118 PITTED KERATOLYSIS

Michael J. Babcock, MD
Richard P. Usatine, MD

PATIENT STORY

A 34-year-old man comes to the office with a terrible foot odor problem. He is wearing cowboy boots and he says that his feet are always sweaty. He is embarrassed to remove his boots, but when the physician convinces him to do so the odor is overwhelming. While breathing through the mouth, the physician sees the typical pits of pitted keratolysis. His socks are moist and the skin is somewhat macerated from the hyperhidrosis. His foot has many crateriform pits on the heel (**Figure 118-1**). He is prescribed topical erythromycin solution for the pitted keratolysis and topical aluminum chloride for the hyperhidrosis. It is suggested that he wear a lighter and more breathable shoe until this problem improves.

INTRODUCTION

Pitted keratolysis is a superficial foot infection caused by Gram-positive bacteria. These bacteria degrade the keratin of the stratum corneum leaving visible pits on the soles of the feet.

EPIDEMIOLOGY

- Seen more commonly in men.
- Often a complication of hyperhidrosis.
- Seen more often in hot and humid climates.
- Prevalence can be as high as 42.5% among paddy field workers.¹
- May be common in athletes with moist, sweaty feet.²

ETIOLOGY AND PATHOPHYSIOLOGY

- *Kytococcus sedentarius* (formerly *Micrococcus* spp.), *Corynebacterium* species, and *Dermatophilus congolensis* have all been shown to cause pitted keratolysis.³
- Proteases produced by the bacteria degrade keratins to give the clinical appearance.⁴
- The associated malodor is likely secondary to the production of sulfur byproducts.³

DIAGNOSIS

CLINICAL FEATURES

Pitted keratolysis usually presents as painless, malodorous, crateriform pits coalescing into larger superficial erosions of the stratum corneum (**Figures 118-1 to 118-4**). It may be associated with itching and a burning sensation in some patients (**Figure 118-3**).

FIGURE 118-1 Many crateriform pits on the heel of a foot in a man with pitted keratolysis and hyperhidrosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 118-2 Pitted keratolysis on the pressure-bearing areas of the toes and the ball of the foot. (Courtesy of Richard P. Usatine, MD.)

TYPICAL DISTRIBUTION

Pitted keratolysis usually involves the callused pressure-bearing areas of the foot, such as the heel, ball of the foot, and plantar great toe. It can also be found in friction areas between the toes.⁵

LABORATORY STUDIES

Typically a clinical diagnosis but biopsy will reveal keratin pits lined by bacteria.

DIFFERENTIAL DIAGNOSIS

- Characteristic clinical features make the diagnosis easy, but it is possible to have other diseases causing plantar pits, which can be included in the differential. These other diseases include plantar warts, basal cell nevus syndrome, and arsenic toxicity.
- Plantar warts are typically not as numerous. They have a firm callus ring around a soft core with small black dots from thrombosed capillaries (see Chapter 134, Plantar Warts).
- Basal cell nevus syndrome typically has pits involving the palms and soles, bone abnormalities, a history of many basal cell carcinomas, and a characteristic facies with frontal bossing, hypoplastic maxilla, and hypertelorism (wide-set eyes) (see Chapter 170, Basal Cell Carcinoma).
- Arsenic toxicity can result in pits on the palms and soles, but it can also have hyperpigmentation, many skin cancers, Mees lines (white lines on the fingernails), or other nail disorders.

MANAGEMENT

- Treatment is based on bacterial elimination and reducing the moist environment in which the bacteria thrive. Various topical antibiotics are effective for pitted keratolysis.
- Topical erythromycin or clindamycin solution or gel can be applied twice daily until the condition resolves. **SOR C** Generic 2% erythromycin solution with an applicator top is a very inexpensive and effective preparation. It may take 3 to 4 weeks to clear the odor and skin lesions.
- Topical mupirocin is more expensive but also effective. **SOR C**
- Oral erythromycin is effective and may be considered if topical therapy fails. **SOR C**
- Treating underlying hyperhidrosis is also important to prevent recurrence. This can be done with topical aluminum chloride of varying concentrations. **SOR C** Drysol is 20% aluminum chloride solution and can be prescribed with an applicator top.
- Botulinum toxin injection is an expensive and effective treatment for hyperhidrosis.⁶ **SOR C** It should be reserved for treatment failures because of the cost, the discomfort of the multiple injections, and the need to repeat the treatment every 3 to 4 months.

FOLLOW-UP

Follow-up is needed for treatment failures, recurrences, and the treatment of underlying hyperhidrosis if present. Follow-up can be

FIGURE 118-3 Pitted keratolysis with hyperpigmented crateriform pits on the pressure-bearing areas of the foot. The patient complained of itching and burning on the feet. (Courtesy of Richard P. Usatine, MD.)

FIGURE 118-4 Pitted keratolysis with many crateriform pits on the heel. (Courtesy of Richard P. Usatine, MD.)

performed annually for prescription aluminum chloride or approximately every 4 months for botulinum toxin injections.

