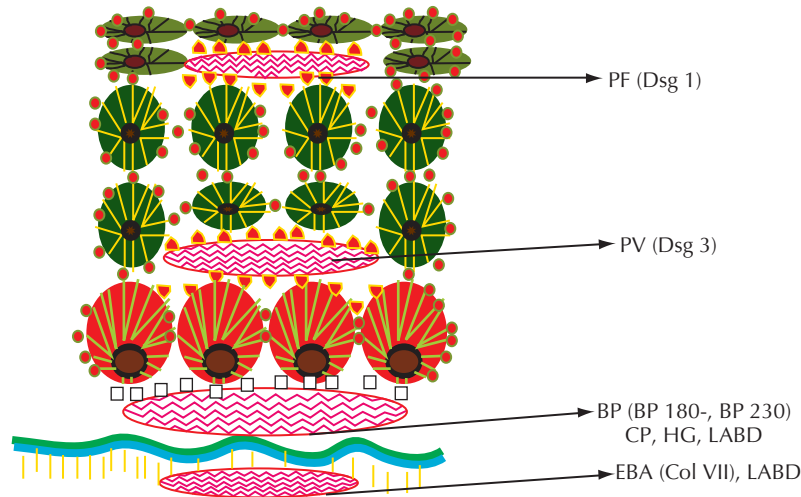

Management and Therapy

Optimum Treatment

Localized BP may respond to ultrapotent topical or intralesional corticosteroids. Initial management should utilize systemic corticosteroids with the subsequent addition of a steroid-sparing agent such as azathioprine. Higher doses of prednisone or additional immunosuppressive agents

- Dermatitis herpetiformis

such as cyclosporine may be necessary to control severe disease. Some patients respond to tetracycline and niacinamide. These agents are particularly useful in the elderly patient with focal stable disease and medical problems exacerbated by prednisone.

BULLOUS PEMPHIGOID-LIKE DISEASES

Related autoimmune diseases in which autoantibodies target the hemidesmosome complex include cicatricial pemphigoid (CP), herpes gestationis (HG), and linear IgA

bullous dermatoses (LABD). CP is a group of chronic, progressive diseases in which autoantibodies target the β_4 -integrin subunit, BP180, or laminin 5. HG is an autoimmune blistering disease of pregnant women. In LABD, a disease of adults and children, IgA antibodies to BP180 and to type VII collagen have been described. These processes present as subepidermal blistering diseases. The workup should include biopsies for routine histologic analysis and for direct immunofluorescence. Immunosuppressive agents, including prednisone, azathioprine, and cyclophosphamide, are used for treatment. For CP, the

Figure 175-2 Bullous Pemphigoid.

Tense bulla and urticarial plaques in bullous pemphigoid. *Courtesy of Dr. Walter Barkey.*

risk for blindness with ocular disease and stenosis with esophageal and laryngeal disease warrants aggressive therapy with high-dose systemic corticosteroids and adjunctive agents (azathioprine or cyclophosphamide). Less aggressive disease with minimal mucosal involvement should be treated with dapsone or ultrapotent topical corticosteroids. HG resolves postpartum; therefore, the goals of therapy are symptom relief and decreased blister formation. Mild disease can often be controlled with antihistamines and topical corticosteroids, whereas aggressive disease may require systemic corticosteroids. LABD is often self-limited in children, spontaneously resolving within several years. In adults, the disease may persist for many years. Dapsone or systemic corticosteroids can be used to control disease. Mucosal disease, particularly involving the eyes, is an indication for aggressive therapy.

EPIDERMOLYSIS BULLOSA ACQUISITA**Etiology and Pathogenesis**

In this autoimmune process, patients make antibodies against type VII collagen, which is the major protein component of anchoring fibrils.

Clinical Presentation

EBA is a disease of middle-aged adults characterized by noninflammatory vesicles, bullae, and erosions on trauma-prone areas (knees, elbows, extensor hands and fingers, sacrum). It heals with scar and milia formation. Permanent nail dystrophy or loss and scarring alopecia may result. A BP-like variant of EBA presents with blisters and vesicles on an inflammatory base.

Differential Diagnosis

Porphyria cutanea tarda can be distinguished by the presence of photoexacerbation, hirsutism, and positive urine porphyrins. Bullous lupus can present with vesicles and bullae identical to those seen in EBA. However, in addition to collagen VII autoantibodies, patients have a positive antinuclear antigen and other more typical lupus erythematosus lesions. The BP-like variant of EBA is distinguished from BP by immunofluorescence on salt split skin.

Diagnostic Approach

Biopsy specimens reveal a subepidermal blister in which the presence of an inflammatory infiltrate is variable. Direct immunofluorescence demonstrates linear staining of IgG with or without C3, IgA, and IgM along the basement membrane zone. Incubating perilesional skin biopsies in 1M NaCl (salt split skin) results in separation of the epidermis from the dermis by cleavage formation within the lamina lucida. In EBA, immunoreactants localize to the dermal side of salt split skin. In BP, the immunoreactants localize to the epidermal side. Indirect immunofluorescence is positive in greater than 50% of patients with EBA. Immunoelectron microscopy demonstrates the localization of immunoreactants below the lamina densa.

Management and Therapy

Immunosuppressive therapy does not alter the course. Avoidance of trauma, hot environments, and wound care are beneficial.

PEMPHIGUS VULGARIS**Etiology and Pathogenesis**

Pemphigus vulgaris (PV) is an autoimmune disease in which autoantibodies target the desmosomal cadherin desmoglein-3 (dsg-3). Passive transfer of anti-dsg-3 PV IgG to neonatal mice reproduces the clinical and histologic findings of PV, demonstrating that the IgG is pathogenic. Studies in both human skin cultures and the PV mouse model suggest that PV IgG triggers intracellular signaling mediated by p38 mitogen-activated protein kinase (MAPK) and heat-shock protein 27. Pharmacologic inhibition of p38MAPK prevents PV IgG-induced blistering in the mouse model.

Clinical Presentation

Patients in their 50s and 60s present with flaccid vesicles, bullae, and erosions of the skin with prominent mucosal lesions (Fig. 175-3). Examination for ocular lesions is imperative; scarring can result in loss of vision. Most patients have oral lesions, often as the initial presentation.

Figure 175-3 Pemphigus Vulgaris.
Flaccid vesicles and erosions of pemphigus.

Lesions are painful, but not usually pruritic. Severe oral pain can lead to decreased oral intake and dehydration. Loss of skin barrier function places these patients at risk for secondary infection and fluid and electrolyte disturbances. Skin fragility is demonstrated by Nikolsky's sign, in which minimal mechanical traction causes lateral movement of the epidermis relative to the underlying structures.

Differential Diagnosis

Histologic studies and immunofluorescence distinguish PV from erythema multiforme major and toxic epidermal necrolysis.

Diagnostic Approach

Biopsy specimens reveal suprabasal acantholysis, which is a loss of cell-cell adhesion just above the basal layer (see Fig. 175-1). Direct immunofluorescence demonstrates IgG outlining keratinocyte cell membranes.

Management and Therapy

Optimum Treatment

PV is life threatening. Untreated, the mortality rate approaches 60%. Rapid therapeutic response necessitates high-dose systemic corticosteroids. Consider adjunctive steroid-sparing agents (azathioprine or cyclophosphamide). Mycophenolate mofetil, as a single agent or as a steroid-sparing agent, is successful in treating PV, pemphigus foliaceus (PF), and paraneoplastic pemphigus (PNP). Ocular involvement should be managed with an ophthalmologist.

Figure 175-4 Pemphigus Foliaceus.
Crusted erosions of the trunk in pemphigus foliaceus.

PEMPHIGUS FOLIACEUS

Etiology and Pathogenesis

In this autoimmune disease, autoantibodies target desmoglein-1 (dsg-1), a major component of suprabasal keratinocyte desmosomes. Anti-dsg-1 PF IgG is pathogenic; passive transfer to neonatal mice reproduces the clinical and histologic findings of PF. Endemic PF, fogo selvagem, occurs in native populations of Brazil. Both hereditary susceptibility and environmental factors likely combine to incite the production of autoantibodies in susceptible individuals.

Clinical Presentation

Acantholysis in the upper epidermis results in fragile vesicles that are often not identified clinically. Examination reveals painful or burning, scaling, and crusted erosions of the scalp, face, and trunk (Fig. 175-4).

Differential Diagnosis

PF is distinguished from exfoliative dermatitis by histologic studies and direct immunofluorescence.

Diagnostic Approach

Biopsy specimens reveal acantholysis in the subcorneal and granular layers of the epidermis (see Fig. 175-1). Direct immunofluorescence shows IgG outlining keratinocyte cell membranes. Indirect immunofluorescence on skin substrates demonstrates antikeratinocyte IgG in 80% to 90% of patients. A highly sensitive and specific enzyme-linked immunosorbent assay is available to detect anti-dsg-1 IgG in PF sera.

Management and Therapy

Optimum Treatment

Local disease is managed with potent topical corticosteroids. Widespread disease is managed with systemic prednisone. Steroid-sparing agents (azathioprine or cyclophosphamide) are added to lower the prednisone dose or if patients fail to respond adequately to prednisone alone.

PARANEOPLASTIC PEMPHIGUS

Etiology and Pathogenesis

Paraneoplastic pemphigus (PNP) is a blistering disease associated with an underlying lymphoproliferative disorder. The autoantibody response may represent an immune response to tumor antigens and includes antibodies to desmoplakin I (250 kD), desmoplakin II, BP antigen 1 (230 kD), envoplakin (210 kD), periplakin (190 kD), dsG-3, and dsG-1. Passive transfer experiments show that the anti-dsG-3 IgGs cause acantholysis.

Clinical Presentation

PNP aggressively involves the oral and ocular mucosa. Pulmonary and esophageal epithelia may be similarly affected. Patients present with painful oral erosions and ulcerations and a variety of cutaneous lesions that may mimic the flaccid bullae and erosions of PV, the crusted plaques of PF, the dusky targetoid lesions of erythema multiforme, or even the widespread erythema and skin necrosis of toxic epidermal necrolysis.

Differential Diagnosis

PNP is distinguished from PV, PF, ulcerative oral lichen planus, erythema multiforme major, and toxic epidermal necrolysis by indirect immunofluorescence on bladder epithelia and by immunoprecipitation studies.

Diagnostic Approach

Biopsy specimens demonstrate variable features, including suprabasilar acantholysis; keratinocyte necrosis, a dense lichenoid infiltrate at the dermoepidermal junction; and subepidermal blistering. Direct immunofluorescence shows IgG and C3 staining of keratinocyte cell membranes. Features consistent with BP include IgG or C3 staining of the basement membrane zone. Differentiation of PNP from other variants of pemphigus is made by (1) indirect immunofluorescence of patient sera on rat bladder epithelium substrates (positive in 75% to 85% of PNP patients, but unusual in PV and PF); and (2) the presence of periplakin and envoplakin autoantibodies in PNP, but not PV nor PF. PNP can affect the palms and soles, which is unusual in PV.

Management and Therapy

Optimum Treatment

Patients with PNP should be evaluated for the presence of an underlying neoplasm. Surgical excision for benign tumors often results in clearing of the disease within 6 to 18 months. When associated with malignancy, PNP is difficult to treat. Numerous therapies have been tried, including treatment of the underlying malignancy, prednisone, azathioprine, cyclophosphamide, cyclosporine, dapsone, and plasmapheresis. However, none is uniformly successful. Most patients with PNP and malignant neoplasms die within 2 years of the onset of PNP. Involvement of the pulmonary epithelium can result in respiratory failure.

DERMATITIS HERPETIFORMIS

Etiology and Pathogenesis

Dermatitis herpetiformis (DH) is an autoimmune blistering disease associated with gluten-sensitive enteropathy; IgA autoantibodies can be identified in the papillary dermis.

Clinical Presentation

DH is a chronic disease that typically affects people in the second to fourth decades and presents as extremely pruritic, grouped vesicles symmetrically distributed on extensor surfaces, typically the scalp, back, elbows, knees, and buttocks. Scratching often makes it difficult to find intact vesicles on physical examination. Examination may reveal only secondary grouped, crusted lesions.

Differential Diagnosis

DH is differentiated from linear IgA disease, BP, HG, scabies, and erythema multiforme by histologic and immunofluorescent studies.

Diagnostic Approach

Biopsy specimens reveal a subepidermal vesicle with papillary dermal neutrophils and variable numbers of eosinophils. Direct immunofluorescence shows granular deposits of IgA at the tips of the dermal papilla.

Management and Therapy

Optimum Treatment

Dapsone is the treatment of choice. Patients respond within 1 to 2 days with decreased pruritus and no new lesion formation. Once control is achieved, the dose should be titrated down to the lowest level that controls disease. The risk for agranulocytosis necessitates monitoring the

complete blood cell count when initiating therapy. Dapsone can cause hemolysis and methemoglobinemia, which can be severe in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. For this reason, G6PD status should be determined before beginning dapsone. Patients on dapsone should be monitored for the development of peripheral neuropathy. Sulfapyridine is an alternative to dapsone. Clearing of DH lesions can occur with gluten-free diets; however, most patients do not tolerate restrictive diets and may take up to 1 year for the skin to clear.

Avoiding Treatment Errors

Many of the blistering disorders described in this chapter are treated with potent systemic or immunosuppressive agents. Use of these agents requires familiarity with their potential side effects. Constant vigilance and thorough monitoring is essential for reducing the risk for adverse events.

Future Directions

Current research on autoimmune blistering disease is aimed at (1) determining the mechanism by which autoantibodies cause loss of keratinocyte adhesion, (2) developing treatments that prevent the loss of cell adhesion without the need for global immunosuppression, and (3) identifying the triggers that incite the autoantibody response. For example, PV IgG trigger activation of p38MAPK within the target keratinocytes and pharmacologic inhibitors of p38MAPK block the ability of PV IgG to induce blistering in the PV mouse model. Several companies are developing inhibitors of p38MAPK. Should these drugs prove safe, p38 inhibitors may prove effective in the treatment of PV. Additionally, ongoing studies of fogo selvagem, the endemic form of PF, have revealed close associations between certain environmental triggers that lead to host cross-reactive immune responses. Studies of fogo selvagem are likely to yield insights into the biology of autoimmunity that extend far beyond cutaneous pathology.

This article reviews the data supporting epidermolysis bullosa acquisita (EBA) as a chronic subepidermal autoimmune blistering disease of the skin caused by antibodies to type VII collagen.

Alopecia

Introduction

Hair loss results from a number of pathologic and physiologic processes (Fig. 176-1). Identification of the causative agents of hair loss enables the clinician to design a rational approach to treatment. This chapter will briefly familiarize the reader with the basic diagnostic tools and treatment options for common causes of hair loss (Box 176-1).

NONSCARRING ALOPECIA

Nonscarring alopecia is hair loss in the setting of a normal-appearing scalp. The hair-pull test will differentiate breaking from shedding.

The hair-pull test is performed by taking 50 to 100 hairs and gently pulling from the scalp. Repeat this several times all over the scalp. If more than a few hairs come out from the roots, the test result is positive. The hair bulbs should be examined under the microscope to determine whether the hairs are anagen or telogen hairs (Fig. 176-2). This will help differentiate between different causes of nonscarring alopecia.

In the patient with brittle hair, the hair pull test will reveal broken off hair with no visible bulb. Patients with brittle hair should be questioned regarding hair care. Improper hair care is the most common cause of brittle hair in adults. Treatment is gentle hair care. Brittle hair in children, in the absence of tinea capitis, can be the result of a heritable structural defect of the hair shaft. These patients should be referred to a dermatologist.

ALOPECIA AREATA

Etiology and Pathogenesis

The precise etiology of alopecia areata is unknown. However, a genetic predisposition and autoimmunity appear important. Alopecia areata is associated with a number of autoimmune disorders, including atopy, autoimmune thyroid disease, vitiligo, diabetes mellitus, Addison's disease, pernicious anemia, systemic lupus erythematosus, and rheumatoid arthritis.

Clinical Presentation

Alopecia areata is most common in children and young adults. It affects men and women equally. Patients note a sudden loss of hair in oval patches (Fig. 176-3). Nonscalp hair-bearing areas are rarely affected. Regrowth occurs after 1 to 3 months. Hair loss may occur in new areas while regrowth occurs.

Examination reveals 1- to 4-cm oval patches of alopecia with a smooth scalp or short stubs of hair (exclamation point hairs). Nail pitting occurs in 3% to 30% of patients.

Differential Diagnosis

Secondary syphilis is in the differential diagnosis.

Diagnostic Approach

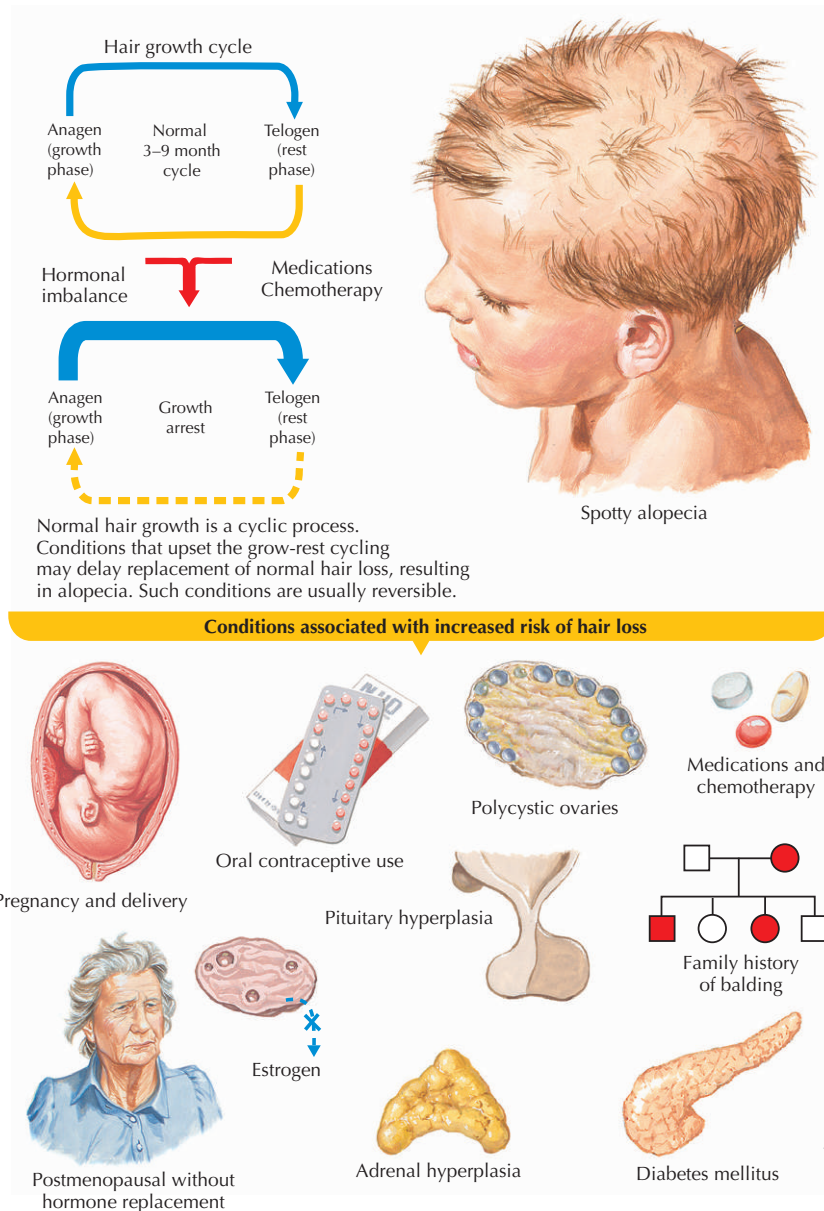

The diagnosis is usually clinical. The hair-pull test shows dystrophic anagen and telogen hairs. Serologic testing should be performed to check for thyroid disorders. Biopsy is rarely necessary.

Management and Therapy

Optimum Treatment

Limited alopecia areata frequently resolves spontaneously, and treatment is not always necessary. The therapy of choice is intradermal injection of triamcinolone acetonide repeated every 4 weeks until regrowth is achieved. Atrophy is the major side effect. Potent topical steroids (clobetasol propionate) in cycles of 2 weeks on and 1 week off are an

Figure 176-1 Hair Loss.

alternative, particularly in widespread disease and in children. Other treatment options include tacrolimus ointment, squaric acid, and topical minoxidil.

ANDROGENETIC ALOPECIA

Etiology and Pathogenesis

Androgenetic alopecia predisposes affected individuals to lose hair from androgen-sensitive follicles on the scalp. Proposed mechanisms include autosomal dominance with incomplete penetrance and polygenic inheritance.

Clinical Presentation

Affecting men and women equally, hair loss begins in the 20s and is fully expressed by middle age. Men have frontal

recession, proceeding to loss of hair in the crown and sometimes to total hair loss in the central scalp. The terminal scalp hairs become vellus hairs. In advanced cases, the scalp is shiny and smooth. Women have miniaturized hairs, increased space between individual hairs, and preservation of the frontal hairline.

Differential Diagnosis

Alopecia areata and telogen effluvium are the two other conditions to consider.

Diagnostic Approach

A thorough history and examination are usually adequate. A careful medication history will exclude drug-induced alopecia. Medications associated with hair loss include

Box 176-1 Evaluation of the Patient with Hair Loss**History**

- Determine whether the hair loss is abnormal. Hair counts distinguish pathologic from physiologic hair loss. Have patients collect shed hairs for 7 days for the evaluation. Loss of more than 50 to 100 hairs per day indicates pathologic processes.
- Determine the timing of hair loss. Is it acute or gradual? Has it been present since birth?
- Identify associated symptoms such as pain, tenderness, and pruritus.
- Determine whether there are other skin complaints.
- Elicit a history of recent illness, stress, or medication use.
- Identify associated medical problems.
- Identify affected family members.

Clinical Examination

- Determine whether the hair loss is scarring or nonscarring. Scarring alopecia is characterized by the permanent loss of hair follicles within the foci of alopecia.
- Determine whether the process is inflammatory or noninflammatory. Inflammatory processes present with erythema, pruritus, or pain.
- Assess the presence or absence of scale, pustules, and adenopathy.
- Determine the pattern of hair loss. Is it restricted to focal areas of the scalp, or does it involve other hair-bearing regions?

Laboratory Examination

- The hair-pull test identifies pathologic hair loss. About 50 hairs are gently pulled from the base of the hairs. Release of two or more hairs is abnormal.
- Examine the bulbs of the released hairs microscopically to determine the phase of the hair cycle. Telogen hairs have rounded, nonpigmented bulbs. Anagen hairs have a cylindrical or tapered pigmented bulb (see Fig. 176-2).
- Hair shaft examination identifies traumatic or genetic causes for hair loss.
- Punch biopsy aids in identifying underlying pathology, particularly in cases of scarring or permanent hair loss.
- Potassium hydroxide preparation and fungal cultures are performed for suspected cases of tinea capitis.

anticoagulants, angiotensin-converting enzyme inhibitors, β -blockers, lithium, oral contraceptives, retinoids, valproic acid, and vitamin A excess. In women, menstrual irregularity, hirsutism, severe acne, or infertility should prompt endocrinologic evaluation for a hyperandrogenetic state.

Management and Therapy**Optimum Treatment**

Minoxidil, applied twice a day to a dry scalp, is the mainstay of therapy. It prevents further hair loss and provides moderate regrowth at the vertex of the scalp in 30% of patients. Results take at least 3 months to become evident. It must be used continually to preserve the beneficial effect. In men, finasteride (1 mg/day) used continuously to preserve regrowth is effective for hair loss at the crown. Decreased libido and erectile dysfunction occur in less

Figure 176-2 Telogen and Anagen Hair Bulbs.**Figure 176-3** Alopecia Areata.

Short exclamation point hairs are visible within the patches of nonscarring hair loss.

than 2% of men. Finasteride is contraindicated in women. Minoxidil and finasteride may be used in combination. Advanced hair loss requires surgical intervention (hair transplantation or scalp reduction).

TELOGEN EFFLUVIUM

Etiology and Pathogenesis

A traumatic event (Box 176-2) can induce a large number of anagen (growing) hairs to prematurely enter catagen, then telogen (resting). Telogen hairs are shed 2 to 3 months after the event, with 50% of the hair affected.

Clinical Presentation

Telogen effluvium occurs in both sexes and all age groups with an abrupt onset of diffuse shedding. A precipitating event 3 months before the onset of the hair loss usually can be identified. Physical examination may appear unremarkable.

Differential Diagnosis

The differential diagnosis includes androgenetic alopecia, diffuse alopecia areata, and anagen effluvium. Anagen effluvium begins within 2 to 4 weeks after chemotherapy, produces much more marked hair loss, and is characterized by the presence of anagen hairs on the hair-pull test.

Diagnostic Approach

The characteristic history in a patient with a normal scalp is usually adequate. The hair-pull test is positive, revealing nondystrophic club telogen hairs. Biopsy is not indicated.

Management and Therapy

This condition spontaneously resolves in 6 to 12 months.

TINEA CAPITIS

Etiology and Pathogenesis

Tinea capitis is a contagious infection of the scalp and hair caused by superficial fungi (*Trichophyton tonsurans*, *Micro-*

porum canis). It is common in children and in patients chronically using topical corticosteroids in the scalp. Replication of fungi within and around the hair shaft leads to breakage as it exits the hair follicle, resulting in nonscarring hair loss. A vigorous inflammatory reaction called a *kerion* may develop. Chronic inflammation from the kerion or from secondary bacterial infection can lead to scalp fibrosis and permanent hair loss.

Clinical Presentation

Tinea capitis presents as single or multiple dry scaling patches, with numerous hairs broken off as they exit the follicle (black dot ringworm), with or without an inflammatory border. Kerion is characterized by boggy indurated plaques with pustules often associated with preauricular, postauricular, and cervical adenopathy.

Differential Diagnosis

Seborrheic dermatitis may also have this presentation.

Diagnostic Approach

Potassium hydroxide (KOH) preparation of plucked hairs and skin scrapings from the border of the lesion identifies spores within (endothrix) or outside (ectothrix) the hair shaft and hyphal elements. Fungal cultures are helpful in identifying suspicious KOH-negative cases. A punch biopsy with periodic acid–Schiff stain can demonstrate fungi.

Management and Therapy

Optimum Treatment

Griseofulvin, itraconazole, or terbinafine with adjunctive daily use of ketoconazole shampoo decreases the risk for infecting contacts. Concomitant use of systemic corticosteroids may reduce the inflammation and risk for fibrosis associated with kerion.

SCARRING (CICATRICAL) ALOPECIA

Processes that lead to scarring alopecia result in irreversible hair loss. The hallmarks of scarring alopecia are visible loss of follicular ostia on clinical examination and destruction of the hair follicle on histopathology. The various conditions that lead to end-stage scarring alopecia can be distinguished by scalp biopsy. Two scalp biopsies for transverse and vertical sectioning are recommended.

DISCOID LUPUS ERYTHEMATOSUS

Etiology and Pathogenesis

Discoid lupus erythematosus (DLE) is an autoimmune disorder of unclear etiology. Ultraviolet light and trauma are possible contributing factors. Five to 10% of patients with DLE have signs and symptoms of systemic lupus.

Box 176-2 Causes of Telogen Effluvium

- Psychological stress
- Physical stress: systemic illness, surgery
- Anemia
- Endocrine: postpartum, perimenopausal or postmenopausal states, hypothyroidism or hyperthyroidism, oral contraceptives
- Nutritional: protein-calorie deprivation, essential fatty acid deficiency, zinc deficiency, biotin deficiency, iron deficiency, vitamin A excess
- Medications

Figure 176-4 Discoid Lupus Erythematosus.
Note areas of scar formation and complete absence of hair follicles.

Clinical Presentation

Early lesions are erythematous to violaceous patches and plaques with adherent scale and follicular plugging. A hair-pull test may reveal anagen hairs. With progression, patients develop mottled dyspigmentation, atrophy, telangiectasias, and fibrosis or scar (Fig. 176-4). Similar appearing cutaneous lesions can be found in areas other than the scalp. Often there are superficial ulcerations of the palate as well as proximal nail-fold erythema and telangiectasias.

Differential Diagnosis

Psoriasis, tinea capitis, and lichen planopilaris can be ruled out by punch biopsy.

Diagnostic Approach

A punch biopsy specimen from the lesion border will demonstrate superficial and deep perivascular lymphocytic infiltrate, interface dermatitis, follicular plugging, and increased mucin deposition.

Management and Therapy

Optimum Treatment

Focal lesions can be treated with ultrapotent topical corticosteroids or intralesional triamcinolone acetonide to the active inflammatory borders. Widespread disease often requires the use of systemic agents (hydroxychloroquine, quinacrine, chloroquine, or acitretin). End-stage fibrotic lesions are not amenable to medical treatment. Cosmetics may be useful in masking the atrophic hypopigmented patches of end-stage lesions.

LICHEN PLANOPILARIS

Etiology and Pathogenesis

Lichen planopilaris is a progressive, scarring inflammatory hair loss that may represent an autoimmune process. An antigenic trigger may initiate the disease process.

Clinical Presentation

This condition typically affects middle-aged adults and is more common in women. Patients present with focal patches of hair loss with inflammatory violaceous to brown keratotic papules at the lesion periphery. Tufts of three or more hairs may remain within scarred foci. A hair-pull test is positive for anagen hairs. Clinical lesions of lichen planus may be seen at sites other than the scalp, including the mucous membrane (lacy white reticulated Wickham's striae of the oral cavity), skin (violaceous polygonal flat-topped papules and plaques), and nail changes (pterygium).

Differential Diagnosis

DLE is the sole differential diagnosis.

Diagnostic Approach

Punch biopsy specimens reveal a lichenoid perifollicular lymphocytic infiltrate. Giemsa stain demonstrates decreased or absent perifollicular elastic fibers. Direct immunofluorescence studies show globular deposits of IgM and IgA at the follicular basement membrane referred to as *cytoid bodies*.

Management and Therapy

Optimum Treatment

High-potency topical corticosteroids or intralesional triamcinolone acetonide can be used for local disease. Tapering courses of systemic corticosteroids over 3 months may be effective in slowing or halting hair loss before use of acitretin or hydroxychloroquine. Patients often experience relapse after discontinuation of therapy.

ACNE KELOIDALIS

Etiology and Pathogenesis

Acne keloidalis is an inflammatory condition that may be associated with the unique property of the pilosebaceous unit, hair shaft, or scalp skin of African American people. It may be precipitated by mechanical trauma, excoriation, seborrhea, infection with *Demodex* or bacteria, and autoimmunity.

Clinical Presentation

This condition occurs mostly in African American men after adolescence. Patients present with firm, skin-colored

to erythematous follicular papules on the posterior neck and occipital scalp. These papules may coalesce to form keloidal nodules or plaques with associated hair loss. Symptoms include pruritus and burning.

Differential Diagnosis

Folliculitis is in the differential diagnosis.

Diagnostic Approach

The diagnosis is usually clinical. A punch biopsy shows perifollicular lymphocytes and plasma cells pronounced at the level of the sebaceous glands. Ongoing disease leads to complete follicular destruction.

Management and Therapy

Optimum Treatment

Mild disease can be controlled with high-potency topical steroids in combination with topical antibiotics. More severe disease is treated with monthly intralesional triamcinolone acetonide and oral antibiotics. Adjunctive use of antibacterial soaps is recommended.

DISSECTING CELLULITIS

Etiology and Pathogenesis

Dissecting cellulitis may represent an aberrant immune response to *Staphylococcus aureus* or *Propionibacterium acnes*; however, the etiology remains unknown.

Clinical Presentation

Active lesions present as a vigorous inflammatory reaction characterized by pustules, fluctuant abscesses, and sinus tracts. This painful, chronic, progressive, suppurative process commonly affects young African American men and eventually results in true scarring and permanent hair loss. When cultured, pustules are typically sterile or grow skin commensals.

Differential Diagnosis

Kerion and furunculosis are in the differential for the presentation of dissecting cellulitis.

Diagnostic Approach

Perform a culture to rule out fungal and bacterial pathogens. Punch biopsy specimens demonstrate follicular abscesses containing neutrophils. Lymphocytes, plasma cells, and foreign body giant cells may also be present. Late-stage lesions show destruction of follicles with true scarring. Special stains for microbial pathogens should be performed. Secondary bacterial infection is not uncommon.

Management and Therapy

Optimum Treatment

Tetracycline, doxycycline, minocycline, cephalexin, and isotretinoin are the mainstays of treatment. Tumor necrosis factor- α inhibitors such as etanercept and infliximab may be used for resistant disease.

SARCOID

Etiology and Pathogenesis

Granuloma formation may represent an immune response to a persistent antigen.

Clinical Presentation

This slowly progressive hair loss is more common in African American women. Sarcoid has variable morphologies and may present as papules, plaques, atrophic patches, or ulcerations with or without crust or scale, often in association with pulmonary sarcoid and other cutaneous sarcoidal lesions (erythema nodosum). Sarcoid causes true scarring (Fig. 176-5), although nonscarring sarcoidal alopecia has also been reported.

Differential Diagnosis

Discoid lupus erythematosus (DLE) can usually be ruled out by a punch biopsy.

Diagnostic Approach

A punch biopsy specimen reveals noncaseating granulomas and true scarring with decreased elastic fibers. Workup includes a full body examination for other cutaneous manifestations of sarcoid and chest radiographs to look for pulmonary disease.

Management and Therapy

Optimum Treatment

Ultrapotent topical corticosteroids, intralesional corticosteroids, systemic prednisone, hydroxychloroquine, and low-dose methotrexate are effective treatments.

PRIMARY OR METASTATIC NEOPLASMS

Etiology and Pathogenesis

Infiltrating tumor cells result in the destruction of normal skin architecture, including hair follicles.

Clinical Presentation

Examination reveals a firm nodule, plaque, or space-occupying mass that visibly replaces cutaneous appendageal structures.

Figure 176-5 Sarcoid.

No hair follicles are discernable in this plaque of alopecia.

Differential Diagnosis

Common malignancies that infiltrate the scalp to cause hair loss include cutaneous T- or B-cell lymphomas and metastatic breast, lung, and prostate carcinoma.

Diagnostic Approach

Punch or incisional biopsy is essential to demonstrate the malignant histology.

Management and Therapy

Optimum Treatment

Treatment includes local excision and treatment of the underlying malignancy.

Avoiding Treatment Errors

For all types of alopecia, it is important to establish the correct diagnosis. If the etiology is unclear or the condition is not responding to treatment, a punch biopsy of the scalp may be indicated. Treatment with intralesional triamcinolone acetonide or ultrapotent topical corticosteroids on a long-term basis may cause atrophy of the skin.

Future Directions

Recent studies have shown that the nuclear receptor hairless (HR) controls the timing of Wnt signaling required for hair cycling. This observation raises the intriguing possibility that drugs could be designed to stimulate new hair growth by activation of this pathway. Such therapies would be useful in treating nonscarring hair loss, particularly androgenetic alopecia.

Scabies and Pediculosis

SCABIES

Scabies is a contagious disease characterized by extreme pruritus. Severe outbreaks and complicated scabies are more common in institutions, such as nursing homes and hospitals, and among socially disadvantaged populations and immunocompromised hosts. Scabies occurs in all age groups, both sexes, all ethnic groups, and at all socioeconomic levels.

Etiology and Pathogenesis

Scabies results from the infestation of the skin with the mite *Sarcoptes scabiei* var. *hominis*. The mite completes its entire life cycle on human skin. The female mite burrows through the stratum corneum, laying three to four eggs a day for up to a month. The eggs hatch, and the larvae mature, perpetuating the cycle.

Although the predominant route of transmission is through close skin-to-skin contact, scabies can be transmitted indirectly through bedding and clothing. The likelihood of transmission of the infestation directly correlates with the number of mites harbored as in crusted scabies with hyperinfestation (see later).

Skin lesions result from a combination of infestation and a delayed hypersensitivity reaction to the mite, feces, and eggs in the skin. After initial infestation, there is usually a 3- to 6-week delay before the onset of pruritus and skin lesions. This delayed hypersensitivity reaction is the most likely reason that most patients continue to itch for 2 to 4 weeks after the mite is eradicated.

Clinical Presentation

Patients complain of pruritus that is usually worse at night. A history of pruritus in other members of the household is particularly suggestive.

Physical examination reveals inflammatory papules, which are often excoriated. There is a predilection for the finger webs, flexor aspects of the wrists, elbows, anterior axillary folds, buttocks, and genitalia (Fig. 177-1). The pathognomonic burrow is a 2- to 5-mm dirty white, slightly

scaly, thread-like line found in the characteristic locations. Occasionally a black dot representing the mite is seen at the end of the burrow. Secondary impetiginization and eczematous change are common.

Scabies in infants and young children often presents as a widespread, pruritic eruption involving the face, scalp, palms, and soles. Elderly and immunosuppressed patients are less likely to develop a brisk inflammatory response and may present with pruritus and few skin lesions. Crusted (Norwegian) scabies is a hyperinfestation with thousands of mites that are present in exfoliating scales. This form of scabies is most often found in institutionalized elderly people or immunologically compromised hosts. Clinically, the skin lesions may resemble psoriasis, and pruritus is frequently absent.

Differential Diagnosis

In patients with few skin lesions, scabies can be misdiagnosed as a neurodermatosis with excoriations. Crusted scabies is easily confused with a papulosquamous disorder. Scabies can mimic many diseases, including atopic dermatitis, papular urticaria, pyoderma, insect bites, and dermatitis herpetiformis.

Diagnostic Approach

The clinical diagnosis of scabies in a patient with pruritus is based on finding the characteristic skin lesions in typical predilection sites or a history of exposure. A definitive diagnosis requires the identification of the mite, egg, or feces from a skin scraping (see Fig. 177-1). Because of the very low sensitivity of skin scrapings, the failure to find mites does not rule out scabies.

Management and Therapy

Scabies has traditionally been treated with topical scabicides (Fig. 177-2); however, oral therapy with ivermectin has evolved into a very useful alternative. Treatment of the index case as well as all household members and sexual contacts, even if asymptomatic, is the mainstay of therapy. The ease of transmission of crusted scabies necessitates the

Figure 177-1 Dermatoses Secondary to Ectoparasites.

treatment of all contacts, including patient care staff and support staff in institutional settings.

Scabicides should be applied in a thin layer from the head down to the soles of the feet, with special attention to the areas between the fingers and toes, under the nails, the umbilicus, genitalia, and between the buttocks. The medication should be washed off after 8 to 14 hours. After therapy, all linens, towels, bedclothes, and underwear should be washed in a washing machine with hot water (60° C). Children's plush toys, if not washable, should be put out of human contact for 72 hours, allowing the mite to die. For both oral and topical therapy, most experts advocate a second treatment 1 week to 14 days later.

Permethrin 5% cream is the first choice in topical scabicides because of its high efficacy and low potential for toxicity. Although not approved for infants younger than 2 months or pregnant or lactating women, 5% permethrin

is U.S. Food and Drug Administration pregnancy category B and safe for use on young children.

Lindane 1% cream has similar efficacy to permethrin but has much higher potential for central nervous system toxicity. Lindane should not be used in children younger than 3 years, in pregnant or lactating women, or in patients with underlying neurologic disorders. It should not be applied on broken skin or used in those with the potential for misuse of the medication.

Precipitated 6% sulfur in petrolatum is an alternative for infants younger than 2 months and in pregnant or lactating women. Crotamiton is also safe in children and infants but has questionable efficacy.

Ivermectin, an oral antiparasitic agent used extensively for several other parasitic infections, is safe and efficacious in the treatment of scabies in nonpregnant or lactating patients more than 15 kg in weight. Ivermectin is pre-

Figure 177-2 Sexually Transmitted Ectoparasites.

scribed at 200 µg/kg and repeated 7 to 14 days later. Patients who have no response to topical scabicides, who have generalized eczema, or who are unable to tolerate or comply with topical therapy are ideal candidates for ivermectin.

Oral antihistamines and medium-potency topical steroids provide symptomatic relief of the pruritus that often persists for up to 1 month after therapy.

Avoiding Treatment Errors

Treatment failure often results when other close contacts are not treated or when patients do not treat their entire

skin surface. Even if asymptomatic, all household members and sexual contacts should be treated at the same time as the index case. As noted, patients should pay special attention to the areas between the fingers and toes, under the nails, the umbilicus, genitalia, and between the buttocks when applying topical scabicides.

PEDICULOSIS

Pediculosis is an infestation by *Pediculus capitis* (head louse), *Pediculus humanus* (body louse), or *Phthirus pubis* (pubic louse). Head lice are mainly found in children, and pubic lice in sexually active adults. Both head lice and pubic

lice are found in patients of all socioeconomic levels; in contrast, body lice are associated with poor hygiene, poverty, and overcrowding.

Head Lice

Head lice affect all levels of society and all races, with the exception of African Americans, in whom incidence is extremely low. The louse is transmitted by direct head-to-head contact or through shared towels or hair-grooming instruments. Head lice infestations are a common problem.

Clinical Presentation

The hallmark of head lice is intense scalp pruritus. Physical examination reveals nits and adult lice in the scalp hair. Nits are gray or brown oval egg capsules that adhere firmly to the hair shaft (see Fig. 177-2). Secondary changes resulting from immunologic response to lice saliva or excreta include scaling and erythema of the scalp with erythematous papules on the posterior neck and excoriations secondary to scratching. Intense scratching may lead to secondary infection of the scalp with associated honey-colored crusting over matted hair and lymphadenopathy.

Diagnosis

Active infestations are confirmed by observing live adult lice in the scalp or hair. Nits may be identified by their adherence to the hair shaft and microscopically by the presence of a breathing aperture at the superior aspect of the egg casing. The presence of nits alone does not confirm active infection. Because of their tight adherence to hair and resistance to degradation, hatched or nonviable nits may remain attached to hair for several weeks after resolution of an infestation.