PATIENT EDUCATION

Patients should be taught about the etiology of this disorder to help avoid recurrence. Helpful preventive strategies include avoiding occlusive footwear and using moisture-wicking socks or changing sweaty socks frequently.

119 ERYTHRASMA

Anna Allred, MD
Richard P. Usatine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 12-year-old Hispanic girl, accompanied by her mother, presents with a 1-year history of a red irritated rash in both axillae (**Figure 119-1**). She has been seen by multiple physicians and many antifungal creams had been tried with no results. Even hydrocortisone did not help. She had stopped wearing deodorant for fear that she was allergic to all deodorants. Although the rash barely fluoresced at all, the physical examination and history were most consistent with erythrasma. The patient was given a prescription for oral erythromycin and the erythrasma cleared to the great delight of the patient and her mother.

INTRODUCTION

Erythrasma is a chronic superficial bacterial skin infection that usually occurs in a skin fold.

EPIDEMIOLOGY

- The incidence of erythrasma is approximately 4%.¹
- Both sexes are equally affected.
- The inguinal location is more common in men.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Corynebacterium minutissimum*, a lipophilic Gram-positive non-spore-forming rod-shaped organism, is the causative agent.
- Under favorable conditions, such as heat and humidity, this organism invades and proliferates the upper one-third of the stratum corneum.
- The organism produces porphyrins that result in the coral red fluorescence seen under a Wood lamp (**Figure 119-2**).

RISK FACTORS¹

- Warm climate.
- Diabetes mellitus.
- Immunocompromised states.
- Obesity.
- Hyperhidrosis.
- Poor hygiene.
- Advanced age.

FIGURE 119-1 Erythrasma in the axilla of a 12-year-old Hispanic girl. (Courtesy of Richard P. Usatine, MD.)

FIGURE 119-2 Coral red fluorescence seen with a Wood lamp held in the axilla of a patient with erythrasma. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

DIAGNOSIS

CLINICAL FEATURES

- Erythrasma is a sharply delineated, dry, red-brown patch with slightly scaling patches. Some lesions appear redder, whereas others have a browner color (**Figures 119-3** and **119-4**).
- The lesions may appear with central clearing and be slightly raised from the surrounding skin (**Figure 119-5**).
- The lesions are typically asymptomatic; however, patients sometimes complain of itching and burning when lesions occur in the groin (**Figure 119-6**).

TYPICAL DISTRIBUTION

Erythrasma is characteristically found in the intertriginous areas, especially the axilla and the groin. Patches of erythrasma may also be found in the interspaces of the toes, intergluteal cleft, perianal skin, and inframammary area.

LABORATORY STUDIES

- Illumination of the plaque with a Wood lamp reveals coral-red fluorescence. It should be noted that washing the area before examination may eliminate the fluorescence.
- The diagnosis may be confirmed by applying Gram stain or methylene blue stain to scrapings from the skin to reveal Gram-positive rods and dark blue granules, respectively. However, if the presentation is typical and the plaque reveals fluorescence then microscopic examination and cultures are not needed.
- Microscopic examination is useful if erythrasma is suspected but the plaque does not fluoresce.

DIFFERENTIAL DIAGNOSIS

- Psoriasis—Inverse psoriasis occurs in the same areas as erythrasma and also causes pink to red plaques with well-demarcated borders. The best way to distinguish psoriasis from erythrasma is to look for other clues of psoriasis in the patient, including nail pitting or onycholysis and hyperkeratotic plaques on the elbows, knees, or scalp. Also, inverse psoriasis may be seen in the intergluteal cleft as well as below the breasts or pannus in overweight individuals (see Chapter 152, Psoriasis). The Wood lamp may help differentiate between these diagnoses.
- Dermatophytosis—Cutaneous fungal infections also closely resemble erythrasma when they occur in the axillary and inguinal areas. Tinea infections also have well-demarcated borders that can be raised with central clearing. This distinctive ringworm look is more obvious with tinea than erythrasma but a scraping for microscopic examination should be able to distinguish between the two conditions. Examination of the feet will frequently show tinea pedis and onychomycosis when there are tinea infections elsewhere on the body (see Chapters 138, Tinea Corporis and 139, Tinea Cruris).
- Candidiasis—Look for satellite lesions to help distinguish candidiasis from erythrasma. Candidiasis will not fluoresce and a microscopic examination of a *Candida* infection should show branching pseudohyphae (see Chapter 136, Candidiasis).

FIGURE 119-3 Light brown erythrasma in the groin of a young man. It does not have the degree of scaling usually seen with tinea cruris. (Courtesy of Dan Stulberg, MD.)

FIGURE 119-4 Brown erythrasma in the groin of a man with diabetes. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

- Intertrigo—This is a term for inflammation in intertriginous areas (skin folds). It is caused or exacerbated by heat, moisture, maceration, friction, and lack of air circulation. It is frequently made worse by infection with *Candida*, bacteria, or dermatophytes, and therefore overlaps with the erythrasma, *Candida*, and dermatophytosis. Obesity and diabetes especially predispose to this condition. All efforts should be made to find coexisting infections and treat them.
- Contact dermatitis to deodorants can mimic erythrasma. The history and Wood lamp should help to differentiate the two conditions (see Chapter 146, Contact Dermatitis).