Differential Diagnosis

Other causes of scalp pruritus, including tinea capitis and seborrheic dermatitis, should be considered, especially in children.

Management and Therapy

Permethrin cream rinse 1% and pyrethrin with piperonyl butoxide are available over the counter. Both are highly efficacious with a low toxicity profile. After treatment, nits can be removed with a fine-toothed comb. Despite instructions to the contrary on many package inserts, two applications 1 week apart are advised with all topical preparations. This approach ensures the killing of any surviving nits and decreases the risk for resistance.

Following therapy, all clothing, towels, bed linens, hair ribbons, and clothes should be machine washed and dried

or dry-cleaned. Plush toys should be stored in plastic bags in a warm place for 2 weeks. Washing hair-grooming implements in hot, soapy water for 20 minutes is essential, and thorough vacuuming of floors and furniture is important to remove any shed hairs with viable eggs. Most practitioners recommend treating all family members with signs of active infection.

The increasing resistance to permethrin and pyrethrins with piperonyl butoxide has increased the need to use prescription products. Topical malathion applied overnight for 8 to 12 hours has not resulted in any reports of resistance in the United States. The use of topical lindane should be limited because of reports of central nervous system toxicity in patients who overused or misused the product. This drug is only recommended in patients who fail to respond to other approved lice therapies. One dose of oral ivermectin at 250 µg/kg with a repeat dose 7 to 10 days later has not been thoroughly studied in clinical trials, but appears very effective in resistant cases.

Treatment is successful when live lice can no longer be found within the scalp hair. Residual nits do not signify active infestation and should not be used to exclude a child from school.

Body Lice

Body lice are found where poor hygiene and crowded living conditions predominate. In the United States, body lice are usually seen in homeless people. The louse is spread through infested clothing and bedding.

Clinical Manifestations

The primary symptom is severe pruritus. These patients frequently have numerous linear excoriations over the trunk and neck due to intense scratching. Secondary bacterial superinfection is common. Close examination may reveal a few macules or papules at the sites where the louse has fed. Lice are rarely present on the patient, but both lice and nits are often found in the seams of clothing.

Diagnosis

The diagnosis should be suspected in indigent patients with severe pruritus and few primary skin lesions. Although the louse is rarely present on the infested individual, nits are present on the clothing, particularly the seams near the body folds. The identification of nits or live lice in clothing confirms the diagnosis.

Differential Diagnosis

Pediculosis corporis can easily be misdiagnosed as neurodermatitis unless the patient's clothing is examined.

Management and Therapy

The mainstay of therapy is deinfestation of clothing and bedding. The patient's clothing, towels, and bed linens should be laundered with hot, soapy water or dry-cleaned or boiled. One application of 5% permethrin cream is the usual therapy as described in the management of scabies.

Pubic (Crab) Lice

Pediculosis pubis is a sexually transmitted disease. Although it is found in all socioeconomic levels and ethnic groups, it is most common among homosexual men. The presence of pubic lice should elicit increased vigilance for other sexually transmitted diseases.

Clinical Manifestations

Pubic lice most commonly affect the pubis, but any hair, including the short hair in the inguinal area, perianal area, thighs, and trunk, may be affected. In children, the eyelashes and periphery of the scalp hair can be involved. Patients complain of pruritus in the affected area.

Patients most often present with pruritus of the pubic region. Close examination reveals lice and nits cemented to the pubic and perianal hair (see Fig 177-2). Excoriations, secondary bacterial infection, and lymphadenopathy may accompany the infestation.

Diagnosis

Diagnosis is confirmed by plucking an affected hair and examining it microscopically. The presence of nits suggests past or present infestation, whereas live lice confirm active infestation. It is important to examine all hair-bearing sites in infected patients because sites outside the pubic area are frequently involved.

Management and Therapy

Treatment consists of topical application of various preparations. The entire pubic area should be treated as well as the thighs, trunk, and axillary regions. The simultaneous treatment of sexual partners is essential. Unaffected household members do not require therapy. Following therapy, all underwear, clothing, linens, and towels that came into contact with the infested person should be washed in hot, soapy water.

As with head lice, therapy with all topical insecticides requires two applications, 1 week apart. The most commonly used agents are topical 1% permethrin, synergized pyrethrin shampoos, 5% permethrin cream, and 1% lindane shampoo. A fine-toothed comb may be used to remove residual nits and lice. When topical therapy is

unsuccessful or undesirable, oral ivermectin is indicated at a dose of 250 µg/kg repeated in 7 days. Involvement of the eyelashes should be treated by oral ivermectin or by petrolatum applied twice daily for a week followed by removal of any remaining nits.

Avoiding Treatment Errors

Resistant cases of lice are most often due to improper application of pediculicides, reinfestation, or misdiagnosis. Pediculicides should be applied to dry hair or body surfaces and always reapplied after 7 to 10 days. Prevent reinfestation by treating all family members at the same time, washing bed sheets and clothing in hot water, and washing hair-grooming supplies in hot, soapy water for 20 minutes or storing them in plastic bags for 1 week. The presence of nits alone does not confirm active infestation, and one should search for live lice before diagnosing resistant lice.

Future Directions

Future management of pediculosis and scabies will likely involve changes in the diagnosis and management of these infestations. The detection of serum antibodies to scabies by enzyme-linked immunosorbent assay is available for domestic animals and will likely become commercially available to improve the detection of scabies infestation in humans. Treatment of pediculosis will continue to evolve to a more physician-managed disease as increasing resistance to over-the-counter medications leads more and more patients to seek prescription therapy.

Drug Therapy in the Elderly: Appropriate Prescribing for the Older Patient

Introduction

With an increased concern for patient safety and error reduction has come the recognition that older patients are especially vulnerable to complications related to what is often inappropriate medication use. Surveys demonstrate that older patients use the most prescription medications; the older the person, the higher the number of medications. More than 90% of community-dwelling women take at least one medication, and more than 10% take more than 10 medications. Those who live in assisted living or skilled nursing facilities are more likely to take even more medications. As the population ages, this problem will become an even more significant public health issue. The challenge for the physician is to balance the need to treat elderly patients who may benefit from evidence-based drug regimens with the risks. Nearly one third of all elders have an adverse drug event necessitating medical intervention yearly—a risk directly related to the number of medications being taken.

Etiology and Pathogenesis

The etiology of polypharmacy and adverse drug events is complex. Even the definition is not clear—what entails *polypharmacy*? Is it simply the number of medications a patient is taking? How many is too many? With an aging society, chronic diseases such as diabetes, heart failure, and hypertension are increasingly common. There are evidence-based standards of care for each problem that often support the use of multiple medications. We now recognize that older patients who have a very high risk for a bad outcome with a certain diagnosis may actually gain the most from treatment. Moreover, we are less commonly using age alone as a reason not to treat a given condition. To complicate matters, patients today are more likely to receive their medications from multiple prescribers, multiple settings, and multiple pharmacies. Pharmaceutical companies now directly market to patients, including older

adults, as consumers. The use of herbal agents and over-the-counter medications has increased in elderly people. Nearly 25% of older patients in some surveys use an herbal medication, and more than half of those never report it to their primary physician.

The pathogenesis of adverse drug events in older patients is just as complex. Several major factors make older patients more susceptible to bad outcomes:

1. The pharmacokinetic changes of aging include the altered distribution, metabolism, and excretion of drugs. The volume of drug distribution in elderly people is altered by a decrease in lean body mass and an increase in body fat. Hepatic clearance is often decreased, and there is a well-documented decline in renal blood flow and glomerular filtration rate, increasing the half-life and decreasing the excretion of many drugs. Because of the decreased production of creatinine associated with

a decreased lean body mass in many older adults, a normal creatinine may actually represent a significant impairment in renal function.

2. Pharmacodynamic changes produce variances in the effect a given drug has on an individual. The fact that a therapeutic level of a certain drug may still have adverse effects mandates lower initial doses and careful titration of most drugs.
3. Drug-drug interactions are more common in older patients who take more medications.
4. Drug-disease interactions are also more common in older patients because of an increased prevalence of comorbidities. An older person with underlying cognitive impairment may become completely delirious after receiving a small dose of diphenhydramine, in contrast to a younger patient who merely becomes sedated for the night. A younger patient may become slightly hypotensive and lightheaded after receiving a tricyclic antidepressant, whereas an older person may have a syncopal episode and, because of underlying osteoporosis, sustain a hip fracture.
5. The use of multiple prescription drugs, polypharmacy, is more likely in older patients because of an increased prevalence of significant chronic diseases. The absolute risk for an adverse drug event is directly related to the number of drugs one takes—the higher the number of medications, the higher the risk. This is the major risk factor for having an adverse medication effect, even when controlling for other comorbidities and confounders.
6. Failure to recognize an adverse drug event is common in older patients. Side effects such as dizziness, confusion, and constipation are often attributed to other disease processes. When a symptom is not recognized as a side effect and then treated with an additional pharmacologic agent, the “prescribing cascade” may begin. There are many examples of the prescribing cascade—consider the older woman who is taking over-the-counter naproxen and has an elevation in her blood pressure for which she is prescribed hydrochlorothiazide. She perceives an increase in her urinary incontinence, sees her physician, and is then prescribed an agent such as oxybutynin. She later presents with constipation and is given polyethylene glycol. The story, of course, could continue.

Clinical Presentation

Unfortunately, the clinical presentation for inappropriate prescribing in the older adult is too often a significant adverse drug event that results in significant morbidity and mortality. Common adverse events include delirium, falls, fractures, orthostasis, constipation, and urinary retention. Care must be taken to identify such outcomes as possible adverse drug events and to target the underlying cause for

the problem in order to avoid falling into the prescribing cascade. Simply stated, it is always important to “first think drugs” in the case of elderly patients who present with new symptoms.

Management

Optimum Treatment

Optimum appropriate prescribing in older adults primarily requires awareness and vigilance in balancing adequate treatment and the potential for harm from the side effects of treatment. There are some basic strategies that are helpful:

1. Recognize and avoid potentially inappropriate medications (PIMs). A complete list of high-risk medications is included in the updated Beers criteria, a well-known document that addresses the issue of inappropriate medications in older patients. The Beers group reviewed medications that generally should be avoided or that should be avoided in certain medical conditions based on their level of risk for adverse outcomes, their lack of established effectiveness, and whether safer alternatives exist. Major offenders on the list include many muscle relaxants, tricyclic antidepressants, long-acting benzodiazepines, antispasmodic drugs such as dicyclomine and belladonna, anticholinergic agents such as diphenhydramine, narcotics such as meperidine and propoxyphene/acetaminophen, and many of the nonsteroidal anti-inflammatory agents.

It is important to recognize that the PIM is not an absolute—there are often exceptions that need to be considered. For example, a severely anxious patient who is actively dying and requesting an anxiolytic may benefit from a low dose of a short-acting benzodiazepine. Making treatment plans based on the individual and recognizing the potential negative outcomes are the most important issues.
2. Recognize negative outcomes as possible adverse drug events and discontinue the drug instead of falling into the prescribing cascade.
3. Routinely ask about the use of over-the-counter medications, herbal agents, and vitamins and other supplements, and document their use.
4. Consider the use of databases that identify common drug-drug interactions.
5. Establish quality improvement–based protocols for monitoring levels, hepatic and renal function, anticoagulation effect, and so forth.
6. Record and report suspected adverse drug events.
7. Use generic drug names whenever possible. The use of both generic and trade names may result in confusion, even leading to patients’ taking multiple agents that are similar or identical.

8. Educate patients regarding their medications, including the indications for each agent.
9. Have patients carry an updated medication list with them at all times. This is particularly helpful when patients are admitted and for medication “reconciliation” at the time of discharge.
10. Consider medication weaning as part of routine diagnostic decision making. This is especially important if goals of care have shifted to a more comfort-based approach or other changes have occurred such as weight loss, development of dementia, or a return from an admission to the hospital. Agents such as proton pump inhibitors may have been started in the hospital, and the patient may have no indication for their continued use. Steroids may be started for an acute problem and never weaned. Psychotropic medications may have unclear goals and effectiveness. The basic point: if an agent has not provided any significant benefit, consider discontinuation.
11. Have patients bring in pill bottles, not just a list, to the clinic for review. Errors can include pharmacy errors, patient-related errors, or prescribing errors that will otherwise not be identified.
12. Identify individual patient factors that may increase the risk for a negative outcome with prescription medications. These include literacy, visual loss, arthritis, and cognitive decline.

Avoiding Treatment Errors

The goal is to achieve an optimal balance between the indications for therapy and the potential negative side effects that come with the use of any medication. Older patients may have significant benefit from treatment of

chronic disease states. It is especially important to avoid undertreatment based on age alone.

Future Directions

Prescribing medications for elderly patients is challenging and will become a problem faced by physicians in nearly every field as this segment of the population continues to grow. Clinical trials, which have traditionally excluded elderly people, need to continue to expand eligibility requirements and even specifically focus on this population. The balance between too much and too little in the older patient is something that will become increasingly challenging as the numbers of our elders, as well as our therapeutic options, continue to expand.

This article provides a review for rational drug prescribing for older patients.

Falls

Introduction

Falling is a common and serious problem in older people. A fall occurs when a person comes to rest inadvertently on the ground or a lower level. About 35% to 40% of community-dwelling adults older than 65 years and more than 50% of those in nursing homes and hospitals will fall each year. Falls are associated with considerable mortality, morbidity, and premature nursing home admission. Twenty-five percent of those who fall will die within 6 months, 60% have restricted mobility, and 25% remain functionally more dependent. Additionally, the fear of falling can result in decreased activity, isolation, and further decline. Medical costs of falling exceed \$2 billion annually and account for 6% of all medical expenditures for persons age 65 years and older in the United States.

Etiology and Pathogenesis

The cause of falling is multifactorial and frequently preventable. There are intrinsic factors, such as medical conditions and normal age-related changes, and extrinsic factors, such as medications or environment. These factors may either predispose or precipitate a fall. Conditions such as arthritis; depressive symptoms; orthostasis; impaired cognition, vision, balance, gait, or muscle strength; and the use of four or more prescription medications have been shown to increase the risk for falling in two or more observational studies.

Several studies document strong correlations between exercise, strength and balance retraining, and decreased incidence of falls in the elderly. More specifically, hip abductor strength has been studied as a strong indicator of fall risk in the elderly population. Decreased hip abductor strength impairs protective extension and postural correction response time, which can increase fall risk.

Polypharmacy alone (taking four or more prescription medications) can predispose to falling. Medications commonly associated with falling in the elderly include sedative-hypnotics, especially long-acting benzodiazepines, and neuroleptic agents. Serotonin reuptake inhibitors and tricyclic antidepressants are also associated with an increase in falls. Cardiac medications such as digoxin, diuretics, and type 1A antiarrhythmics are weakly associated with falls.

Several studies suggest that the risk for falling increases dramatically as the number of risk factors increases. One

study reported the percentage of community-dwelling older adults falling increased from 27% for those with no or one risk factor to 78% for those with four or more risk factors.

It is the combination of high degree of susceptibility to falls, because of multiple risk factors, and propensity to fall-related injury, caused by comorbidities such as osteoporosis and age-related changes, that makes falling a major problem in older adults.

Clinical Presentation

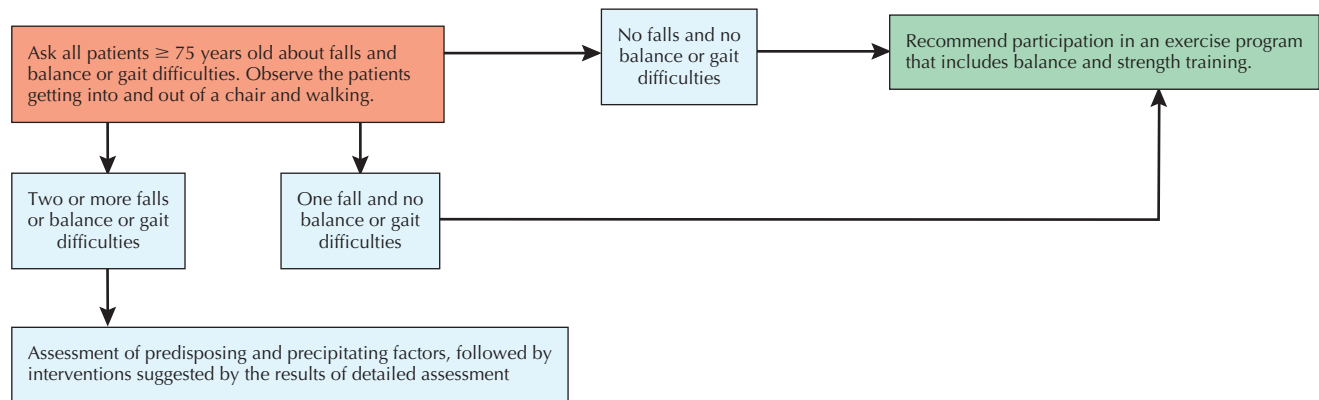

Falls in the community commonly present in association with accidents or environmental factors (37%). They can also result from weakness and balance or gait problems (12%). Drop attacks (11%), dizziness or vertigo (8%), and orthostatic hypotension (5%) also contribute to a significant proportion of falls. Eighteen percent of falls are caused by acute illness, confusion, drugs, or decreased vision, and many people fall for unknown reasons (8%).

In long-term care, the most common causes of falls are generalized weakness (31%) and environmental hazards (27%). Orthostatic hypotension causes about 16% of falls. Acute illness (5%), gait or balance disorders (4%), and drugs (5%) contribute to falls as well. In about 10%, the reason for falling in the nursing home is unknown.

Most falls result in some type of injury, usually soft tissue injury such as bruises or skin tears. About 10% to 15% result in fracture or other serious injury.

Figure 179-1 Clinical Approach to the Prevention of Falls.

From Tinetti M: *Clinical Practice. Preventing falls in elderly persons. N Engl J Med* 348(1):42-49, 2003.

Of those who fall, only half are able to get up without help, thus experiencing the *found-down syndrome*, which is associated with decline in functional status and can complicate fall-related injuries.

Differential Diagnosis

Although falling is considered a common geriatric syndrome by itself, falls can also occur in association with other clinical diagnoses. Falls associated with loss of consciousness should lead to a workup for syncope (see Chapter 38). Falls can also occur in the setting of acute illness such as urinary tract infection or pneumonia. A diagnosis of Parkinson's disease can sometimes be made on the initial presentation to a physician after a fall. It is important to have a high index of clinical suspicion for these problems as well as other factors contributing to falls and fall risk.

Diagnostic Approach

The clinical approach to the prevention of falls is presented in Figure 179-1.

History

Although some patients present with fall as the chief complaint, many older adults may not give a history of falls unless inquiry is made. Therefore, eliciting a history of falls and balance or gait difficulties is an important component of the review of systems and should be performed at least once per year in all patients 75 years or older.

The previous history of falling should include the location and circumstances (including a witness account), associated symptoms, history of previous falls, risk factors for falls such as medications (prescription and over-the-counter), functional status, and injury (if presenting after fall).

The medication list should be reviewed for total number of drugs and specific high-risk medications. For those who are taking four or more medications, reduction of the total number should be strongly considered. The balance of risk and benefit for medications such as benzodiazepines, other sleep agents, neuroleptics, antidepressants, anticonvulsants, or class 1A antiarrhythmics should be considered, and appropriate tapering should be attempted.

Physical Examination

Especially in those patients who present with presyncope symptoms or syncope associated with fall, orthostatic blood pressure (Fig. 179-2) should be assessed along with targeted cardiovascular and neurologic examination. In addition to heart rate and rhythm, the cardiovascular exam should include carotid sinus massage with assessment of pulse. Many unexplained nonaccidental falls can be explained by carotid sinus hypersensitivity and potentially treated with pacemaker placement. The examiner should only perform carotid sinus massage in a controlled environment with access to cardiac monitoring and resuscitation equipment.

The ability for patients to maintain their center of mass within their base of support is crucial to preventing a fall. The three major receptive senses involved in balance are the visual, proprioceptive, and vestibular systems. The neurologic exam should focus on testing for impaired vision, sensation, vestibular dysfunction, and cognition. Visual acuity can be tested with a Snellen eye chart or grossly by asking the patient to read any available print in the examination room. In the older population, vibration sense is a more sensitive marker of neuropathy than impaired proprioception. Vibration can be tested using a low-pitched tuning fork of 128 Hz or 256 Hz and asking patients when they feel the vibration stop. Vestibular function can be evaluated by performing the Dix-Hallpike maneuver and assessing extraocular movements for

Figure 179-2 Orthostatic Hypotension.

Fall associated with orthostatic hypotension can occur when arising from bed. Orthostatic blood pressure is assessed by taking a blood pressure reading after ≥ 5 minutes in a supine position and immediately after standing. ≥ 20 mm Hg (or 20%) drop in systolic blood pressure with or without symptoms, either immediately or after 2 minutes of standing, is diagnostic of orthostatic hypotension

nystagmus. The neurologic exam should also test cognition and look for changes associated with Parkinson's disease. Assessment for Parkinson's disease can be made by observing for festinating gait, tremor, muscle rigidity or cogwheeling, and bradykinesia (Fig. 179-3).

Musculoskeletal examination should focus on lower extremity joint abnormalities and dysfunction, such as limitation in range of motion as a result of arthritic change, and strength. With aging, skeletal muscles decrease in bulk, as evidenced by atrophy; however, muscle strength can be relatively well maintained.

If a fall is reported, further assessment of gait and balance should be performed. This can easily be done in the clinic by performing a "get up and go test." Patients are observed standing up from a chair without using their arms, walking 10 feet, turning, then walking back and sitting down in the chair. This should be accomplished in 10 to 20 seconds. Those patients who take longer than 20 seconds are at high risk for falling. The get up and go test can easily be used to screen for gait and balance problems even in the setting of a busy outpatient practice.

Balance can be assessed by having the patient hold a prolonged side-by-side stance, semi-tandem stance, and full tandem stance. The patient should be able to stand in

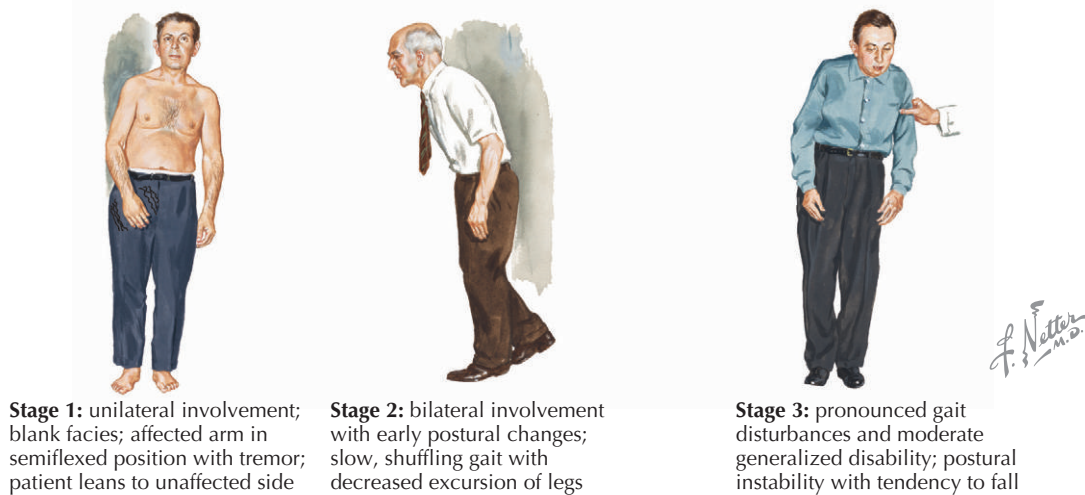

all three positions for 10 seconds. The ability to withstand a nudge on the sternum without falling backward can also be used to assess balance. Because many people fall while reaching for objects on the floor, another clinical test of balance is observation as a patient tries to pick up an object from the floor such as a set of keys.

Laboratory Testing and Imaging

Although there is no standard laboratory testing for falls, complete blood count and basic chemistry can be helpful to rule out anemia, dehydration, and hyperglycemia as etiologies of falling. As well, vitamin B₁₂ and thyroid function tests can be useful in ruling out reversible problems with gait and balance. More costly tests such as magnetic resonance imaging of the head, echocardiogram, or Holter monitoring should be reserved for patients in whom an abnormality is suggested based on findings obtained during the history or physical exam.

Home Hazard Assessment

Because environment is frequently a factor in falls that occur in the home, a home safety evaluation by a nurse,

Figure 179-3 Changes in Gait with Progression of Parkinson's Disease.

occupational therapist, or physical therapist is essential. Specifically assessing the environment for clutter, lighting, stairs, cords, or throw rugs is important. Other considerations include the placement of grab bars in the bathroom and shower. Shoes should be evaluated for appropriateness in the home and outside. Flat hard-sole shoes are considered the safest footwear. Footwear should also be evaluated for proper fit because poorly sized shoes may increase fall risk by providing poor support and increased risk for tripping.

Risk Factors for Injury

Assessment for risk factors for injury should include a bone density scan and considerations for anticoagulation.

Management and Therapy

Management is important not just for those who have recently fallen but also for those at high risk for falling because of the presence of a known risk factor for falling or a history of falls. Both single- and multifactorial-intervention strategies have been studied for the management of falls.

A systematic review of randomized trials of interventions designed to minimize the effect of, or exposure to, risk factors for falling in elderly people was conducted in association with the Cochrane Collaboration of systematic reviews. Main outcomes of interest were the number of fallers, or falls. Trials reporting only intermediate outcomes were excluded. Sixty-two trials involving 21,668 people were included. Single-intervention strategies that have been shown to be effective include a professionally supervised program of balance and gait training and muscle-strengthening; withdrawal of psychotropic medications (benzodiazepines, other sleep agents, neuroleptic

agents, and antidepressants); Tai Chi group exercise intervention; home hazard assessment and modification that is professionally prescribed for older people with a history of falling; and cardiac pacing for fallers with cardioinhibitory carotid sinus hypersensitivity.

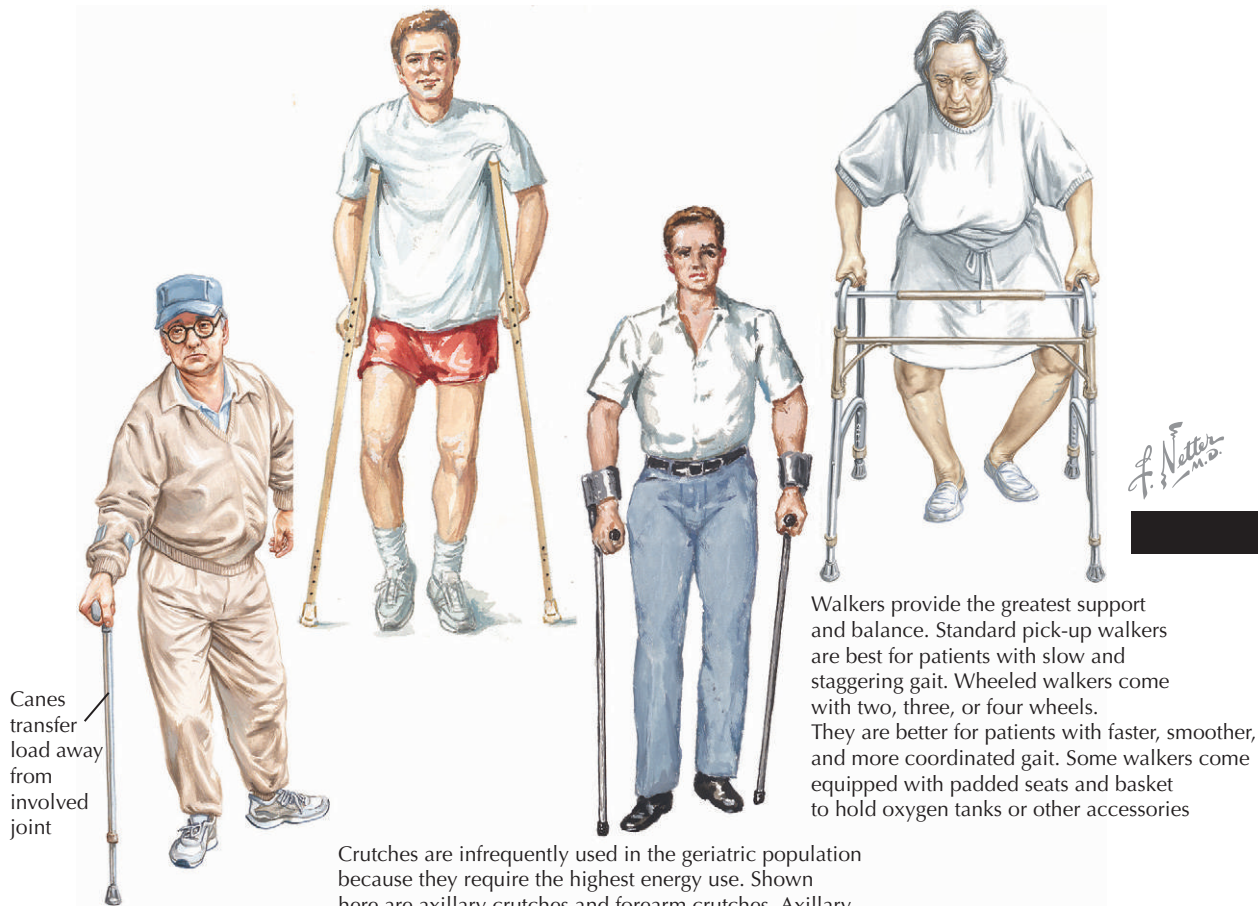

Multidisciplinary, multifactorial risk factor screening and intervention programs in the community for older people with and without a history of falling, or risk factors for falling, were shown to be beneficial. This was also true for those patients in residential care facilities. This finding was supported by another study performed with the Cochrane Collaboration of systematic reviews, which showed that the rate of injuries caused by falls decreased after population-based programs were introduced. This conclusion was qualified by the reviewers by stating that more studies of better quality are still needed to back up this conclusion.

Assistive devices such as canes and walkers seen in Figure 179-4 can help support weight and provide greater balance by increasing the patient's base of support. They must be prescribed and used correctly to achieve maximum safety. Physical therapists are helpful in instructing patients in the appropriate and safe use of such devices. Patients may benefit from learning about various types of assistive devices, such as three- and four-wheeled walkers, that can improve mobility safety without significantly limiting ambulation speed or outdoor mobility over varied terrain.

Fall management relies heavily on prevention of falls and the complications of falls. Evaluation and treatment of osteoporosis to prevent fracture in case of fall is an important consideration. Hip protectors are padded undergarments used to prevent hip fractures associated with fall. Although the data are controversial, earlier studies of hip protectors showed benefit in preventing hip fractures in

Figure 179-4 Canes, Crutches, and Walkers.

Assistive devices are used to increase the area of support, stability, and sensory feedback, and decrease weight bearing on lower extremities

Walkers provide the greatest support and balance. Standard pick-up walkers are best for patients with slow and staggering gait. Wheeled walkers come with two, three, or four wheels. They are better for patients with faster, smoother, and more coordinated gait. Some walkers come equipped with padded seats and basket to hold oxygen tanks or other accessories

Canes can support up to 20% of the body weight and should be held on the patient's unaffected side. Proper length for a cane should measure from the patient's wrist crease to the ground. Shown here is a standard cane. Canes come in a variety of handles and up to four tips (quad cane)

Crutches are infrequently used in the geriatric population because they require the highest energy use. Shown here are axillary crutches and forearm crutches. Axillary crutches are commonly used after injury with either swing-through or swing-to gait pattern. Forearm crutches are often used in chronic conditions such as neuromuscular disorders

those patients who wear them. This was not substantiated in later meta-analyses of randomized trials. Further, the lack of efficacy of hip protectors may be caused by low compliance and poor patient acceptance.

Anticoagulation in patients with atrial fibrillation is another important consideration in those patients who have a history of fall or are at high risk for falling. Although potential head trauma and subsequent subdural hematoma is an important complication of anticoagulation, recent studies have shown that the benefits of anticoagulation warrant the risks. Specifically, persons with an average risk for stroke from atrial fibrillation must fall about 300 times in 1 year for the risks of anticoagulation to outweigh its benefits.

Found-down syndrome can complicate injuries resulting from falls. Prevention of this includes placement of lifeline or accessible telephones in the home. Isolated elderly persons can benefit from friendly phone calls or visitors on a daily basis. In addition, teaching patients how to properly rise from the floor after a fall can be helpful in preventing found-down syndrome.

Optimum Treatment

Given that the etiology of falls is multifactorial and multifaceted, optimum treatment must be tailored to each individual. Even if a practitioner has experience in evaluating and treating falls, frequently referral to specialty services

is necessary to optimize management. A geriatric medicine specialist may be necessary to assist with assessment of patients who have fallen or are at high risk for falls. Similarly, referral to physical therapy and occupational therapy is very important not only for assessment of the patient and home, but also in directing and implementing a treatment plan. These initial referrals are usually covered by Medicare; however, documentation of progress is necessary for ongoing coverage of therapy services.

Avoiding Treatment Errors

In managing a problem in which prevention and treatment are enmeshed, the key to avoiding treatment errors is in the clinical interview. Unless a patient presents with an injury related to a fall, many falls do not come to clinical attention because either the health care provider may not inquire or the patients do not report a fall. Patients may be reluctant to discuss a recent fall because of embarrassment, or the invalid assumption that falls are an inevitable part of aging. The American Geriatrics Society, the British Geriatrics Society, and the American Academy of Orthopaedic Surgeons, in a joint evidence-based guideline for prevention of falls, recommend that all elderly patients be asked about any falls that have occurred during the previous year and that they undergo a quick test of gait and balance. Additionally, the U.S. Preventive Services Task Force recommends that all persons 75 years or older, as well as those 70 to 74 years of age who have a known risk factor, be counseled about specific measures to prevent falls. It also recommends individualized multifactorial interventions for elderly persons at high risk for falling.

By identifying those patients at high risk and intervening appropriately, we can decrease the morbidity and mortality caused by falls, and subsequent complications.

Future Directions

There are several high priority issues identified for future research and analysis by the American Geriatrics Society Panel on Falls Prevention. Cost-effectiveness of recommended strategies and specific elements of successful strategies need to be evaluated to streamline management. For example, what are the effective elements of exercise programs (type, duration, intensity, and frequency), or can fall-prone individuals be risk-stratified in terms of who will benefit most from assessment and interventions? Because the etiology of falls is multifactorial and the elderly population is heterogeneous, these questions will prove challenging to answer.

Additional Resources

Leipzig RM, Cumming RG, Tinetti MD: Drugs and falls in older people: A systematic review and meta-analysis. II. Cardiac and analgesic drugs. *J Am Geriatr Soc* 47:40-50, 1999.

This meta-analysis critically evaluates the evidence regarding cardiac and analgesic drugs and the risk for falls in older people. Although the evidence to date is based solely on observational data, there is a weak association between the use of digoxin, type IA antiarrhythmic, and diuretic and falls in older adults. Also noted is that older adults taking more than three or four medications were at increased risk for recurrent falls.

Leipzig RM, Cumming RG, Tinetti ME: Drugs and falls in older people: A systematic review and meta-analysis. I. Psychotropic drugs. *J Am Geriatr Soc* 47:30-39, 1999.

This meta-analysis critically evaluated the evidence regarding psychotropic drugs and the risk for falls in older people. Although the evidence to date is based solely on observational data, there is a consistent association between the use of most classes of psychotropic drugs and falls.

Thapa PB, Gideon P, Cost TW, et al: Antidepressants and the risk of falls among nursing home residents. *N Engl J Med* 339:875-872, 1998.

This article reviews the risk for falls associated with selective serotonin reuptake inhibitor antidepressants versus tricyclic and other heterocyclic antidepressants. The authors find little difference in rates of falls between those treated with tricyclic antidepressants and those treated with selective serotonin reuptake inhibitors.

Tinetti ME, Speechley M, Ginter SF: Risk factors for falls among elderly persons living in the community. *N Engl J Med* 319:1701, 1988.

A one-year prospective investigation to study risk factors for falling in community dwelling persons 75 years of age or older noted that the risk for falling increased linearly with the number of risk factors. Falls among older persons in the community are common, and clinical assessment can identify the elderly persons at greatest risk.

Rubenstein LZ, Robbins AS, Josephson KR, et al: The value of assessing falls in an elderly population. *Ann Intern Med* 113(4):308-316, 1990.

A randomized controlled trial of elderly persons in long-term care assigned to either comprehensive postfall assessment or usual care found that through assessment, many remediable problems were detected that led to a statistically significant decrease in hospitalizations and reduction in hospital days.

EVIDENCE

1. Assessing Care of Vulnerable Elders (ACOVE) Physician Education Program for Falls and Mobility Disorders. Santa Monica, CA, RAND Corporation, 2004.

This is a CD-ROM physician education program produced by Pfizer, the RAND Corporation, and the American Geriatrics Society to improve the quality care for older adults. It is an interactive program with printable forms and educational materials for the physician and patient.

This is a website from the Centers for Disease Control and Prevention and National Center for Injury Prevention and Control. The site has fact sheets for physicians as well as patient education materials. There are links to other fall-related websites.

3. Cummings RG, Thomas M, Szony G, et al: Home visits by an occupational therapist for assessment and modification of environmental hazards: A randomized trial of falls prevention. *J Am Geriatr Soc* 47(12):1397-1402, 1999.

This randomized controlled trial was the first to show the effectiveness of a trained occupational therapist home visit to assess and modify the

environment. There were limitations of this study because of potential confounding factors. The fact that falls away from home were also reduced in the treatment group suggested that the intervention influenced not only the environment but also the individual.

4. Gillespie LD, Gillespie WJ, Robertson MC, et al: Interventions for preventing falls in elderly people. *Cochrane Database Syst Rev* (4):CD000340, 2003.

This is a comprehensive systematic review of randomized trials to assess the effects of interventions designed to minimize the effect of, or exposure to, risk factors for falling in elderly people. The review is extensive and serves as a good reference.

5. Guideline for the prevention of falls in older persons. American Geriatrics Society, British Geriatrics Society, and American Academy of Orthopaedic Surgeons Panel on Falls Prevention. *J Am Geriatr Soc* 49(5):664-672, 2001.

The webpage from the American Geriatrics Society (http://www.americangeriatrics.org/news/media_adv_5.shtml) also contains a link to the Falls Intervention Evidence Tables (PDF). The evidence tables are a comprehensive list of studies leading up to the 2001 meeting and commentary regarding the strength of the evidence. There is also a Consumer Pamphlet (PDF) for patients to review and list all of their medications to discuss with the physician at their next visit.

6. Man-Son-Hing M, Laupacis A: Anticoagulant-related bleeding in older persons with atrial fibrillation: Physicians' fears often unfounded. *Arch Intern Med* 14;163(13):1580-1586, 2003.

This systematic review of the literature critically appraised whether the presence of clinical factors that increase the risk for bleeding affect the chance of anticoagulant-related hemorrhage. They found that many factors that are purported to be barriers in older patients, such as predisposition to falls and old age itself, should not influence the choice of stroke prophylaxis.

7. McClure R, Turner C, Peel N, et al: Population-based interventions for the prevention of fall-related injuries in older people. *Cochrane Database Syst Rev* (1):CD004441, 2005.

This systematic review assesses the effectiveness of population-based interventions for reducing fall-related injuries among older people. The authors include studies that report changes in medically treated fall-related injuries among older people following the implementation of a controlled population-based intervention. In all of the five studies that met inclusion criteria, none of which were randomized controlled trials, they find significant decreases or downward trends in fall-related injuries with relative reduction of 6% to 33%. The conclusions are limited because of the quality of the studies reviewed.

8. Parker MJ, Gillespie WJ, Gillespie LD: Hip protectors for preventing hip fractures in the elderly. *Cochrane Database Syst Rev* (3):CD001266, 2005.

This comprehensive systematic review of all randomized or quasi-randomized controlled trials compare the use of hip protectors with a control group to determine whether external hip protectors reduce the incidence of hip fractures in older people following a fall. The 15 trials include data from nursing homes and community-dwelling participants. Although earlier evidence shows that in institutions with high rates of hip fracture, the use of hip protectors may reduce the risk for a hip fracture, new evidence shows the effect may be less certain. There is no evidence of any benefit for older people living in the community. Long-term compliance overall is poor because of discomfort and practicality.

9. Tinetti M: Clinical practice: Preventing falls in elderly persons. *N Engl J Med* 2;348(1):42-49, 2003.

This Clinical Practice review begins with a case vignette followed by evidence supporting various strategies for evaluation and management of falls in elderly persons. It is concise and well written, with an extensive list of references.

Hypertension in the Elderly

Introduction

As more of us are getting older and older, we are facing the risks associated with hypertension. By 2025, it is estimated that 20% of the U.S. population will be older than 65 years. The subgroup of people older than 80 years is one of the fastest growing segments of the population. It is now recognized that hypertension, especially isolated systolic hypertension, is indeed connected to age. Up to 50% of people ages 60 to 69 years have hypertension, but nearly 75% of those older than 70 years have some degree of hypertension. More startling is the finding that the risk for developing hypertension if one lives to the age of 85 years is 80% to 90%. In older patients, it is clear that the systolic blood pressure is a more important predictor of future cardiovascular events than the diastolic blood pressure. And the risk for developing hypertension and future cardiovascular disease is also increased in those with blood pressures in the range of 120 to 139 mm Hg, levels previously considered normal. Multiple trials have demonstrated a reduction in mortality, cardiovascular mortality, stroke, and congestive heart failure with treatment. Despite this, systolic hypertension in elderly people is often inadequately treated. There are multiple reasons for this: reaching goal blood pressure usually requires multiple medications; patients and physicians may have negative attitudes regarding treatment in this age group; and older patients may have more complications with orthostasis and other side effects.