MANAGEMENT

NONPHARMACOLOGIC

- It has been advocated that the areas should be vigorously washed with soap and water prior to application of topical antibiotics.⁵ SOR C
- Consider loose-fitting cotton undergarments during treatment and to help prevent recurrence.⁵ SOR C

MEDICATIONS

- Although the bacteria responds to a variety of antibacterial agents (e.g., penicillins, first-generation cephalosporins), the treatment of choice is oral erythromycin 250 mg 4 times a day for 14 days. Erythromycin shows cure rates as high as 100%.²⁻⁴ SOR B
- However, some advocate that oral erythromycin is only required for the treatment of extensive or resistant cases.⁵ SOR C
- Topical therapy (antibacterial, antifungal, benzoic acid 6%) has been recommended in addition to oral therapy in patients with hidden reservoirs of infection (i.e., interdigital involvement). SOR C
- Topical clindamycin may be applied once daily during the course of oral erythromycin therapy and for 2 weeks after physical clearance of the lesions for treatment and prophylaxis.^{3,6} SOR C
- Topical erythromycin 2% solution applied twice daily.^{4,5,7} SOR C
- In a Turkish study, topical fusidic acid was more effective than erythromycin or single-dose clarithromycin based on Wood light reflection scores.⁸
- Optimal blood glucose control is recommended in the management of a diabetic patient with erythrasma.² SOR C

PROGNOSIS

- Usually a benign condition; however, in immunocompromised individuals, *Corynebacterium* can cause abscess formation, bacteremia, endocarditis, pyelonephritis, cellulitis, and meningitis.¹
- The condition tends to recur if the predisposing condition is not addressed.

FOLLOW-UP

Have the patient follow up in 2 to 4 weeks as needed to determine if erythrasma has resolved.

FIGURE 119-5 Pinkish erythrasma in the axilla of a 32-year-old man with some central clearing and elevated borders. (Courtesy of Richard P. Usatine, MD.)

FIGURE 119-6 Pinkish erythrasma in the groin of the man in Figure 119-5. Men are more likely to have erythrasma in the crural region. (Courtesy of Richard P. Usatine, MD.)

PATIENT EDUCATION

Reassure the patient that erythrasma is curable with antibiotic treatment.

120 CELLULITIS

Richard P. Usatine, MD

PATIENT STORY

A 4-year-old child presents with a fever and a red and swollen foot (**Figure 120-1**). The patient injured her foot 3 days before with a door. On physical examination, the foot was warm, tender, red, and swollen, and the child's temperature was 39.4°C (103°F). This is classic cellulitis and the child was admitted for IV antibiotics.

INTRODUCTION

Cellulitis is an acute infection of the skin that involves the dermis and subcutaneous tissues.

EPIDEMIOLOGY

- Facial cellulitis occurs more often in adults ages 50 years or older, or in children ages 6 months to 3 years.
- Perianal cellulitis occurs more commonly in young children but can be seen in adults as well (see Chapter 111, Diaper Rash and Perianal Dermatitis).

ETIOLOGY AND PATHOPHYSIOLOGY

- Often begins with a break in the skin caused by trauma, a bite, or an underlying dermatosis (e.g., tinea pedis, stasis dermatitis) (**Figures 120-2 to 120-4**).
- Is most often caused by group A β -hemolytic *Streptococcus* (GABHS) or *Staphylococcus aureus*. The most common etiology of cellulitis with intact skin, when it has been determined through needle aspiration and/or punch biopsy, is *S. aureus*, outnumbering GABHS by a ratio of nearly 2:1.¹

There are increasing concerns about the role of community-acquired methicillin-resistant *S. aureus* (MRSA) in all soft-tissue infections including cellulitis.²⁻⁵

- After a cat or dog bite, cellulitis is often caused by *Pasteurella multocida*.
- After saltwater exposure, cellulitis can be secondary to *Vibrio vulnificus* in warm climates (**Figure 120-5**). A *Vibrio vulnificus* infection can be especially deadly.

Erysipelas is a specific type of superficial cellulitis with prominent lymphatic involvement and leading to a sharply defined and elevated border (**Figure 120-6**).

DIAGNOSIS

CLINICAL FEATURES

Rubor (red), calor (warm), tumor (swollen), and dolor (painful).

FIGURE 120-1 Cellulitis of the foot after an injury with a door in a 4-year-old girl. (Courtesy of Richard P. Usatine, MD.)

FIGURE 120-2 Cellulitis and abscess of the finger after a clenched fist injury in which the patient cut his finger on the tooth of the man he assaulted. (Courtesy of Richard P. Usatine, MD.)

TYPICAL DISTRIBUTION

Can occur on any part of the body, but is most often seen on the extremities and face (**Figures 120-1 to 120-8**). Periorbital cellulitis can be life-threatening (**Figure 120-9**). Cellulitis can also occur around the anus. This is called perianal cellulitis (**Figure 120-10**).