Etiology and Pathogenesis

Most cases of combined systolic and diastolic hypertension occur by the age of 55 years. Systolic hypertension, defined as a systolic blood pressure of more than 140 mm Hg with a diastolic blood pressure of less than 90 mm Hg, is principally associated with aging. Other differences seen in elderly people include lower renin levels, higher sensitivity to sodium loads, and increased peripheral vascular resistance.

Clinical Presentation

Most patients do not have symptoms, which contributes to the lack of recognition of this problem and the associated public health epidemic. Patients may present with symptoms of cardiovascular disease, heart failure, stroke, or renal failure. The physical exam may reveal evidence of left ventricular hypertrophy, indicating an increased risk for cardiovascular disease (Fig. 180-1).

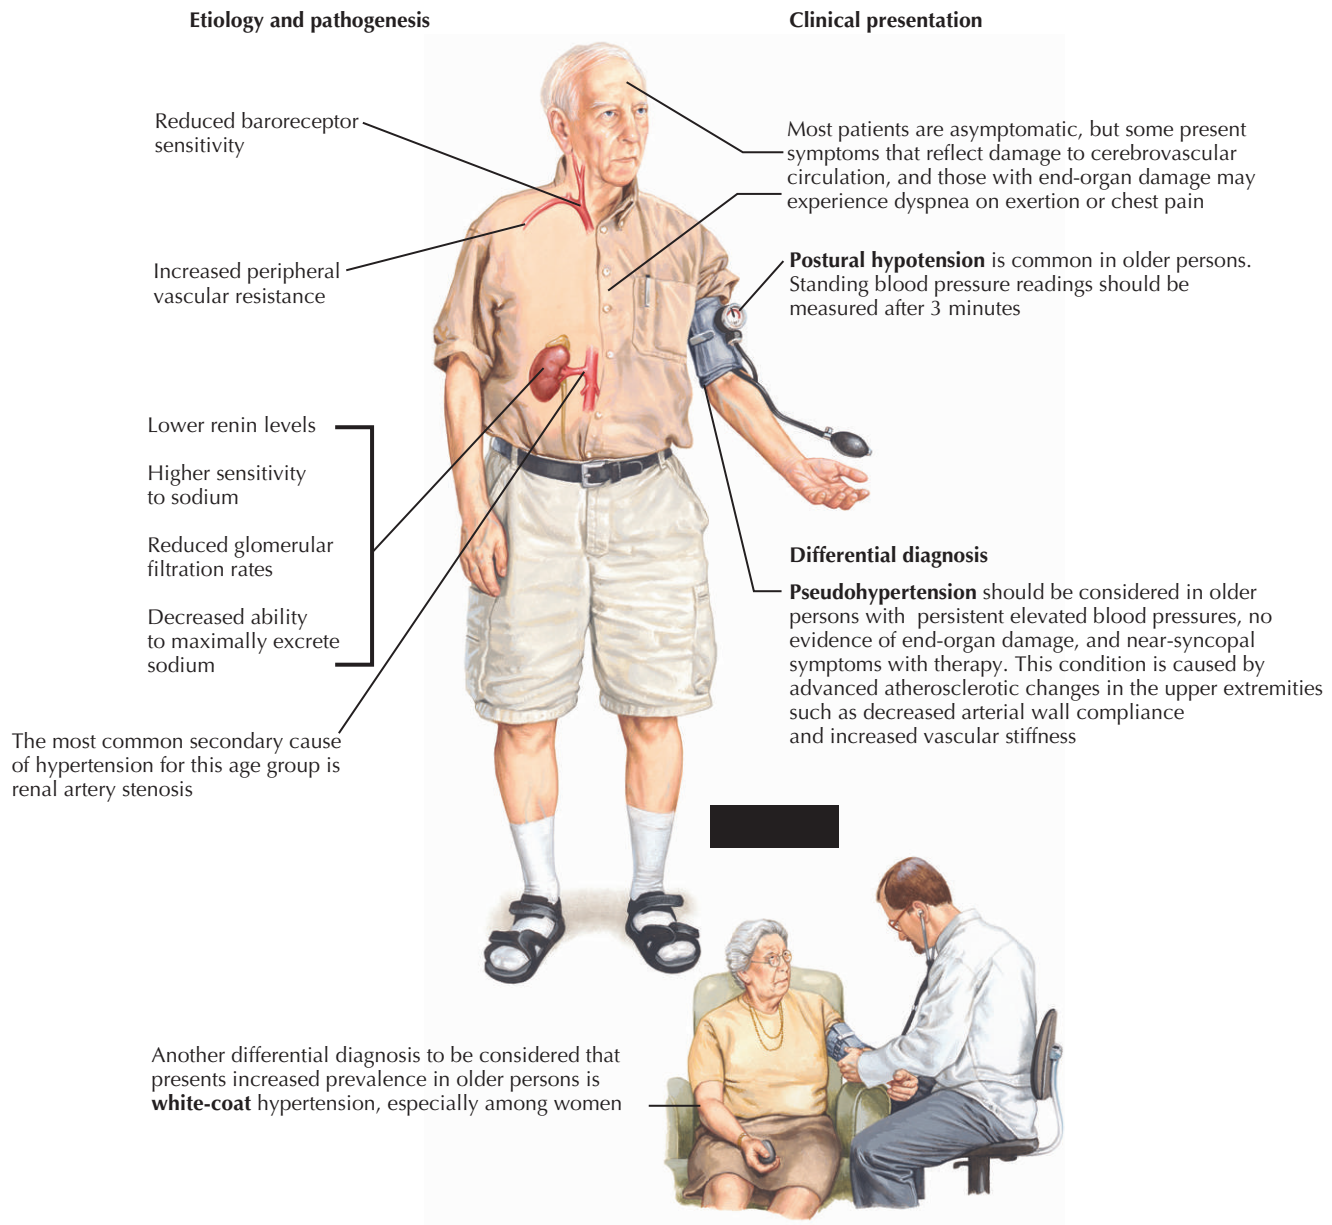

Differential Diagnosis

Pseudohypertension, falsely high sphygmomanometer readings secondary to decreased arterial wall compliance and increased vascular stiffness, should be considered in older persons with persistently elevated blood pressure measurements, no evidence of end-organ damage, near-syncopal symptoms with therapy, or a discrepancy in blood pressure readings between arms.

White-coat hypertension, with blood pressure readings taken during clinic visits that greatly exceed those taken at home or after the patient has had time to relax, is more commonly seen in older patients. The noncompliant vascular tree probably makes elders more susceptible to labile blood pressure swings. Ambulatory blood pressure monitoring can be helpful to identify this and is reimbursed by Medicare. In addition to identifying lower blood pressures that may correlate better with future cardiovascular events than clinic readings, the lack of a decrease in blood

Figure 180-1 Hypertension in the Elderly.

The diagnosis of hypertension for all adults is based on the finding of systolic blood pressure of more than 140 mm Hg with diastolic blood pressure of more than 90 mm Hg, after two or more readings. Each reading must be performed after the person has been sitting for 3 minutes. A single reading with systolic blood pressure of more than 210 mm Hg or diastolic blood pressure of more than 120 mm Hg is consistent with hypertension

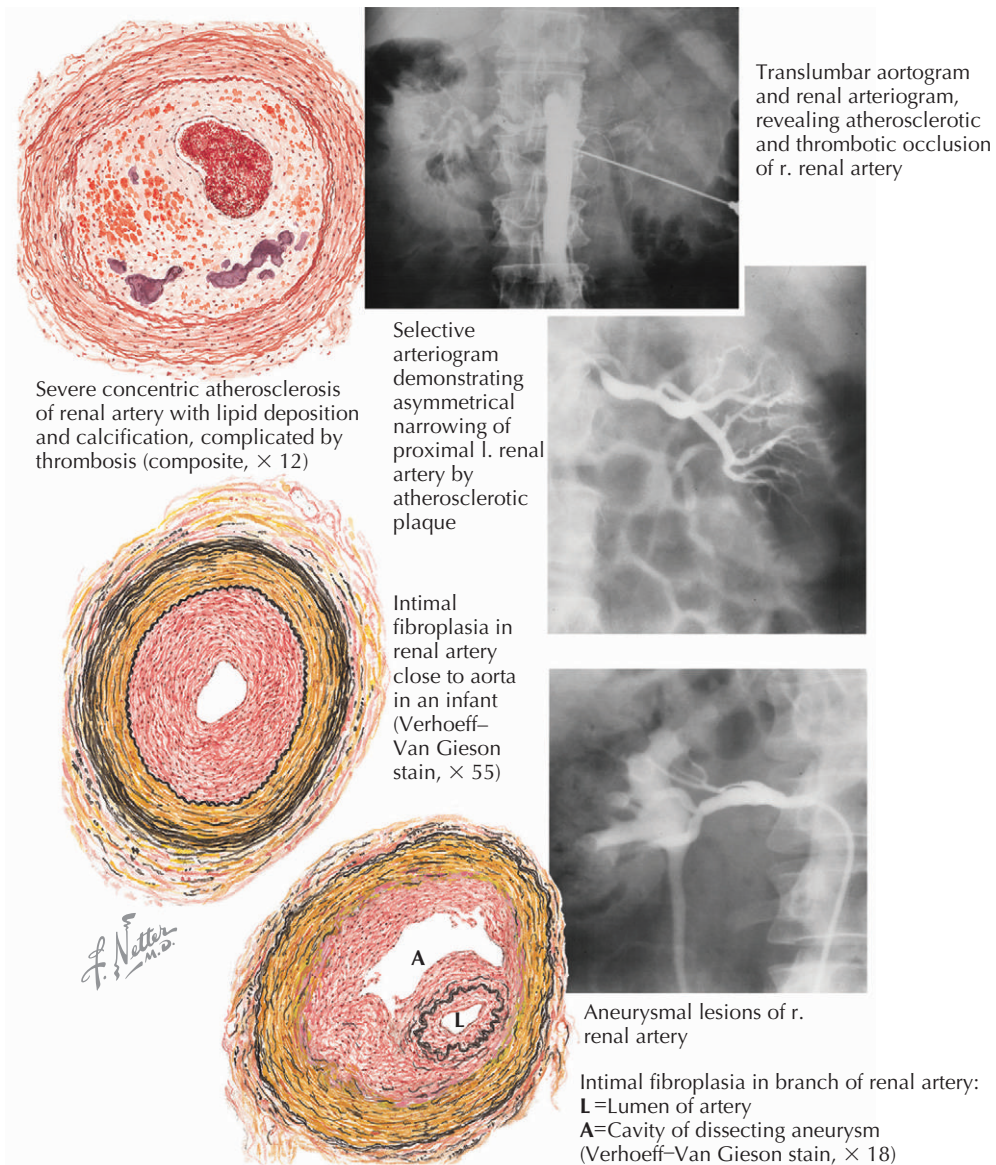

pressure at night may identify patients who are particularly high risk for future cardiovascular events.

Secondary causes of hypertension are far less common in older patients, and further evaluation is indicated only with documented new onset and pronounced hypertension or new difficulty in controlling blood pressure. Renal artery stenosis is the most common secondary cause of elevated blood pressures in this age group (Fig. 180-2). The challenge is that many patients in this age group also have underlying diffuse small vessel disease because of atherosclerosis, and any correction of stenosis at the level

of the renal artery does not necessarily correct the underlying renovascular compromise.

Diagnostic Approach

The diagnosis of hypertension is based on the classification system used by the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure for all adults (systolic blood pressure greater than 140 mm Hg or diastolic blood pressure greater than 90 mm Hg). Systolic hypertension, previously known as

Figure 180-2 Varieties of Renal Artery Disease that May Induce Hypertension.

isolated systolic hypertension, is defined as a systolic blood pressure of more than 140 mm Hg with a diastolic blood pressure of less than 90 mm Hg. Hypertension is diagnosed based on two or more readings with an appropriately sized cuff, after the person has been sitting for 3 minutes. Because blood pressure variability is more common in elderly people, multiple readings are of great importance. Postural hypotension is common in elderly people; so, before initiating or altering treatment, blood pressure should be measured after the patient has been standing for 3 minutes.

Management and Therapy

Why Treat?

There is strong evidence that pharmacologic treatment of systolic hypertension in older patients reduces cardiovas-

cular events, including strokes and heart failure. Studies have consistently demonstrated a 35% reduction in stroke, 50% reduction in congestive heart failure, and 30% reduction in overall cardiovascular events in older patients who are treated. One meta-analysis examining the risks and benefits of treatment for isolated systolic hypertension in elderly people found that treatment decreased total mortality by 13%, cardiovascular mortality by 18%, all cardiovascular complications by 26%, and stroke by 30%. Greater benefits were seen in men, patients older than 70 years, and patients with prior cardiovascular complications. Notably, benefits are seen in the oldest patients, those older than 80 years, with 22% reductions in cardiovascular events and 39% reductions in heart failure. Whether treatment in very elderly patients improves mortality is less clear; however, there is significant benefit in improved

quality of life and a reduction in stroke and heart failure in this age group.

Optimum Treatment

Treatment guidelines for older and younger patients are similar. Thiazide-type diuretics should be considered first line—these are the agents that were used in the major trials for the treatment of systolic hypertension in elderly patients. In addition, these agents are inexpensive, are usually well tolerated, and recently were demonstrated to be of equal or better effectiveness in reducing future cardiovascular events. Most older patients with systolic hypertension require more than one drug—many will need three medications to reach goal blood pressure. Other agents such as β -blockers, angiotensin-converting enzyme inhibitors, and calcium channel blockers are also effective and should be added depending on specific patient comorbidities like congestive heart failure.

Avoiding Treatment Errors

Older patients are much more likely to have orthostatic drops in blood pressure, labile blood pressures, and white-coat hypertension. Standing blood pressure readings should be checked in all older patients, and treatment should be based on these readings. Ambulatory blood pressure monitoring is often useful in patients who experience significant side effects and symptoms of orthostasis on therapy despite normal or even high blood pressure readings in clinic.

Age alone or fear of negative side effects should not lead to the avoidance of treatment. Good data document that older patients tolerate treatment with little or no impact on quality of life.

Future Directions

More focus is being directed toward decreasing the risk for dementia. Increasing evidence from multiple large trials of the treatment of systolic hypertension in elderly people documents the association of dementia with prior hypertension. The risk appears to include not only vascular dementia but also Alzheimer's-type dementia. Can we prevent or modify the development of dementia by more aggressively treating hypertension? Given the intricate ties among age, dementia, and hypertension, coupled with the aging of adults in the United States, this question is of great public health importance.

Knowledge about the treatment of hypertension in elderly people will grow as the prevalence of the disease within this age group is recognized and trials are designed specifically for these patients. In the past, there was a ten-

dency to undertreat older patients for fear of causing harm. Because older patients are at high risk for cardiovascular disease, any intervention that is of benefit actually stands to be of greater absolute benefit. Will we begin to recognize age as the new cardiovascular equivalent and aim to treat hypertension in older patients more aggressively?

Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7). Available at: <http://www.nhlbi.nih.gov/guidelines/hypertension/jnc7full.htm>.

This report was sponsored by the National Heart, Lung, and Blood Institute and provides information for patients, public, and health professionals. A complete review of data and summary of recommendations are provided.

EVIDENCE

1. Forette F, Seux ML, Staessen JA, Thijs L: Prevention of dementia in randomized double-blind placebo-controlled Systolic in Europe (Syst-Eur) Trial. *Lancet* 352:1347-1351, 1998; and SHEP Cooperative Research Group: Prevention of stroke by antihypertensive drug treatment in older persons with isolated systolic hypertension. Final results of the Systolic Hypertension in the Elderly Program (SHEP). *JAMA* 265:3255-3264, 1991.

The follow-up studies from the original work looking at treating systolic hypertension in the elderly demonstrates that older patients in the original treatment groups have a significant reduction in future risk for developing cognitive impairment when compared with those patients in the original placebo groups. One of the more interesting caveats to this is that all causes of dementia, vascular and Alzheimer's, were less in the original treatment groups.

2. Gueyffier F, Bulpitt C, Boissel JP, et al: Antihypertensive drugs in very old people: A subgroup meta-analysis of randomized controlled trials. *INDANA Group. Lancet* 353:793-796, 1999.

This study addressed the issue of treating very elderly people, the fastest growing population in the United States, and found that even in this group, treatment of systolic hypertension appears to be of benefit in reducing heart failure and stroke. Although no clear mortality benefit is demonstrated, it is thought that the significant morbidity benefit of stroke reduction in very elderly people justifies therapy.

3. Hansson L, Lindholm LH, Ekblom T, et al: Randomised trial of old and new antihypertensive drugs in elderly patients: Cardiovascular mortality and morbidity. The Swedish Trial in Old Patients with Hypertension-2 Study. *Lancet* 354:1751-1756, 1999.

This landmark study addresses the issue of which antihypertensive is best and found that the older agents such as thiazide diuretics are of equal, if not better, efficacy in preventing negative cardiovascular outcomes when compared with the newer agents often used and promoted today.

4. Straessen JA, Fagard R, Thijs L, et al: A randomised double-blind comparison of placebo and active treatment for older patients with isolated systolic hypertension. The Systolic Hypertension in Europe (Syst-Eur) Trial Investigators. *Lancet* 350:757-764, 1997.

This and other large trials of this time period look at older patients with isolated systolic hypertension and clearly demonstrate that treatment of systolic hypertension leads to a decrease in cardiovascular events, strokes, and heart failure.

Delirium

Introduction

Delirium is a bilateral, physiologic disturbance of cortical function associated with disturbances of consciousness, attention, cognition, and perception that develops acutely or subacutely and characteristically fluctuates during the course of a day. Other terms for delirium include acute organic brain syndrome, metabolic or toxic encephalopathy, toxic brain syndrome, and acute confusional state. This potentially life-threatening condition often goes unrecognized or is misdiagnosed by health care professionals, making the recognition of the condition and the search for and mitigation of causative factors the central treatment goals.

Historically, a lack of clear criteria for defining delirium has confounded prevalence estimates, but it is a common condition, by any measure. Costs are estimated to be greater than \$8 billion annually. Delirium is very common in hospitalized patients (10% to 30%), with the numbers being particularly notable in special populations, such as elderly patients (up to 50%), AIDS patients (30% to 40%), postsurgical patients (up to 50%), and burn unit patients. Prevalence rates in terminally ill patients can be as high as 80%. Additionally, 6% to 7% of nursing home patients, 5% to 10% of elderly emergency department admissions, and 1% to 2% of community populations suffer from delirium as well.

Risk factors include advanced age, cognitive impairment (especially dementia), preexisting brain injury, chronic medical illnesses, and drug intoxication. Dementia is a particularly important risk factor for delirium in hospitalized patients. Almost half of all dementia patients admitted to the hospital will have or will develop a delirium. Conversely, 25% to 80% of hospitalized patients with delirium will be found to have a preexisting dementia. Dementia is such a strong risk factor for delirium that all sudden mental status changes in a demented individual should be considered a delirium until proven otherwise. Other predictive risks for inpatients include use of physical restraints, malnutrition, more than three new medications, use of bladder catheter, hearing and vision impairment, high number of room changes, postoperative pain levels, use of meperidine, and any iatrogenic event.

Etiology and Pathogenesis

Potential causes of delirium can be predicted based on an understanding of the physical and metabolic needs of the brain to maintain optimal functioning. Essential factors include adequate oxygenation and nutrition, avoidance of toxins and infection, tight temperature regulation, and proper hydration. Thus, causes are varied and usually include combinations of factors that upset this delicate physiologic balance (Table 181-1). The exact pathogenesis remains unclear, but impairments in the reticular activating system and in cholinergic transmission may be present in most deliria. Ultimately, delirium can be seen as an early sign of impending brain failure, with

those areas of the brain less immediately essential to life (i.e., the cortex) faltering while more essential regions (midbrain and brainstem) hang on. Seen from this perspective, the seriousness of this disorder can be better appreciated.

Using *Diagnostic and Statistical Manual of Mental Disorders*, 4th edition (*DSM-IV*) diagnostic criteria, causes can be grossly classified as attributed to a general medical condition, caused by substance abuse or withdrawal, because of multiple etiologies, or having an unspecified etiology.

International Statistical Classification of Diseases and Related Health Problems, 10th revision (*ICD-10*) choices include: delirium not induced by alcohol and other psychoactive substances; delirium not superimposed on Dementia,

Table 181-1 Potential Causes of Delirium

Potential Causes of Delirium	Examples (Partial List)
Drug induced	Neuroleptic malignant syndrome (NMS), anticholinergic toxicity, idiosyncratic neurotoxicity, allergic reactions, combination effects (e.g., narcotics plus antihistamines)
Metabolic abnormalities	Hypoxia, anemias, hypoglycemia, electrolyte imbalances, water imbalance (including dehydration), uremia, hepatic encephalopathy
Infectious processes	Intracranial (encephalopathy, meningitis) Systemic (pneumonia, sepsis, hepatitis, influenza)
Central nervous system disorders	Head trauma, space-occupying lesions, degenerative disorders, cerebrovascular disease, vasculitides
Acute vitamin deficiencies	Thiamine (Wernicke's encephalopathy), cyanocobalamin
Toxins	Organophosphates, CO, organic solvents, ethylene glycol, heavy metals
Intoxications	Stimulants, anticholinergics, hallucinogens, phencyclidine
Withdrawal states	Alcohol (delirium tremens), sedative-hypnotics, opiates
Miscellaneous	Seizures (partial-status, postictal delirium) Sensory deprivation Rapid-eye-movement sleep deprivation Temperature dysregulation (high fevers)

Box 181-1 Common Symptoms and Signs of Delirium**Common Symptoms of Delirium**

Disorientation to time, place, and situation (and occasionally person)
 Impaired recent memory, confused recall, visuospatial impairments
 Perceptual disturbances (misinterpretations, illusions, hallucinations)
 Disorganized thinking and speech, irrelevant conversation, delusions
 Emotional lability, especially fearfulness (which can lead to aggression and escape behaviors)

Common Signs of Delirium

Psychomotor disturbances, including hyperactivity (often with psychosis), hypoactivity with somnolence, and mixed states
 Electroencephalogram with generalized slowing (except sedative-hypnotic or ethanol withdrawal states)
 Dysarthria, aphasia, dysgraphia, dysnomia
 Specific physical examination findings: asterixis in hepatic encephalopathy and cranial nerve palsies in Wernicke's encephalopathy

Delirium, Superimposed on Dementia, and Other Delirium (including delirium of mixed origin, and subacute confusional states).

Clinical Presentation

The essential feature of delirium is a reduced level of consciousness with impaired ability to sustain, shift, or focus attention (Fig. 181-1). Because of this core deficit, a host of other signs and symptoms can be expected (Box 181-1). Typically, symptoms fluctuate over time and are often worse at night (*sundowning*). Onset may be acute or subacute, with prodromal symptoms of restlessness, anxiety,

irritability, distractibility, or sleep disturbance progressing to delirium over 24 to 72 hours. Symptoms may last from less than 1 week to many months, with most resolving within 10 to 12 days; 15% last longer than 30 days, and symptoms often persist after discharge. A persistent cognitive deficit after maximal recovery is common in elderly patients and in patients with AIDS and may represent an unmasking of dementia. Delirium in the medically ill is associated with significant morbidity, including pneumonia, decubitus ulcers, longer hospital stays, and increased postoperative complications; 25% die within 6 months, and the mortality rate for hospitalized patients with delirium is 3 to 7 times higher than for patients without delirium (matched for age and illness severity). The general presentation can be hyperactive (most commonly recognized), hypoactive (frequently missed), and mixed states (most common). A quiet delirium may be more serious because of increased risk for dehydration, malnourishment, and misdiagnosis.

Differential Diagnosis

Delirium is most frequently confused with dementia, severe depression, or other functional psychotic disorders; however, it is critical not to let psychiatric symptoms lead to reduced medical surveillance. An evolving dementia may look like a delirium, especially in advanced cases in which reliable history is hard to obtain, but most acute mental status changes in dementia patients are caused by delirium (although not uncommonly, when the delirium resolves, the dementia will be seen to have progressed). In the case of mood disorders, cognitive impairment is usually a result of lack of effort rather than true deficits. Psychosis with severe cognitive disorganization can look like delirium with disorientation, memory impairments, and general confusion. However, a decrease in level of consciousness

Figure 181-1 Delirium.

is not seen with psychosis alone, and a normal electroencephalogram is most consistent with a nondelirious psychosis. *Although the symptoms of all these conditions can overlap at times, the fluctuating pattern of symptom expression in conjunction with reduced conscious awareness is unique to delirium.*

Diagnostic Approach

All patients with delirium of *uncertain etiology* require blood chemistries (electrolytes, glucose, calcium, albumin, blood urea nitrogen, aspartate transaminase, alanine transaminase, bilirubin, alkaline phosphatase, magnesium, PO_4), complete blood count with differential, electrocardiogram, chest x-ray, measurement of O_2 saturation or arterial blood

gases, urinalysis with culture and sensitivity, and urine drug-toxicology screen.

When clinically indicated, consider specific blood tests: VDRL or fluorescent treponemal antibody, heavy metal screen, vitamin B_{12} and folate, antinuclear antibodies, urine porphyrins, blood ammonia, HIV, thyroid-stimulating hormone, blood cultures, medication blood levels (e.g., digoxin, lithium, phenobarbital, diphenylhydantoin [phenytoin], theophylline, tricyclics), lumbar puncture, and neuroimaging (computed tomography or magnetic resonance imaging). An electroencephalogram is probably more helpful in ruling out (when normal) than ruling in delirium.

A careful history can identify precipitating factors or predisposing conditions, whereas the physical exam can

be useful in identifying contributing disorders. Most important, perhaps, is the need for a careful medication review, including all over-the-counter medications and nutraceuticals, concentrating in particular on anticholinergic agents and central nervous system depressants. For hospitalized patients, it is important to note that the cause of a delirium is frequently multifactorial, *so the search for a cause should not stop at the first identifiable factor.*

Management and Therapy

Optimum Treatment

Optimum treatment requires that a delirium be identified when present and that an aggressive search for *all* modifiable medical causes be undertaken. Early recognition of delirium may offer significant opportunities to prevent disability and irreversible deterioration. However, by one estimate, 32% to 67% of all deliria go undetected. While the search for causes is in progress, efforts to reduce patient distress and ensure safety should be initiated. Strategies for accomplishing both are listed in Box 181-2.

Medications can sometimes be useful to control symptoms or to increase patient comfort but should never detract from the main goal of identifying and mitigating causative factors. Antipsychotics and benzodiazepines have

been the mainstays of pharmacologic treatment, although other agents are sometimes useful for specific conditions.

Antipsychotics can be useful for the psychosis, agitation, and emotional lability seen with delirium. They have been shown to be superior to benzodiazepines in effectiveness, with fewer side effects in most studies except for sedative-hypnotic or ethanol withdrawal syndromes. High-potency agents are preferred because of minimal anticholinergic effects and sedation. Extrapyramidal side effects, although possible with these agents, are generally not a contraindication to short-term use in delirium. Anticholinergic antidotes should be avoided. Antipsychotics are absolutely contraindicated in neuroleptic malignant syndrome (NMS). If the QTc is greater than 450 msec, further assess cardiac status before beginning or continuing use of these agents.

Traditional choices include *haloperidol*, 1 to 2 mg every 4 hours orally, intramuscularly, or intravenously (0.25 to 0.50 mg for elderly patients), with titration to higher doses as indicated for continued agitation (intravenous dosing should be no more than 1 mg/min to reduce cardiac complications), and *droperidol* (more rapid onset of action, more sedating, similar dosing guidelines, but can prolong QTc).

There are few empirical data concerning the use of the newer atypical antipsychotic agents in delirium, and the better side-effect profile for long-term use of these agents in primary psychotic disorders may not be relevant for delirium. Nevertheless, newer agents such as *risperidone* (0.25 to 1 mg every 6 hours orally) and *olanzapine* (2.5 to 5 mg once or twice per day, orally or intramuscularly) have been effective in small open studies and case reports. *Quetiapine* may also be useful, especially in hyperactive delirium when sedation is needed (*25 to 50 mg PO two to three times per day*).

Benzodiazepines can be useful for agitation and fearfulness. Use as monotherapy for sedative-hypnotic or ethanol withdrawal delirium or adjunctively with antipsychotics if antipsychotics alone are not working for agitation. Lorazepam is the drug of choice because it is short acting and has no active metabolites. Avoid its use in patients with hepatic encephalopathy. Remember that benzodiazepines can promote amnesia and respiratory depression, which might worsen confusion.

Anticholinesterases (physostigmine, donepezil, rivastigmine) can be useful in anticholinergic delirium, and may work for other types of delirium as well, because brainstem cholinergic neurons support cortical activation, and many deliria may result from underactivity in this system (although, in alcohol withdrawal, the problem may be catecholaminergic overactivation). An example of dosing is as follows: physostigmine, 0.50 to 2 mg intravenously or intramuscularly or by continuous intravenous infusion at 3 mg/hour; donepezil: 5 to 10 mg once per day; or rivastigmine, 1.5 mg orally twice a day, maximum dosage 6 mg twice a day.

Additional treatment strategies include mitigating specific causes (such as *thiamine* for Wernicke's encephalopathy).

Box 181-2 General Treatment Strategies

- Identify causative factors and mitigate if possible.
- Ensure safety and comfort of the patient and others.
- Avoid restraints if possible, but use if necessary for safety.
- Improve function and decrease symptoms (consider medications for severe symptoms).
- Reduce factors that may exacerbate delirium (such as anticholinergic medicines).
- Provide an optimal level of environmental stimulation: The room should be adequately lighted, including the use of night lights in the evening.
- Avoid overstimulation and understimulation. Keep exposure to chaotic environments to a minimum because many delirious patients are hyperresponsive to stimuli.
- Reduce sensory impairments (let patients use glasses and hearing aids if the clinical state allows).
- Provide environmental cues to facilitate orientation: The room should have a large, easily viewable calendar and clock.
- Staff and family should make the effort to remind the patient of the day, date, and situation frequently. Reminders of who people are may be necessary as well.
- If possible, familiar items from home should be brought into the room.
- Encourage frequent interactions with staff and family.
- Consider telling the patient that he (or she) is confused and disoriented.
- Eliminate nonessential medications and ensure adequate hydration and nutrition.

lopathy) or attenuating cortical dysfunction (such as *electroconvulsive therapy* for refractory NMS or prolonged delirium).

Avoiding Treatment Errors

The most common mistake in the treatment of delirium is the misidentification of the syndrome or failure to recognize it altogether. This prevents the appropriate mitigating interventions and can lead to the prescription of medications (such as anticholinergic antipsychotics or benzodiazepines) that can worsen the condition.

Future Directions

For delirium, the improvement in treatment will likely parallel advances in the recognition and management of the medical conditions that are etiologic. Concurrently, further work targeting the neurochemical disturbances in delirium will be needed to examine whether memory-enhancing agents that work through cholinergic mechanisms to reverse the symptoms of anticholinergic delirium or excitotoxic modulators such as memantine can be beneficial in other types of delirium as well. Along this same line of thought, research into efforts to prevent or reduce the likelihood of a delirium in high-risk situations, including the use of prophylactic anticholinesterases, is warranted.

Dementia

Introduction

Dementia is an acquired syndrome characterized by multiple cognitive deficits leading to reduced intellectual capacity and impairments in social or occupational functioning. Deficits always include short-term memory impairment and one or more of the following: impaired language skills (aphasia), motor planning difficulties (apraxia), sensory deficits (agnosia), and difficulties in judgment, planning, or abstract thinking (executive function).

The prevalence of dementia increases dramatically with age. Although exact numbers are not known, it is estimated that 4.5 million individuals in the United States suffer from Alzheimer's disease (AD) alone. Incidence and prevalence figures accelerate dramatically in people older than 85 years, with prevalence rates for AD approaching 50% in this population (Table 182-1). Besides AD, the most common dementias include vascular (VaD), Lewy-body (LBD), and alcohol-related dementias.

Dementias can be broadly classified as primary versus secondary, based on the pathophysiology leading to damaged brain tissue; cortical versus subcortical, depending on the location of the primary deficits; reversible versus irreversible, depending on optimal treatment expectations; and early versus late onset, depending on age of onset. Frontotemporal dementias, familial AD, and some VaDs are the most common early-onset dementias, whereas AD is the most common late-onset dementia. HIV is the most common cause of dementias beginning before age 55 years.

Most dementias have an insidious onset with progressive decline over many years. Some dementias have a more fulminate course (Creutzfeldt-Jacob disease [CJD]), and others may remit spontaneously or with treatment (vitamin B₁₂ deficiency). Despite initial differences in presentation, late-stage dementias often look alike. Common causes of death in advanced dementia include aspiration pneumonia, sepsis from stasis ulcers, dehydration, and urinary tract infections.

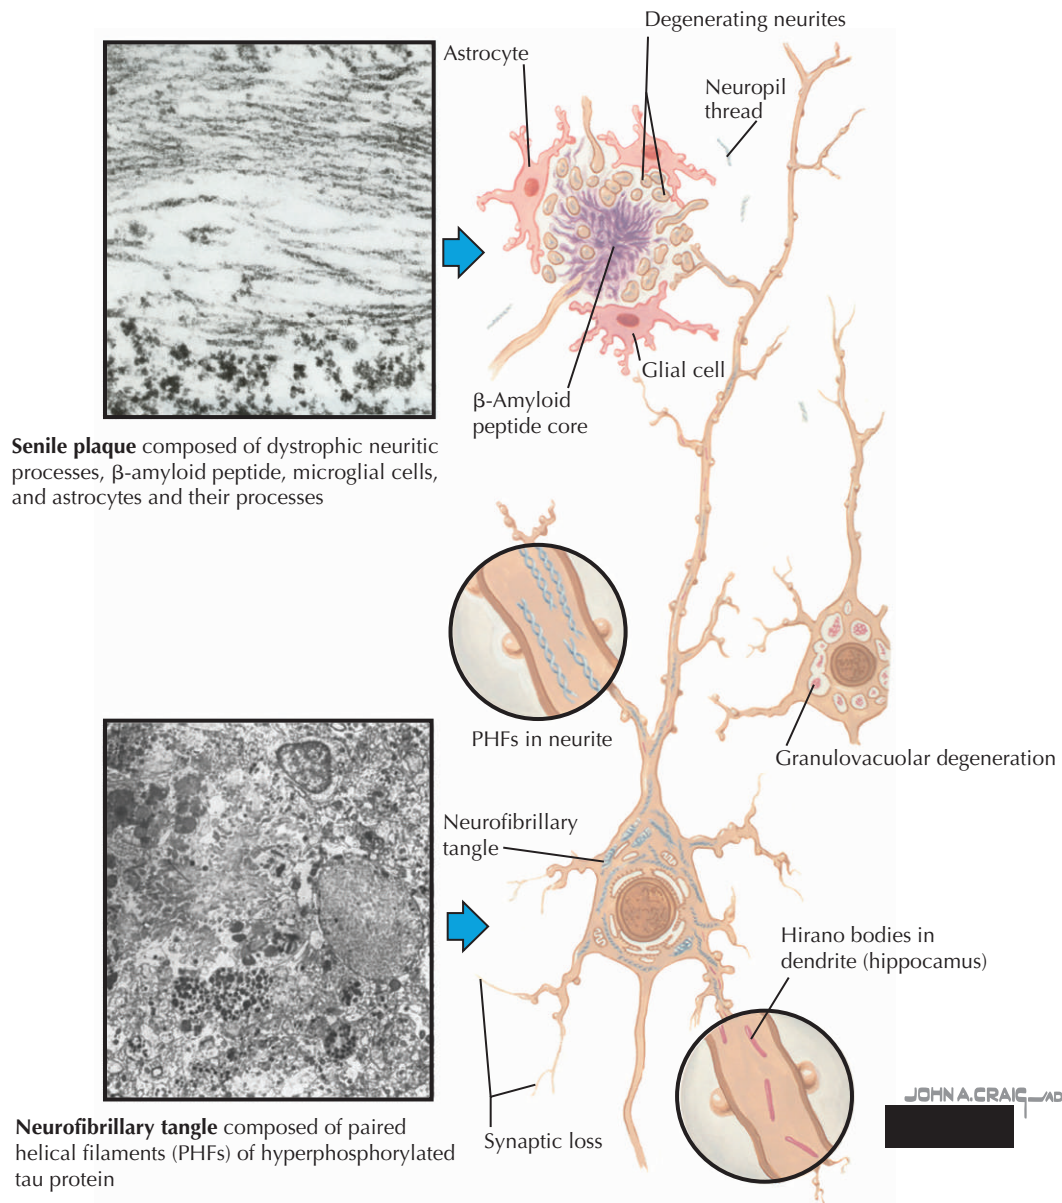

Etiology and Pathogenesis

AD is the most common dementia and accounts for 50% to 75% of the total cases (with an even higher percentage of cases beginning after age 80 years). It has a predictable progression that can be reliably staged. Cognitive and social skills are often lost in the reverse order of development, and individuals may appear to function well on a superficial social level long after they have become incompetent to handle complex decision making such as financial planning. Alzheimer's patients typically live 8 to 10 years after diagnosis, and diagnosis often occurs 3 to 4 years after symptoms first appear.

Pathophysiology consists of higher than expected concentrations of neuritic (senile) plaques (abnormal insoluble

amyloid protein fragments) and neurofibrillary tangles (disturbed tau-microtubule complexes), especially in hippocampal and posterior temporoparietal areas (Fig. 182-1). There is cholinergic system degeneration with decreased acetylcholine (ACh) levels and significant loss of neurons in areas such as the nucleus basalis of Meynert. Decreases in serotonin and norepinephrine and increases in glutamine activity have also been reported in AD.

Well-established risk factors include age, family history, Down syndrome, head trauma, female gender, and genetics. The apolipoprotein E-4 (APO E-4) allele on chromosome 19 has been associated with late-onset disease, and multiple autosomal dominant gene mutations on chromosomes 1, 14, and 21 have been associated with early-onset cases. Additional risk factors include ethnicity (African

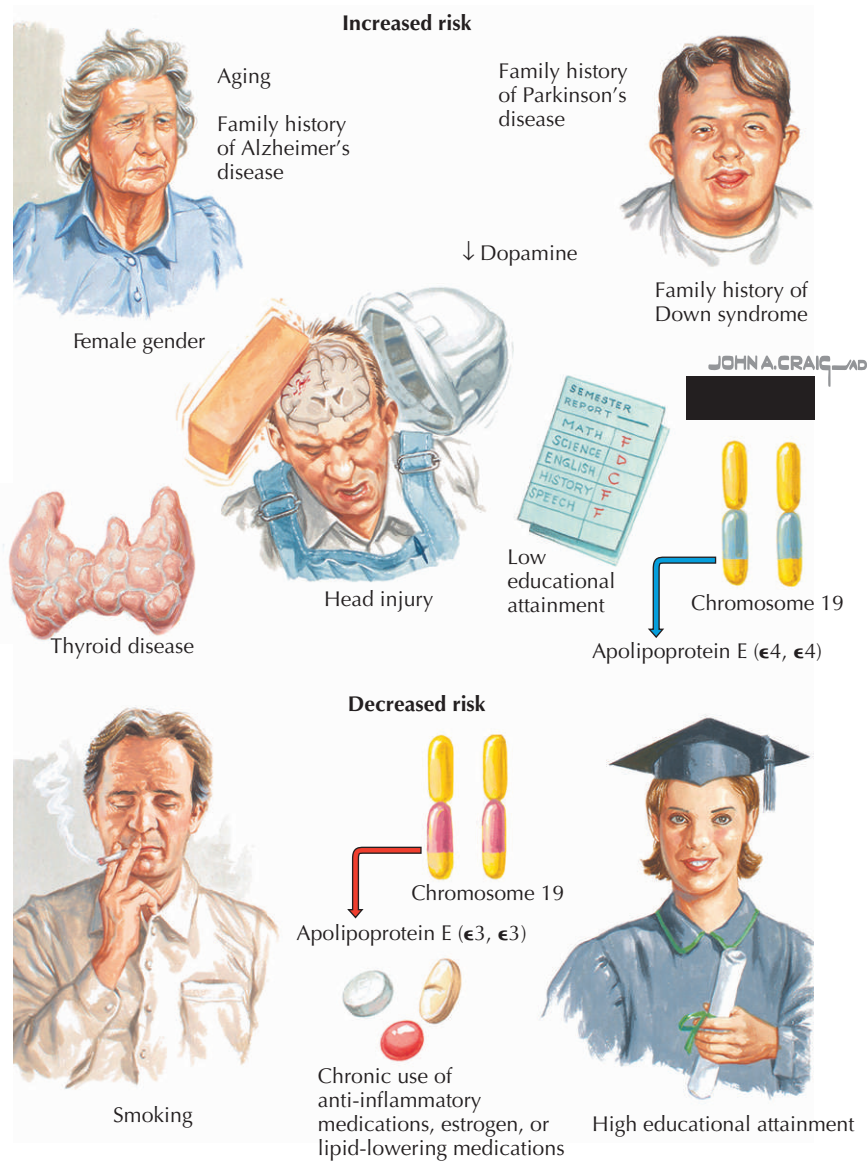

Figure 182-1 Microscopic Pathology in Alzheimer's Disease.**Table 182-1** Prevalence Estimates for Dementia

Age	Prevalence Estimates for Dementia*	Age (yr)	Incidence Estimates for Dementia
>65	5%-10%	65-74	0.5%-1%
>75	10%-20%	75-84	2%-4%
>85	25%-50%	85-95	6%-8%
>95	40%-70%	100+	May level off or decline after age 100 yr

* Lower numbers reflect prevalence of moderate to severe dementias.

Americans more than whites), late-onset depression, diabetes, and cerebrovascular disease. Possible protective factors include education, use of some anti-inflammatory agents, estrogen replacement, antioxidants, statins, and APO E-3 genotypes (Fig. 182-2).