LABORATORY TESTS

- Aspiration—If there is fluctuance within the area of erythema, a needle aspiration or incision and drainage should be performed (**Figure 120-11**). If pus is aspirated, perform a culture to guide antibiotic use.
- Blood cultures—Results are positive in only 5% of cases and the results of culture of needle aspirations of the inflamed skin are variable and not recommended.⁴

DIFFERENTIAL DIAGNOSIS

- Thrombophlebitis—Inflammation of a vein caused by a blood clot. The pain and tenderness are over the involved vein.
- Venous stasis—Swelling, discoloration, and pain of the lower extremities that can lead to cellulitis. Venous stasis dermatitis can add erythema and scaling to the picture and resemble cellulitis (**Figure 120-4**) (see Chapter 52, Venous Stasis).
- Allergic reactions—Allergic reactions to vaccines or bug bites may resemble cellulitis because of the erythema and swelling (**Figure 120-12**).
- Acute gout—May resemble cellulitis if there is significant cutaneous inflammation beyond the involved joint (see Chapter 100, Gout).
- Necrotizing fasciitis—Deep infection of the subcutaneous tissues and fascia with diffuse swelling, severe pain, and bullae in a toxic-appearing patient. It is important to recognize the difference between standard cellulitis and necrotizing fasciitis. Imaging procedures can detect gas in the soft tissues. Rapid progression from mild erythema to violaceous or necrotic lesions and/or bullae in a number of hours is a red flag for necrotizing fasciitis. The toxicity of the patient and the other physical findings should encourage rapid surgical consultation (see Chapter 122, Necrotizing Fasciitis).

MANAGEMENT

- The first decision is whether or not the patient needs hospitalization and IV antibiotics. It is often best to hospitalize any immunocompromised patients (e.g., HIV, transplant recipient, chronic renal or liver disease, on prednisone, diabetes out of control) with cellulitis because they may decompensate quickly. **SOR C**
- Evidence comparing different durations of treatment, oral versus intravenous antibiotics is lacking.⁶ Randomized controlled trials (RCTs) comparing different antibiotic regimens found clinical cure in 50% to 100% of people, but provided insufficient information on differences between regimens.⁶ **SOR A**
- One quasi-randomized trial in 73 hospitalized people with erysipelas, but excluding patients with clinical signs of septicemia, compared oral versus intravenous penicillin and found no significant difference in clinical efficacy.⁶ **SOR B**

FIGURE 120-3 Cellulitis of the foot of a diabetic person in which there is possible necrosis and gangrene of the second toe, requiring hospitalization and a podiatry consult. (Courtesy of Richard P. Usatine, MD.)

FIGURE 120-4 Cellulitis in an older man with venous stasis dermatitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 120-5 Fatal *Vibrio vulnificus* infection with widespread cellulitis and bullae. The violaceous bullae should be a red flag for this infection and/or necrotizing fasciitis. Even though the infection was identified early, the overwhelming sepsis resulted in death. (Courtesy of Donna Nguyen, MD.)

FIGURE 120-7 Cellulitis of the leg in a 55-year-old man that developed after a minor abrasion and a long plane flight. Petechiae and ecchymoses are visible and not infrequently seen in cellulitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 120-10 Severe perianal cellulitis in an adult man. (Courtesy of Jack Resneck Sr., MD.)

- Standard oral therapy for cellulitis not requiring hospitalization (in the pre-MRSA era) involves covering GABHS and *S. aureus* with cephalexin or dicloxacillin.⁴ **SOR A** The standard dose is 500 mg orally every 6 hours for each antibiotic and the typical duration is 7 to 10 days. **SOR C**
- Penicillin-allergic patients may be treated with clindamycin rather than erythromycin because of macrolide resistance and increasing MRSA prevalence.⁴ **SOR A**
- Parenteral treatment is usually done with penicillinase-resistant penicillins or first-generation cephalosporins such as cefazolin, or, for patients with life-threatening penicillin allergies, clindamycin, or vancomycin.⁴ **SOR A**
- In cases of uncomplicated cellulitis, 5 days of antibiotic treatment with levofloxacin is as effective as a 10-day course.⁷ **SOR B** This is not a good choice if MRSA is suspected.

Two recent studies (published in 2009 and 2010) addressed concerns over community-acquired MRSA (CAMRSA) in cellulitis and came up with different conclusions:

- An electronic chart review of patients seen in a Texas emergency department with cellulitis in 2000 and 2005 was performed. Exclusion criteria were incision and drainage, surgery, or admission on initial visit. Treatment failure was defined as a repeat visit in the subsequent 30 days and a change in antibiotics, admission to the hospital, incision and drainage of abscess, or surgical intervention. There was a significant decrease in β -lactam antibiotics and an increase in CAMRSA-effective antibiotics prescribed in 2005 versus 2000. The difference in treatment failure rates of the β -lactams and CAMRSA antibiotics was statistically insignificant. The β -lactam antibiotics performed as well as “CAMRSA antibiotics” in their setting.⁵ **SOR B**
- A 3-year retrospective cohort study of outpatients with cellulitis empirically treated in Hawaii was performed. Exclusion criteria included patients who received more than one oral antibiotic or were hospitalized. The overall treatment success rate of trimethoprim-sulfamethoxazole was significantly higher than the rate of cephalexin (91% vs. 74%; $P < 0.001$). Clindamycin success rates were higher than those of cephalexin in patients who had subsequently culture-confirmed MRSA infections ($P = 0.01$), had moderately severe cellulitis ($P = 0.03$), and were obese ($P = 0.04$). MRSA was recovered in 72 of 117 positive culture specimens from 405 included patients. The researchers concluded that trimethoprim-sulfamethoxazole and clindamycin are preferred empiric therapy for outpatients with cellulitis in the CAMRSA-prevalent setting.² **SOR B**
- Although MRSA is increasing in its prevalence in skin and soft-tissue infections,³ the difficulty in obtaining microbiologic cultures for cellulitis still makes it difficult to know how much MRSA is a problem in cellulitis with intact skin. If there is a coexisting abscess or crusting lesion, it is best to obtain a culture to guide therapy and start empiric therapy with trimethoprim-sulfamethoxazole and clindamycin.² **SOR B**
- Do not miss necrotizing fasciitis. Patients with severe pain, bullae, crepitus, skin necrosis, or significant toxicity merit imaging and immediate surgical consultation (see Chapter 122, Necrotizing Fasciitis).

FIGURE 120-11 Cellulitis and abscess of the neck and chest in a 2-year-old girl in Ethiopia. Incision and drainage of the fluctuance over the neck revealed pus. A drain was placed to allow the pus to continue to drain from the incision site. She was treated with IV ceftriaxone and she survived. (Courtesy of Richard P. Usatine, MD.)

FIGURE 120-12 Redness and swelling after a pneumococcal vaccine the day before in a 66-year-old woman. This allergic reaction looks like bacterial cellulitis. It resolved with oral diphenhydramine. (Courtesy of Richard P. Usatine, MD.)

- Treat underlying conditions (e.g., tinea pedis, lymphedema) that predispose the patient to the infection. **SOR** 

PATIENT EDUCATION

Recommend that the patient rest and elevate the involved extremity. If outpatient therapy is followed, then provide precautions (e.g., vomiting and unable to hold medicine down) for which the patient should seek more immediate follow-up.

FOLLOW-UP

If prescribing oral outpatient therapy, consider follow-up in 1 to 2 days to assess response to the antibiotic and to determine the adequacy of outpatient therapy.

121 ABSCESS

Richard P. Usatine, MD

PATIENT STORY

A young man is seen in a shelter in San Antonio after being evacuated from New Orleans after the devastating floods of Hurricane Katrina (**Figure 121-1**). He has facial pain and swelling and noticeable pus near the eye. His vision is normal. The area is anesthetized with lidocaine and epinephrine. The abscess is drained with a #11 blade. The patient is started on an oral antibiotic because of the proximity to the eye and the local swelling that could represent early cellulitis. A culture to look for methicillin-resistant *Staphylococcus aureus* (MRSA) was not available in the shelter, but close follow-up was set for the next day and the patient was doing much better.

INTRODUCTION

An abscess is a collection of pus in the infected tissues. The abscess represents a walled-off infection in which there is a pocket of purulence. In abscesses of the skin the offending organism is almost always *S. aureus*.

EPIDEMIOLOGY

- MRSA was the most common identifiable cause of skin and soft-tissue infections among patients presenting to emergency departments in 11 U.S. cities. *S. aureus* was isolated from 76% of these infections and 59% were community-acquired MRSA (CAMRSA).¹
- Risk factors for MRSA infection and other abscesses—Intravenous drug abuse, homelessness, dental disease, contact sports, incarceration, and high prevalence in the community (**Figure 121-2**).

ETIOLOGY AND PATHOPHYSIOLOGY

- Most cutaneous abscesses are caused by *S. aureus*.
- Risk factors for developing an abscess with MRSA include patients who work or are exposed to a healthcare system, intravenous drug use, previous MRSA infection and colonization, recent hospitalization, being homeless, African American, and having used antibiotics within the last 6 months.²
- CAMRSA has become so prevalent in our community that both the patients shown in **Figures 121-3** and **121-4** had no special risk factors and both had abscesses that grew out MRSA. One study that evaluated management of skin abscesses drained in the emergency department showed that there was no significant association between amount of surrounding cellulitis or abscess size with the likelihood of MRSA-positive cultures.²
- A dental abscess can spread into tissue outside the mouth, as in the homeless person in **Figure 121-2**.

FIGURE 121-1 Abscess seen on the face of a man after evacuation from the flood waters of New Orleans following Hurricane Katrina. (Courtesy of Richard P. Usatine, MD.)

FIGURE 121-2 Neck abscess secondary to dental abscess in a homeless man. This was drained in the operating room by an ear, nose, and throat (ENT) specialist. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

Collection of pus in or below the skin. Patients often feel pain and have tenderness at the involved site. There is swelling, erythema, warmth, and fluctuance in most cases (**Figures 121-1 to 121-5**). Determine if the patient is febrile and if there is surrounding cellulitis.