VaD is the second most common dementia (15%-20%) and includes Binswanger's disease, multi-infarct dementia, anoxic damage, postcoronary artery bypass graft conditions, and inflammatory diseases. Age, hypertension, diabetes, and hyperlipidemia are the documented risk factors.

Figure 182-2 Risk Factors for Alzheimer's Disease.

VaDs may show a stepwise progression and are frequently associated with focal neurologic findings. Cortical atrophy and periventricular white matter changes consistent with microvascular disease are the most common findings on head imaging. VaD typically has a shorter course and earlier onset than AD, but the two frequently coexist (mixed dementia). LBDs can have a presentation similar to AD, although subcortical symptoms, higher frequency of visual hallucinations, sensitivity to antipsychotic medications, and fluctuating symptoms can often distinguish the two clinically (Fig. 182-3). Alcohol-related dementias are also common (Box 182-1).

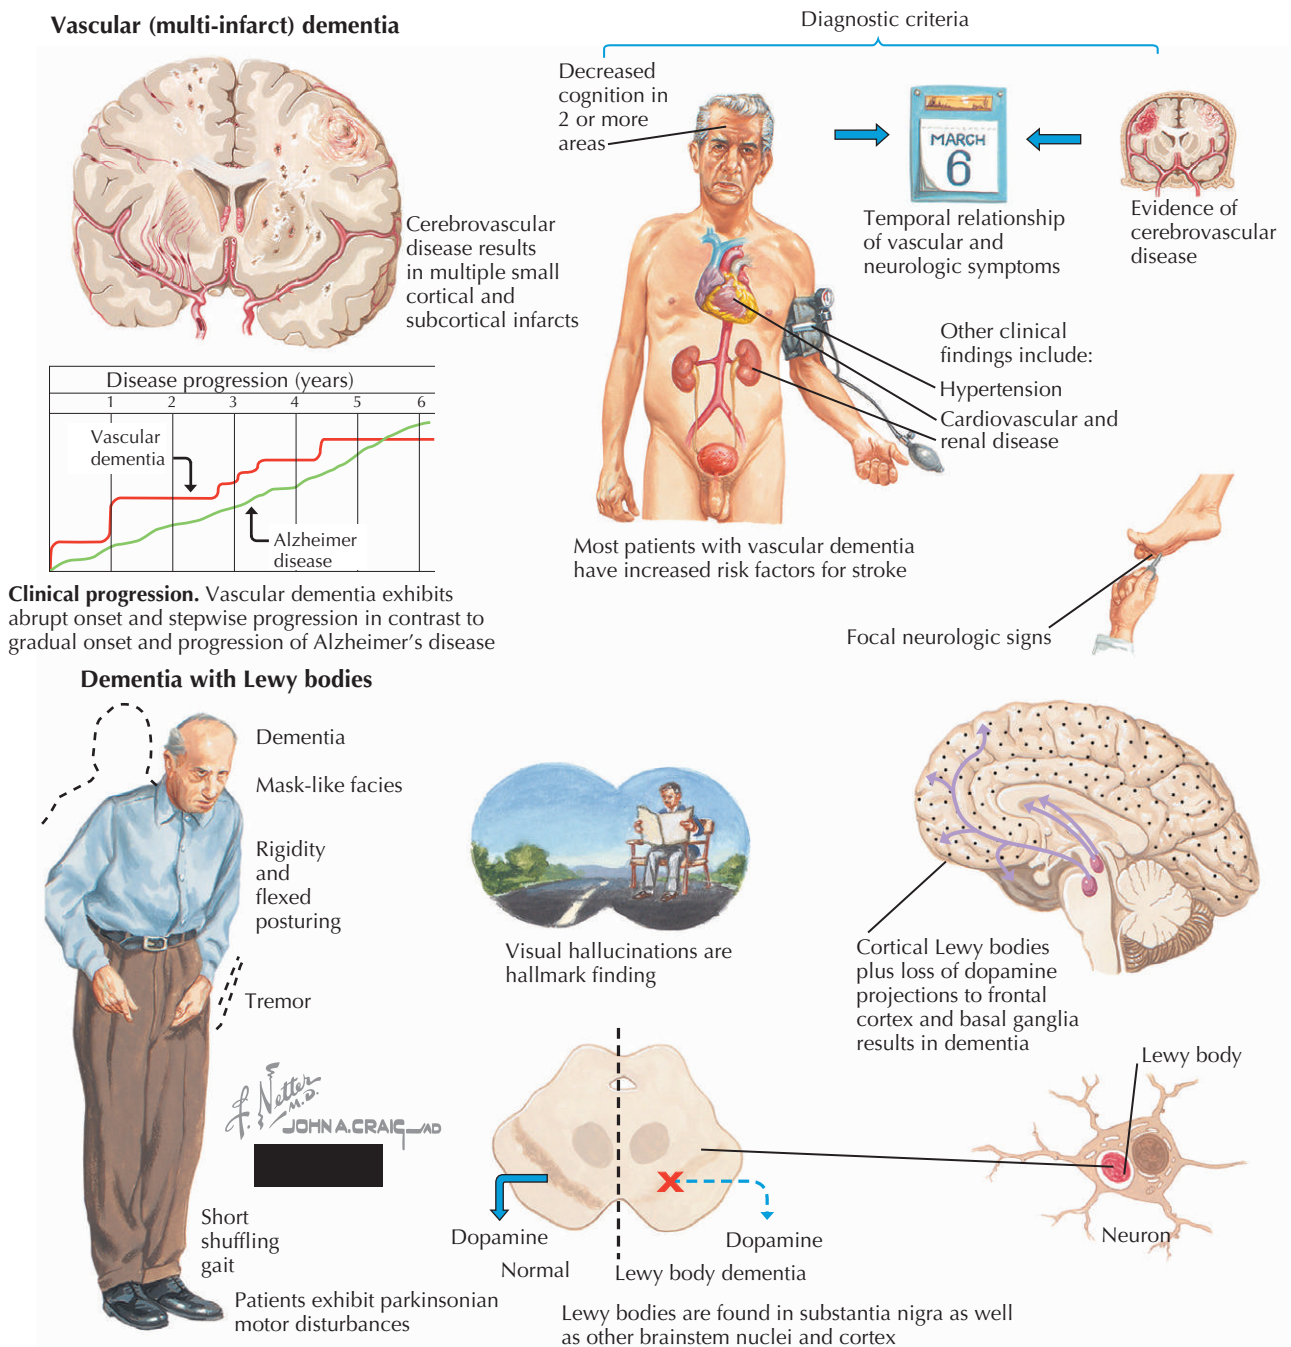

Clinical Presentation

Dementia is always associated with cognitive disturbances and functional impairments, whereas visuospatial deficits

and behavioral disturbances are frequently seen as well. Initial presentations can vary depending on the type of dementia, stage of illness, willingness to seek help, and cultural tolerance for certain types of symptoms. Memory and language impairments include difficulty retaining new information (learning failure); information retrieval deficits (name or word-finding difficulties); personal episodic memory impairment (misplacing items); list generation deficits; and impairments in declarative memory (what) greater than procedural memory (how). Typically sentence structure becomes less complex, whereas auditory comprehension and social conversation are usually preserved. Visuospatial impairments can lead to not recognizing relatives, getting lost in familiar surroundings, and three-dimensional drawing deficits.

Behavioral symptoms are nearly universal and are often the main focus of families' concerns and complaints.

Figure 182-3 Vascular Dementia and Dementia with Lewy Bodies.

Inability to manage these types of symptoms is highly correlated with the need for institutional placement. Personality change occurs early and includes passivity (e.g., apathy, social withdrawal), disinhibition (e.g., inappropriate sexual behavior or language), and self-centered behaviors (e.g., childishness and loss of generosity). Agitation is very common and frequently worsens as the illness progresses. It includes verbal (25%) and physical (30%) aggression and nonaggressive behaviors such as wandering and pacing

(25% to 50%). Aggression strongly correlates with caregiver burnout, especially when wandering is also present. Associated features of dementia include depression (often occurs early, common in AD and VaD); delusions (typically paranoia about theft, infidelity); hallucinations (often visual, particularly common in LBD); and sleep problems (insomnia, sleep-wake cycle disturbances). Functional impairment and performance on cognitive testing may not correlate strongly early in the course of

Neurosyphilis, Lyme disease, HIV
 Viral, parasitic, bacterial, and fungal meningitis or encephalitis
 Postencephalitic dementia (especially following herpes encephalitis)
 Opportunistic infections or brain abscess
 Human prion disease (transmissible spongiform encephalopathies including Creutzfeldt-Jacob disease [CJD], variant CJD [mad cow disease] and kuru)

General Medical Causes of Dementia

Alcohol-related (Korsakoff's syndrome)
 Thyroid and adrenal disease
 Vitamin deficiency states (thiamine, niacin, or B₁₂)
 Metabolic derangements (dialysis dementia, hepatic encephalopathy, hypercalcemia, glucose dysregulation, electrolyte disturbances, posthypoxia)
 Medications (sedatives, antihypertensives, cardiac medications, narcotics, anticholinergics)
 Whipple's disease, sarcoidosis, Wilson's disease
 Toxins (heavy metals, organic poisons)

dementia because an individual may function reasonably well in many areas despite deficits on testing early in the illness or vice versa. The rate and specific pattern of loss will vary by individual. Deficits appear first in instrumental activities of daily living such as managing finances, driving, using the telephone, taking medications, and keeping appointments. Eventually deficits appear in more basic skills such as feeding, grooming, dressing, eating, and toileting (activities of daily living).

Differential Diagnosis

Mild impairments in memory without clear-cut functional decline are referred to as *mild cognitive impairment* (MCI). With Mini Mental State Examination (MMSE) scores typically in the 24 to 30 range, many of these individuals are in the premorbid stage of a dementia, and about 15% per year progress to the full dementia syndrome. However, others remain stable or remit completely over time.

In a pure amnesic syndrome, short-term memory is impaired without significant impairments in other cogni-

tive domains (e.g., alcohol amnesic syndrome), whereas the essential impairment in delirium is a reduced level of consciousness and attention along with rapidly fluctuating symptoms (although most of the symptoms of dementia are present as well).

Mental retardation is a developmental disorder associated with impaired intellectual capacities that may or may not affect memory. *Pseudodementia* refers to cognitive impairment in the context of another psychiatric disorder, such as depression, that is often attributed to decreased concentration or poor effort during testing. Finally, a receptive aphasia may be confused with dementia because of impaired cognitive testing secondary to comprehension failure.

Interestingly, many of these conditions have an association with dementia: For example, Down syndrome patients are at high risk for developing AD at a young age; pseudodementia and MCI often herald the onset of a true dementia; and delirium is an extremely common complication of dementia.

Diagnostic Approach

A careful history from the patient and a reliable informant are critical for early detection with chronology of symptoms and functional impairments of particular importance. A thorough physical examination with particular focus on the neurologic exam is an important part of the initial workup. Cognitive screening tools are helpful for documenting deficits and for monitoring progression. Examples include the MMSE, or the Six-Item Blessed Orientation-Memory-Concentration Test. The MMSE is widely available and easy to use and should be considered in all new patients older than 65 years. Scores less than 24/30 are considered worrisome for individuals with at least a 6th grade education. The Clock Drawing Test is another easy to administer screen for dementia, particularly AD. Neuropsychological assessment or referral to a specialist should be considered when cognitive testing and functional assessment are at odds, when there is a strong suspicion of early dementia in a high-IQ individual with a normal MMSE, for competency assessments in legal proceedings, or if mild impairment is seen with any of the following: low IQ or limited education, trouble with English, or minority racial or ethnic background.

The goal of the diagnostic workup is to rule out disorders besides dementia, to identify reversible (13%) dementias (such as NPH, B₁₂ and folate deficiency, thyroid disease, psychiatric disorders), or to clarify the specific dementia syndrome (Table 182-2). Routine assessment includes complete blood count with differential, serum electrolytes, calcium, glucose, blood urea nitrogen, creatinine, liver function tests, thyroid function tests, B₁₂ and folate, urinalysis, and syphilis serology. Consider sedimentation rate, HIV testing, chest x-ray, 24-hour urine for heavy metals, toxicology screen, neuroimaging, lumbar

Table 182-2 Dementia Types and Diagnosis

Dementia Type	Suggested by	Dementia Type	Suggested by
Alzheimer's disease	Insidious onset and progressive worsening Prominent memory retention deficits early in the course Onset after age 70 yr with no focal signs or gait disturbances Exclusion of reversible dementias List generation difficulties	Vascular dementia	Relatively abrupt onset and stepwise or fluctuating course History of stroke, hypertension, or diabetes Focal neurologic signs or symptoms Emotional lability, depression Somatic complaints with relative preservation of personality
Lewy body dementia	Executive function impairments greater than memory impairments early on Fluctuating deficits during the day Visual hallucinations Mild parkinsonism and sensitivity to antipsychotics	Dementia syndrome of depression (pseudodementia)	Memory, concentration impairments in the absence of apraxia, agnosia, and aphasia Apathy, low motivation, and other neurovegetative signs of depression Exaggerated complaints of memory impairment, poor effort in testing History of cognitive changes with depression
Frontotemporal dementia	Prominent early personality changes with apathy, disinhibition, and antisocial behavior Peculiar behavior and verbal stereotypes such as "let's go, let's go" Preserved visuospatial skills	HIV/AIDS dementia	Forgetfulness, psychomotor slowing, impaired problem solving, apathy Neurologic signs such as tremor, ataxia, hyperreflexia, frontal release signs Age <55 yr
Subcortical dementia	Psychomotor slowing, frontal systems dysfunction, short-term memory impairment Depression and apathy Neurologic findings such as parkinsonism, ataxia, and urinary incontinence Less pronounced language difficulties until late in course	Delirium (<i>as opposed to dementia</i>)	Acute or subacute onset Impaired consciousness and attention Fluctuating course Disorganized thinking Medical illness Mental status change in patient with preexisting dementia

puncture, electroencephalogram (EEG), functional imaging, Lyme titers, endocrine studies (other than thyroid), and rheumatologic studies when indicated. Neuroimaging should be considered in all new cases, although in individuals older than 80 years with no focal symptoms or signs, seizures, or gait disturbances, it can be considered optional. Magnetic resonance imaging (MRI) is preferred if the patient can tolerate it. A lumbar puncture is indicated for suspicion of metastatic cancer, central nervous system (CNS) infection, reactive serum syphilis serology, hydrocephalus, dementia before age 55 years, rapidly progressive dementias, immunosuppression, and suspicion of CNS vasculitis. EEG may be helpful in distinguishing delirium from dementia, diagnosing CJD, and identifying seizure disorders. If available, functional imaging (single-photon emission computed tomography, positron emission tomography [PET], magnetic resonance spectroscopy) may help clarify the type of dementia in diagnostically confusing cases. Staging identifies current care needs and predicts future requirements. Functional assessment scales such as the Functional Activities Questionnaire can be useful for clarifying impairments and tracking responses to interven-

tions. Psychosocial assessment should address patient issues (such as safety and appropriateness of current living situation and presence of comorbid psychiatric conditions), caregiver issues (such as adequacy of support network, presence of depression, and need for financial planning), and environmental issues (such as home safety and driving concerns).

Management and Therapy

Optimum Treatment

Optimum treatment requires a systems approach that recognizes the needs of both the patient and the principal caregivers. The primary goal is to ensure the safety of patient and family, to improve the quality of life for the patient and caregivers, and ultimately to prevent caregiver burnout and forestall institutionalization. For the patient, attempts should be made to minimize cognitive symptoms, recognize and address behavioral and psychiatric comorbidities, and optimize functional adaptation. For caregivers, it is critical to recognize the need for emotional, physical, and financial support and to monitor carefully for

Figure 182-4 Pharmacologic Management Options in Alzheimer's Disease.**Table 182-3** Cholinesterase Inhibitors

Drug	Starting Dose	Goal	Notes
Tacrine	10 mg 4 times a day	120-160 mg/day	NOT FIRST LINE because of 4 times a day dosing and liver function test elevations
Donepezil	5 mg every day	10 mg every day	Maintain starting dose for 1-3 weeks to minimize side effects
Rivastigmine	1.5 mg twice a day	6-12 mg/day	Similar side effects to tacrine, donepezil, and galantamine: nausea, vomiting, bradycardia
Galantamine	4 mg twice a day	8-12 mg twice a day	Reversible anticholinesterase inhibitor plus modulation of receptors to increase acetylcholine release

the presence of clinical depression (which may occur in up to 50% of isolated caregivers). A referral to groups such as the Alzheimer's Association for support or to legal aid for competency questions can often be helpful.

Primary treatment strategies include efforts to mitigate or reverse cognitive symptoms, prevent progression of the illness, or optimize compensatory function. In some cases, specific therapies to reverse an underlying disease process (such as B₁₂ or thyroid replacement) may be all that is required. In most cases, however, the best practice is to try and mitigate the pathophysiologic dysfunction. In AD, (cholinergic dysfunction) excess glutamatergic activity, and the accumulation of abnormal amyloid protein have been the targets of medical intervention. Efforts to

increase cholinergic activity include precursor strategies (such as lecithin) to increase production of ACh, cholinergic agonists (not currently available) to mimic ACh, and cholinesterase inhibitors to prolong synaptic availability (Fig. 182-4). The latter has been most successful, and a number of anticholinesterases are available (Table 182-3). These agents may be useful in non-AD dementias as well. Currently evidence is strongest for VaDs and LBDs. Memantine, a weak antagonist of glutamate-gated NMDA receptor channels, has been shown to improve function in moderate to severe AD. By preventing overactivation during memory formation, it may also be useful in slowing progression of these disorders by preventing excitotoxic damage.

Figure 182-5 Amyloidogenesis in Alzheimer's Disease.

Other promising therapies include gene replacement strategies, tissue transplantation, anti-amyloid vaccines, and agents that interfere with abnormal amyloidogenesis (Fig. 182-5).

Strategies to prevent progression include controlling risk factors (hypertension and diabetes management, stroke prevention); treating underlying medical causes aggressively; and using cerebral shunts for normal-pressure hydrocephalus (which may also reverse symptoms). There is some limited evidence that antioxidants (vitamin E, ginkgo, selegiline), nonsteroidal anti-inflammatory agents,

homocysteine reduction strategies, and other neuroprotective agents (acetyl carnitine) might be useful in progressive dementias. However, evidence is not strong enough to recommend any of these agents routinely, and the safety of even relatively nontoxic agents such as vitamin E has come into question.

Strategies to enhance CNS function (or to promote compensatory mechanisms) include estrogen replacement (which may be useful in delaying onset of AD in postmenopausal women), coping skills training (particularly for nonprogressive or slowly progressive dementias), and

eliminating agents known to interfere with cognitive function such as anticholinergic agents and benzodiazepines (Box 182-2).

Treatment of the associated (secondary) symptoms of dementia often becomes the main focus of treatment because much of the morbidity associated with dementia (in both the patient and caregiver) is related to these symptoms, which include depression, agitation, psychosis, insomnia, and wandering. A careful medical evaluation, especially for sudden mental status changes, new-onset or worsening psychosis, or increased agitation, is a necessary first step. When satisfied that new or ongoing medical problems are being addressed appropriately, specific symptomatic interventions can be tried.

For psychosis, calm reassurance and distraction may be all that is required if there is little distress or danger. Although the atypical antipsychotics are quickly becoming the drugs of choice, haloperidol remains a good choice for the elderly patient owing to few side effects, proven efficacy, and low cost (Table 182-4). Orthostasis and anticholinergic effects are potential problems with both traditional neuroleptics and the new generation agents.

Box 182-2 Common Anticholinergic Agents

Antiparkinson drugs (bentropine, trihexyphenidyl)
Tricyclic antidepressants (especially amitriptyline and imipramine)
Traditional antipsychotics (especially low-potency drugs)
Atypical antipsychotics (especially clozapine and olanzapine)
Urinary agents for incontinence (tolterodine, oxybutynin)
Others (cimetidine, ranitidine, digoxin, furosemide, nifedipine, theophylline, paroxetine)
Sleep aids (diphenhydramine)

Maintain a low threshold for diagnosing depression because this condition is common and can make cognitive symptoms and overall functioning worse. Preservation of autonomy, supportive counseling, and encouragement of enjoyable activities can be useful interventions. Selective serotonin reuptake inhibitors are the first choice for medication treatment, but paroxetine should be avoided because of anticholinergic effects.

For agitation, responding in a direct and calm manner (rather than arguing), redirection, and determining what is upsetting the patient can be helpful. Medications, if needed, should target specific conditions first (e.g., antidepressants for agitation in the context of depression). Nonspecific antiagitation medications include antipsychotics, anticonvulsants, benzodiazepines, trazodone, and buspirone. Anticholinesterases may be effective for these and other secondary symptoms and should be considered if not already prescribed. Antipsychotics, although predictably effective, have come under some scrutiny recently because of the possibility of increased stroke risk in elderly dementia patients. Low-dose trazodone (25 mg every 6 hours as needed) or quetiapine (12.5 to 25 mg every 6 hours as needed) is often well tolerated and effective, although orthostasis can occur with both. Benzodiazepines should always be used cautiously in this population because of the potential for ataxia, worsened memory, and disinhibition.