TYPICAL DISTRIBUTION

Skin abscesses can be found anywhere from head to feet. Frequent sites include the hands, feet, extremities, head, neck, buttocks, and breast (**Figure 121-5**).

LABORATORY STUDIES

Clinical cure is often obtained with incision and drainage alone so the benefits of pathogen identification and sensitivities are low in low-risk patients.² Most clinical studies have excluded patients who were immunocompromised, diabetic, or had other significant comorbidities.² Consequently, it may be reasonable to obtain wound cultures in high-risk patients, those with signs of systemic infection, and in patients with history of high recurrence rates.^{2,3}

DIFFERENTIAL DIAGNOSIS

- Epidermal inclusion cyst with inflammation/infection—These cysts (also known as sebaceous cysts) can become inflamed, swollen, and superinfected. Although the initial erythema may be sterile inflammation, these cysts can become infected with *S. aureus*. The treatment consists of incision and drainage and antibiotics if cellulitis is also present. If these are removed before they become inflamed, the cyst may come out intact (**Figure 121-6**).
- Cellulitis with swelling and no pocket of pus—When it is unclear if an area of infected skin has an abscess, needle aspiration with a large-gauge needle may be helpful to determine whether to incise the skin. Cellulitis alone should have no area of fluctuance (see Chapter 120, Cellulitis).
- Hidradenitis suppurativa—Recurrent inflammation surrounding the apocrine glands of the axilla and inguinal areas (see Chapter 115, Hidradenitis Suppurativa).
- Furuncles and carbuncles—A furuncle or boil is an abscess that starts in hair follicle or sweat gland. A carbuncle occurs when the furuncle extends into the subcutaneous tissue.
- Acne cysts—More sterile inflammation than true abscess, often better to inject with steroid rather than incise and drain (see Chapter 112, Acne Vulgaris).

MANAGEMENT

- The evidence strongly supports the incision and drainage of an abscess.^{2,4} **SOR A** Inject 1% lidocaine with epinephrine into the skin at the site you plan to open using a 27-gauge needle. A ring block can be helpful rather than injecting into the abscess itself (**Figure 121-3**). Open the abscess with a linear incision using a #11 blade scalpel following skin lines if possible.⁵

FIGURE 121-3 MRSA abscess on the back of the neck that patient thought was a spider bite. Note that a ring block was drawn around the abscess with a surgical marker to demonstrate how to perform this block. (Courtesy of Richard P. Usatine, MD.)

FIGURE 121-4 Large MRSA abscess on the leg in a 62-year-old man beginning to drain spontaneously. The abscess cavity was large and patient was placed on trimethoprim-sulfamethoxazole (TMP-SMX) to cover the surrounding cellulitis. (Courtesy of Richard P. Usatine, MD.)

Although many physicians still pack a drained abscess with ribbon gauze, there is limited data on whether or not packing of an abscess cavity improves outcomes. A small study concluded that routine packing of simple cutaneous abscesses is painful and probably unnecessary.⁶ **SOR C** The author of this chapter often packs abscesses lightly and has the patient remove the packing in the shower 2 days later, avoiding additional visits and painful repacking of the healing cavity. **SOR C** However, if a large abscess is not packed it can seal over and the pus may reaccumulate.

Routine use of antibiotics for an initial abscess in addition to incision and drainage is not supported by current evidence.^{2,7-9} **SOR A** Three randomized controlled trials (RCTs) performed since the emergence of CAMRSA have demonstrated that antibiotics do not significantly improve healing rates of superficial skin abscesses, but two of these studies suggest that antibiotics do decrease short-term rates of new lesion development.⁷⁻⁹

Consider the use of oral antibiotics to treat an abscess with suspected CAMRSA in patients who are febrile or have systemic symptoms, have significant surrounding cellulitis, have failed incision and drainage alone, have frequent recurrences, or have a history of close contacts with abscesses.² **SOR C**

If an antibiotic is to be used, CAMRSA is close to 100% sensitive to trimethoprim-sulfamethoxazole.² **SOR B** Although standard dosing of oral trimethoprim-sulfamethoxazole for an infection in adults is 1 DS tablet bid, one study suggests that 2 DS tablets should be used bid for 7 days.¹⁰ **SOR B** Alternative antibiotics include oral clindamycin, tetracycline, or doxycycline. Local sensitivity data should be consulted when available.² **SOR B**

There is no current data to support the use of an antimicrobial medication (mupirocin or rifampin) in the eradication of MRSA colonization.² **SOR C**

PATIENT EDUCATION

Patients may shower daily 24 to 48 hours after incision and drainage and then reapply dressings. Patients should be given return precautions for worsening of symptoms or continued redness, pain, or pus.

FOLLOW-UP

In patients or wounds at higher risk for complications, follow-up should be scheduled in 24 to 48 hours. If packing was placed, it can be removed by the patient or a family member.

122 NECROTIZING FASCIITIS

Richard P. Usatine, MD
Jeremy A. Franklin, MD

PATIENT STORY

A 54-year-old woman with diabetes was brought to the emergency department with right leg swelling, fever, and altered mental status.¹ The patient noted a pimple in her groin 5 days earlier and over the past few days had increasing leg pain. Her right leg was tender, red, hot, and swollen (**Figure 122-1**). Large bullae were present. Her temperature was 38.9°C (102°F) and her blood sugar was 573. The skin had a “woody” feel and a radiograph of her leg showed gas in the muscles and soft tissues (**Figure 122-2**). She was taken to the operating room for debridement of her necrotizing fasciitis. Broad-spectrum antibiotics were also started but the infection continued to advance quickly. The patient died the following day; her wound culture later grew *Escherichia coli*, *Proteus vulgaris*, *Corynebacterium*, *Enterococcus*, *Staphylococcus sp.*, and *Peptostreptococcus*.¹

INTRODUCTION

Necrotizing fasciitis (NF) is a rapidly progressive infection of the deep fascia, with necrosis of the subcutaneous tissues. It usually occurs after surgery or trauma. Patients have erythema and pain disproportionate to the physical findings. Immediate surgical debridement and antibiotic therapy should be initiated.²

SYNONYMS

- Flesh-eating bacteria, necrotizing soft-tissue infection (NSTI), suppurative fasciitis, hospital gangrene, and necrotizing erysipelas. Fournier gangrene is a type of NF or NSTI in the genital and perineal region.³

EPIDEMIOLOGY

- Incidence in adults is 0.40 cases per 100,000 population.⁴
- NF caused by *Streptococcus pyogenes* is the most common form of NF.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Type I NF is a polymicrobial infection with aerobic and anaerobic bacteria:
 - Frequently caused by enteric Gram-negative pathogens including *Enterobacteriaceae* organisms and *Bacteroides*.
 - Can occur with Gram-positive organisms such as non-group A streptococci and *Peptostreptococcus*.⁵

FIGURE 122-1 Necrotizing fasciitis on the leg and groin showing erythema, swelling, and bullae. (From Dufel S, Martino M. Simple cellulitis or a more serious infection? *J Fam Pract.* 2006;55(5):396-400. Reproduced with permission from Frontline Medical Communications.)

FIGURE 122-2 Radiograph of the patient's leg showing gas in the soft tissues and muscles. (Courtesy of Susan Dufel, MD.)¹

- Saltwater variant can occur with penetrating trauma or an open wound contaminated with saltwater containing marine vibrios. *Vibrio vulnificus* is the most virulent (**Figure 122-3**).⁶
- Up to 15 pathogens have been isolated in a single wound.
- Average of five different isolates per wound.⁷
- Type II NF occurs from common skin organisms:
 - Generally a monomicrobial infection caused by *S. pyogenes*:
 - May occur in combination with *Staphylococcus aureus*.
 - Methicillin-resistant *S. aureus* is no longer a rare cause of NF.⁵
 - *S. pyogenes* strains may produce pyrogenic exotoxins, which act as superantigens to stimulate production of tumor necrosis factor (TNF)- α , TNF- β , interleukin (IL)-1, IL-6, and IL-2.⁷

RISK FACTORS

- Risk factors for type I NF (polymicrobial):
 - Diabetes mellitus.
 - Severe peripheral vascular disease.
 - Obesity.
 - Alcoholism and cirrhosis.
 - Intravenous drug use.
 - Decubitus ulcers.
 - Poor nutritional status.
 - Postoperative patients or those with penetrating trauma.
 - Abscess of the female genital tract.
- Risk factors of type II NF (group A β -hemolytic *Streptococcus* [GABHS] and *S. aureus*):
 - Diabetes mellitus.
 - Severe peripheral vascular disease.
 - Recent parturition (**Figure 122-4**).
 - Trauma.
 - Varicella.⁵

DIAGNOSIS

Early recognition based on signs and symptoms is potentially life-saving. Although lab tests and imaging studies can confirm ones' clinical impression, rapid treatment with antibiotics and surgery are crucial to improving survival.

CLINICAL FEATURES

- Rapid progression of erythema to bullae (**Figures 122-3 and 122-5**), ecchymosis, and necrosis or gangrene (**Figure 122-6**).
- The erythematous skin may develop a dusky blue discoloration. Vesicular and bullous lesions form over the erythematous skin, with some serosanguineous drainage. The bullae may become violaceous. The skin can become gangrenous and develop a black eschar.²
- Edematous, wooden feel of subcutaneous tissues extending beyond the margin of erythema.
- High fevers and severe systemic toxicity.
- Unrelenting intense pain out of proportion to cutaneous findings.
- Pain progresses to cutaneous anesthesia as disease evolves. Anesthesia of the skin develops as a result of infarction of cutaneous nerves.²

FIGURE 122-3 Saltwater variant of necrotizing fasciitis due to *Vibrio vulnificus*. Note the bullae and dusky skin. This case was fatal. (Courtesy of Donna Nguyen, MD.)