Wandering can be minimized by secure, well-lit environments, dementia-proof locks, and environmental barriers such as grid patterns on the floor, and by determining whether the patient is anxious or restless. For insomnia, educate patients and caregivers about sleep hygiene measures and determine whether this symptom is a manifestation of another disorder such as depression. Avoid benzodiazepines because of ataxia and amnesia and

Table 182-4 Antipsychotics

Atypical Agent	Useful for	Pros	Cons*	Dose Range
Risperidone	Agitation, psychosis	Well studied, generally well tolerated	EPS common in elderly, prolactin elevations occur	0.25-2 mg twice a day
Olanzapine	Mania, psychosis, agitation	Weight gain can be a plus for some patients, dissolvable pill form available (Zydis)	Weight gain, hyperglycemia, anticholinergic effects	2.5-10 mg every day
Quetiapine	Psychosis, agitation, insomnia	Low doses useful for insomnia; not anticholinergic	Sedating, complicated dosing	12.5-200 mg twice a day
Ziprasidone	Psychosis, agitation	Low sedation and weight gain	Prolongs QTc interval	20-60 mg twice a day
Clozapine	Refractory psychosis (not for first line use)	Parkinson's disease patients may benefit	Sedation, bone marrow suppression, highly anticholinergic	12.5-300 mg every day
Haloperidol	Agitation, psychosis, mania	Best studied, well tolerated in elderly, few side effects, inexpensive, many dose forms	EPS (esp. akathisia); high TD risk with prolonged use	0.5-2 mg once or twice a day

* Potential orthostasis and high cost are problems with all these agents except haloperidol. EPS, extrapyramidal syndrome; TD, tardive dyskinesia.

diphenhydramine because of anticholinergic effects. Consider trazodone (25 to 100 mg) or quetiapine (25 to 50 mg) if medications are needed. Zolpidem (5 to 10 mg) or esopiclone (2 to 3 mg) may be useful for short periods.

Avoiding Treatment Errors

Ignoring the needs of the caregiver and not recognizing the presence of a delirium when mental status changes abruptly in a dementia patient are two common treatment errors. Additionally, failure to recognize treatable comorbidities such as depression and failure to minimize anticholinergic medications such as oxybutynin are also avoidable mistakes.

Future Directions

Research is progressing rapidly in the treatment of AD, the most common and fastest growing dementia. Antiamyloid vaccines, secretase inhibitors (plaque busters), anti-inflammatory strategies, and more specific memory enhancing agents are all being tested with encouraging early results. Gene manipulation and surgical implantation techniques are being investigated along with strategies that enhance the brain's ability to dispose of abnormal proteins. With justified excitement in the treatment realm, the need for accurate early detection strategies is of increasing importance, and the development of a safe, easy to use, and reliable screening test for Alzheimer's (and other degenerative dementias) will be a high priority. Currently, functional imaging, biologic markers, and genetic testing hold the most promise.

This consensus statement on diagnosis and treatment predated the APA guidelines by 2 years and served as a model for the more recent guidelines.

Advance Directives

Introduction

Advance directives are documents that specify an individual's end-of-life care treatment preferences and designate surrogate decision makers if the person lacks decision-making capacity. The primary goal of advance directives, including living wills and health care proxy forms, is to promote respect for patients' treatment preferences when they cannot communicate. Despite a federal law enacted 15 years ago to increase the use of advance directives, low completion rates persist among adults—a fact of special note given prior studies that suggest that patients want physicians to discuss advance directives with them.

Background

The proliferation of life-saving treatments in the 1960s, such as cardiopulmonary resuscitation, mechanical ventilation, and hemodialysis, not only prolonged patients' lives but also prolonged the deaths of those left uncured. During the past three decades, the cases of three young women in persistent vegetative states—Karen Ann Quinlan in the 1970s, Nancy Cruzan in the 1980s, and Terri Schiavo in this decade—epitomize for many Americans the core problem with end-of-life care: dying patients who are unable to communicate their preferences are kept alive using medical technologies they may not want utilized at a time when they are powerless to determine their treatment. The legal conflicts involving these women have helped solidify dying patients' rights to determine their medical decisions, either themselves, through prior expression of their wishes, or through the voices of surrogate decision makers. The principle that respect for patient autonomy should be valued independent of patients' decision-making capacity is now well ingrained within the health care system.

Consensus that capable patients have the right to make their own medical decisions, even decisions that could hasten death, had been reached in the legal and medical communities before the Quinlan, Cruzan, and Schiavo cases. However, as with these women, most life-sustaining treatment withdrawal decisions affect patients who lack decision-making capacity and therefore cannot provide informed consent. Cognitive impairment from dementia,

delirium, and serious illness prevents patients from understanding their condition, from weighing the risks and benefits of treatment decisions, and from expressing a treatment preference.

The decisions reached in these young women's cases established the ethical principles used to make medical decisions for incapacitated patients and provided the legal basis supporting the development of advance directives. In the Quinlan decision, a court supported her parents' request for decision-making authority based on the ethical principle of "substituted judgment," meaning that they could best represent the decisions that Ms. Quinlan would have made if conscious. This decision recognized that the use of a surrogate decision maker, usually a spouse or blood relative, could extend patients' decision-making autonomy to times when they are incapacitated. Physicians ask surrogate decision makers to consider any prior preferences expressed by the patient when making decisions, or to use judgment regarding the patient's best interests when specific instructions have not been given.

The Quinlan case demonstrated the need for incapacitated patients to have loved ones who could represent their treatment preferences. In response, patient advocates proposed advance directives as mechanisms for patients to specify treatment preferences and select preferred decision makers in advance of any condition associated with decision-making incapacity. A United States Supreme Court decision in the Cruzan case had the effect of promoting advance directive use by ruling that states could establish standards regarding the "clear and convincing"

evidence necessary to establish an incapacitated patient's treatment preferences. Based on this decision, all states have included advance directives as a mechanism to satisfy their evidentiary standards.

The nationally publicized Terri Schiavo case serves as the most recent reminder that advance directives can have an important role in end-of-life care decision making. Ms. Schiavo's protracted legal dispute would likely have been avoided if she had signed a living will or formally designated either her husband or one of her parents as her health care proxy.

Definitions and Legal Considerations

The two most commonly completed advance directives are *living wills* and *health care proxy* (or *health care power of attorney*) documents. Living wills can provide either general or specific information regarding patients' end-of-life care treatment preferences in the event of both decision-making incapacity and either a terminal illness or a persistent vegetative state. A living will may state that a person wishes to avoid receiving "extraordinary measures" without detailing the treatments considered by the patient as extraordinary. Other living wills provide a listing of treatment decisions ranging from mechanical ventilation to antibiotic use, and patients note whether or not they would be willing to receive each treatment.

Although living wills may provide information relevant to understanding patients' preferences regarding attempts at cardiopulmonary resuscitation, a separate Do Not Resuscitate order must be signed by a physician if patients wish to avoid cardiac resuscitative measures.

Health care proxy forms designate the individual who will serve as the surrogate decision maker in the event the patient becomes incapacitated. This form can also include the name of an alternate if the primary surrogate is unavailable. Physicians have an ethical and legal obligation to communicate with health care proxies to receive their consent for all medical decisions affecting patients. Although the scope of living wills is generally limited to end-of-life care decisions, the responsibility of health care proxies extends to all treatment considerations. The decision-making authority of health care proxies only pertains to medical decisions; other documents grant powers such as financial decision making when patients are incapacitated.

Patients may complete a living will, a health care proxy document, or both directives. Living wills and health care proxy documents become legally valid once signed in front of the required witnesses, which may include a notary public. A lawyer's assistance is not required to complete an advance directive. Advance directives do not expire unless specified by the patient and may be changed by a capable patient at any time. The laws governing advance directives vary from state to state, so it is important for patients to complete and sign directives that comply with their state's

law. One state's advance directive may not be considered legally valid in other states. Some states honor directives from other states; others will honor out-of-state directives as long as they are in compliance with the state's own law; and some states do not provide clear guidance regarding the legal validity of out-of-state directives.

Although using a state-recognized form does have some advantages over use of other written documents or a physician's note that summarizes a discussion about a patient's stated treatment preferences, a written directive that does not satisfy all legal formalities can still help guide end-of-life care decision making. This document may represent the best evidence of a patient's wishes about life-sustaining treatment. In addition, oral statements previously made by the patient are also legally valid in some states.

A website sponsored by the National Hospice and Palliative Care Organization provides general information about advance directives and free access to the advance directive forms used in all 50 states and the District of Columbia along with completion instructions. A toll-free helpline is also available for patients with questions about advance directives (See Additional Resources). Figure 183-1 is the advance directive form used in North Carolina.

Clinical Implications

Multiple interventions have been implemented to increase advance directive completion rates, including the Patient Self-Determination Act. This Federal legislation enacted in 1991 requires all health care facilities receiving federal funding, including hospitals and nursing homes, to ask patients upon admission if they have an advance directive and to provide patients with help in completing a directive if requested. Unfortunately, this legislation and other efforts have not significantly affected completion rates—less than half of seriously ill patients have a signed directive. Also of note, prior research suggests that advance directives have had a limited impact on overall end-of-life care quality.

Studies have documented several factors that limit advance directive use and effect on end-of-life care decision making. There are significant differences in advance directive completion rates associated with race and ethnicity. Fewer African Americans and Latinos complete a living will or designate a proxy decision maker when compared with whites. Individuals from these minority groups are more likely to prefer continuation of life-sustaining treatments and perceive a living will, which is generally viewed as protecting patients against life prolongation, as antithetical to their interests. They also may be more accustomed to utilizing family consensus as the basis for their decisions and feel uncomfortable deciding on a single health care proxy, a legalistic standard that forces them to choose one decision maker among their loved ones.

Patients do not complete an advance directive for a variety of other reasons: they prefer to avoid contemplating

Figure 183-1 Example of a Living Will.

Note that this living will is the one used in North Carolina and that state laws vary.

**North Carolina Statutory Form, N.C. Gen. Stat. § 90-321
Declaration of a Desire for a Natural Death (Living Will)**

Declaration of a Desire for a Natural Death

STATE OF NORTH CAROLINA COUNTY OF _____

I, _____, being of sound mind, desire that, as specified below, my life not be prolonged by extraordinary means or by artificial nutrition or hydration if my condition is determined to be terminal and incurable or if I am diagnosed as being in a persistent vegetative state. I am aware and understand that this writing authorizes a physician to withhold or discontinue extraordinary means or artificial nutrition or hydration, in accordance with my specifications set forth below:

(Initial any of the following, as desired):

- _____ If my condition is determined to be terminal and incurable, I authorize the following:
 - _____ My physician may withhold or discontinue extraordinary means only.
 - _____ In addition to withholding or discontinuing extraordinary means if such means are necessary, my physician may withhold or discontinue either artificial nutrition or hydration, or both.
- _____ If my physician determines that I am in a persistent vegetative state, I authorize the following:
 - _____ My physician may withhold or discontinue extraordinary means only.
 - _____ In addition to withholding or discontinuing extraordinary means if such means are necessary, my physician may withhold or discontinue either artificial nutrition or hydration, or both.

This the _____ day of _____, 20 _____

Signature _____, Declarant

I hereby state that the declarant, _____, being of sound mind signed the above declaration in my presence and that I am not related to the declarant by blood or marriage and that I do not know or have a reasonable expectation that I would be entitled to any portion of the estate of the declarant under any existing will or codicil of the declarant or as an heir under the Intestate Succession Act if the declarant died on this date without a will. I also state that I am not the declarant's attending physician or an employee of the declarant's attending physician, or an employee of a health facility in which the declarant is a patient or an employee of a nursing home or any group-care home where the declarant resides. I further state that I do not now have any claim against the declarant.

Witness _____

Witness _____

CERTIFICATE

STATE OF NORTH CAROLINA COUNTY OF _____

I, _____, Notary Public for _____ County hereby certify that _____, the declarant, appeared before me and swore to me and to the witnesses in my presence that this instrument is his Declaration Of A Desire For A Natural Death, and that he had willingly and voluntarily made and executed it as his free act and deed for the purposes expressed in it.

I further certify that _____ and _____, witnesses, appeared before me and swore that they witnessed _____, declarant, sign the attached declaration, believing him to be of sound mind; and also swore that at the time they witnessed the declaration (i) they were not related within the third degree to the declarant or to the declarant's spouse, and (ii) they did not know or have a reasonable expectation that they would be entitled to any portion of the estate of the declarant upon the declarant's death under any will of the declarant or codicil thereto then existing or under the Intestate Succession Act as it provides at that time, and (iii) they were not a physician attending the declarant or an employee of an attending physician or an employee of a health facility in which the declarant was a patient or an employee of a nursing home or any group-care home in which the declarant resided, and (iv) they did not have a claim against the declarant. I further certify that I am satisfied as to the genuineness and due execution of the declaration.

This the _____ day of _____, 20 _____.

Notary Public

(Notary Seal)

My Commission Expires: _____

their own mortality; they believe incorrectly that they must hire an attorney to complete a directive and cannot afford this cost; or they think that having a directive will limit their families' ability to make good decisions on their behalf. Patients may also have the misperception that advance directives are only for people who are very ill or very old.

Perhaps the most important factor limiting the use and impact of advance directives is the lack of physician participation when patients consider signing a directive or after they have completed a directive. Any advance directive is only as useful as the personal communication among patients, their physicians, and families that complements its completion. In one study, only 12% of patients with an advance directive had received input from their physicians in its development. Most physicians are unaware of whether their patients have signed a directive. If physicians do not communicate about a patient's motivations underlying the completion of a living will or the designation of a health care proxy, it is unlikely that the directive can constructively inform medical decisions.

There have been successful community-based programs to increase completion of advance directives. In La Crosse, Wisconsin, a relatively homogeneous community with a defined set of health care services, a community-based group developed the Respecting Choices initiative to promote completion of advance directives. Implementation of the Respecting Choices program was associated with almost complete consistency between patients' actual treatment decisions and their previously documented preferences and may have reduced hospital care at the end of life.

In the state of Oregon, public attention to advance directives was catalyzed by the debate around legalization of physician-assisted suicide. A group of health professionals and patient advocates designed a universal and portable set of end-of-life treatment orders that served as a binding directive regardless of the patient's health care setting. The Physician Orders for Life-Sustaining Treatment Program (POLST) is a physician's order regarding end-of-life treatment. It is available to patients in all settings but has primarily been used to increase documentation of nursing home residents' treatment preferences. Most Oregon nursing homes and hospices voluntarily participate in this program, with one study suggesting that no patients received unwanted intensive care, mechanical ventilation, or cardiopulmonary resuscitation. The successes of both the Respecting Choices and POLST programs have led other communities and states to implement these initiatives.

Physician Role

Patients value physician communication about advance directives (Box 183-1). Prior research demonstrates that patient-physician discussion about advance directives is

Box 183-1 Physician Communication Strategies Regarding Advance Directives

1. Ask whether the patient has completed an advance directive (living will and/or health care proxy).
2. If the patient has a directive, obtain a copy and confirm its legal validity according to state law. Also, ask about patient's motivations for completing a directive.
3. Ask whether the patient has any care preferences in the event of serious illness and inability to participate in the decision-making process.
4. Ask whether the patient has a preferred surrogate decision maker (or decision makers). Also, ask patients whether there are any individuals who they would prefer not participate in decision making.
5. Assess for any patient barriers to completing an advance directive.
6. Advise patients regarding the role and limitations of advance directives in end-of-life decision making, including that a separate document may need to be completed if a patient prefers to not have a cardiac resuscitation attempted.
7. Advise patients that an attorney's assistance is not required to complete an advance directive.
8. Assist patients by providing written information about advance directives, including access to websites with advance care planning resources, and by offering follow-up to answer questions that may arise after the visit.
9. Assure patients that advance directives may be changed at any time as long as they retain decision-making capacity.
10. Document the content of the communication in the patient's record.
11. Remind patients to discuss their preferences with their family members.

associated with increased patient satisfaction, decreased patient fear and anxiety about the end of life, and an increased patient belief that physicians understood their wishes. Patient-physician communication about end-of-life care also increases the likelihood that patients will sign advance directives. In one study, one-third of patients would discuss advance directives if physicians brought up the subject, suggesting that some patients will not complete a directive unless first asked by a physician.

Many opportunities exist for physicians to discuss advance directives with their patients, including routine office visits or when the patient experiences a change in health status such as an illness that requires a hospital admission. Although patients may fear that physicians who discuss advance directives in the hospital believe that they will die, office-based discussions can seem too theoretical to patients in the absence of a life-threatening illness.

Avoiding Errors

Perhaps the main error made by physicians regarding advance directives is to fail to ask patients whether they have a completed directive. Patients may sign a directive

without ever informing their physicians, and they may not discuss their motivations for having a living will or health care proxy unless asked by physicians. These directives will certainly have no impact on decision making unless physicians know they exist, and will have greater influence if physicians use patients' completion of a directive as an opportunity to learn more about their end-of-life care goals and preferences.

Another error made by physicians and patients alike is to assume that living wills provide instructions regarding specific treatment preferences, including whether to attempt cardiopulmonary resuscitation. For patients who prefer to have a Do Not Resuscitate order, it may be necessary for their physicians to complete a separate document specifying the patients' preferences and capability to make the decision. Physicians should review their states' Do Not Resuscitate order policies. In addition, physicians should document the specific end-of-life care preferences expressed by patients, and patients should be encouraged to discuss these preferences with their families. When such family discussions do not occur, there is a high risk for misunderstanding and unwanted stress at the time that an advance directive is used.

Future Directions

Advance directives have an important yet limited role in end-of-life care decision making. Although interest in promoting advance directive completion has waned, efforts to improve physicians' end-of-life care communication skills are increasing given the evidence demonstrating the critical roles of physician-patient and physician-family communication in patients' end-of-life experiences. These programs include teaching physicians to communicate effectively about advance directives using culturally appropriate strategies but also provide broader education in areas such as eliciting care goals, fostering trust, and responding to patient and family emotions.

Additional Resources

Caring Connections. National Hospice and Palliative Care Organization (800-658-8898). Available at: <http://www.caringinfo.org>. Accessed February 2, 2007.

This website provides patients with a variety of free resources on end-of-life care topics, including advance care planning and access to state-specific advance directive documents and instructions.

End of Life/Palliative Education Resource Center (EPERC). Available at: <http://www.eperc.mcw.edu>. Accessed March 22, 2007.

This website provides health care professionals with peer-reviewed educational resources, including materials on communication and end-of-life decision making.

EVIDENCE

1. Kagawa-Singer M, Blackhall LJ: Negotiating cross-cultural issues at the end of life: "You got to go where he lives." *JAMA* 286:2993-3001, 2001.

This article outlines some of the major issues in providing cross-cultural end of life care and recommends techniques for negotiating issues influenced by culture that are important in end-of-life care.

2. Kass-Bartelmes BL, Hughes R: Advance care planning: Preferences for care at the end of life. *J Pain Palliat Care Pharmacother* 18:87-109, 2004.

This evidence-based review of research studies on advance care planning includes interventions to improve patient end-of-life decision making.

3. Meisel A, Snyder L, Quill T; American College of Physicians—American Society of Internal Medicine End-of-Life Care Consensus Panel: Seven legal barriers to end-of-life care: Myths, realities, and grains of truth. *JAMA* 284:2495-2501, 2000.

The authors present legal myths about end-of-life care that can undermine good care and ethical medical practice as identified by a consensus panel of medical and bioethics experts. The panel concludes that physicians must know the law of the state in which they practice.

4. Teno JM, Gruneir A, Schwartz A, et al: Association between advance directives and quality of end-of-life care: A national study. *J Am Geriatric Soc* 55:189-194, 2007.

This study completed a national survey of bereaved family members to examine the role of advance directives in end-of-life care and concludes that completion of an advance directive is associated with home deaths, hospice use, and fewer concerns with physician communication.

5. Teno J, Lynn J, Wenger N, et al: Advance directives for seriously ill hospitalized patients: Effectiveness with the patient self-determination act and the SUPPORT intervention. *J Am Geriatr Soc* 45:500-507, 1997.

This article assesses the impact of advance directives on decision making about cardiac resuscitation in a clinical trial of seriously ill hospitalized patients that sought to improve end-of-life care decision making. The authors conclude that advance directives did not substantially enhance physician-patient communication or decision making about resuscitation despite their intervention and the implementation of the Patient Self-Determination Act.

6. Tulsky JA: Beyond advance directives: Importance of communication skills at the end of life. *JAMA* 294:359-365, 2005.

This clinical review for practicing physicians addresses the challenge in creating and implementing advance directives and offers practical suggestions for improving end-of-life communication and decision making.

7. Winzelberg GS, Tulsky JA, Hanson LC: Beyond autonomy: Diversifying end-of-life decision-making approaches to better serve patients and families. *J Am Geriatr Soc* 53:1046-1050, 2005.

This review offers end-of-life communication strategies to physicians when interacting with patients and family caregivers if advance directives have not been completed.