FIGURE 122-4 Necrotizing fasciitis with violaceous color of the skin on the affected skin above the C-section. (Courtesy of Michael Babcock, MD.)

FIGURE 122-5 Necrotizing fasciitis that started when patient stepped on a nail. A large flaccid bulla is visible along with swelling and erythema. A rapid below the knee amputation allowed this patient to survive. (Subramaniam R, Shirley OB. Oozing puncture wound on foot. *J Fam Pract.* 2009 Jan;58(1):37-39.)

- Crepitus occurs when there is gas in the soft tissues.
- Unresponsive to empiric antimicrobial therapy.

TYPICAL DISTRIBUTION

- May occur at any anatomic location.
- Majority of cases occur on the lower extremities (**Figures 122-5 and 122-7**) but can occur on the upper extremities.
- Also common on abdominal wall (**Figure 122-4**) and in perineum (Fournier gangrene).

LABORATORY AND IMAGING

- Routine laboratory tests are nonspecific but common findings include an elevated white blood cell count (WBC), a low serum sodium, and a high blood urea nitrogen (BUN).
- Histology and culture of deep tissue biopsy are essential; surface cultures cannot be relied on alone. Gram staining of the exudate may provide clues about the pathogens while the physician awaits culture results.²
- Standard radiographs are of little value unless air is demonstrated in the tissues (**Figure 122-2**).
- Radiography, CT, ultrasonography, and MRI can be used to detect gas within soft tissues or muscles.²
- Although imaging may help delineate the extent of disease, it should not delay surgical consultation.

BIOPSY

- Gross examination reveals swollen, dull, gray fascia with stringy areas of necrosis.⁶
- Necrosis of superficial fascia and fat produces watery, foul-smelling “dishwater pus.”²
- Histology demonstrates subcutaneous fat necrosis, vasculitis, and local hemorrhage.²

DIFFERENTIAL DIAGNOSIS

- Cellulitis—Acute spreading infection of skin and soft tissues characterized by erythema, edema, pain, and calor. Rapid progression of disease despite antibiotics, systemic toxicity, intense pain, and skin necrosis suggest NF rather than cellulitis (see Chapter 120, Cellulitis).
- Pyomyositis—Suppuration within individual skeletal muscle groups. Synergistic necrotizing cellulitis is a NSTI that involves muscle groups in addition to superficial tissues and fascia.⁷ Although pyomyositis may occur with NF, it can occur independent of cutaneous and soft-tissue infections. Imaging of the muscle confirms the diagnosis.
- Clostridial myonecrosis—Acute necrotizing infection of muscle tissue caused by clostridial organisms. Surgical exploration and cultures are required to differentiate from NF.
- Erythema induratum—Tender, erythematous subcutaneous nodules occurring on the lower legs (especially the calves). Lack of fever, systemic toxicity, and skin necrosis suggest erythema

FIGURE 122-6 Necrotizing fasciitis with gangrene. Even with a radical hemipelvectomy this patient did not survive. (Courtesy of Fred Bongard, MD.)

FIGURE 122-7 Necrotizing fasciitis with violaceous color of the skin on the affected leg. (Courtesy of Fred Bongard, MD.)

induratum rather than NF. Lesions of erythema induratum may have a chronic, recurrent course and the patient frequently has a history of tuberculosis or a positive purified protein derivative (PPD) test.

- Streptococcal or staphylococcal toxic shock syndrome—Systemic inflammatory response to a toxin-producing bacteria characterized by fever, hypotension, generalized erythroderma, myalgia, and multisystem organ involvement. NF may occur as part of the toxic shock syndrome.

MANAGEMENT

Start by maintaining a high index of suspicion for NF. If the first debridement occurs within 24 hours from the onset of symptoms, there is a significantly improved chance of survival.⁸

- Surgical debridement is the primary therapeutic modality.^{2,3,5,7–10} **SOR A**
 - Extensive, definitive debridement should be the goal with the first surgery. This may require amputation of an extremity to control the disease. Surgical debridement is repeated until all infected devitalized tissue is removed.
- Antibiotics are the main adjunctive therapy to surgery. Broad-spectrum empiric antibiotics should be started immediately when NF is suspected and should include coverage of Gram-positive, Gram-negative, and anaerobic organisms.⁷ **SOR A**
 - Antimicrobial therapy must be directed at the known or suspected pathogens and used in appropriate doses until repeated operative procedures are no longer needed, the patient has demonstrated obvious clinical improvement, and fever has been absent for 48 to 72 hours.⁷ **SOR A**
 - Ampicillin is useful for coverage of susceptible enteric aerobic organisms, such as *E. coli*, as well as for Gram-positive organisms, such as *Peptostreptococcus* species, group B, C, or G streptococci, and some anaerobes.⁷ **SOR A**
 - Clindamycin is useful for coverage of anaerobes and aerobic Gram-positive cocci, including most *S. aureus* serogroups.
 - Clindamycin should be considered in initial coverage for its effects on exotoxin production in group A *Streptococcus* (GAS) infections. NF and/or streptococcal toxic shock syndrome caused by group A streptococci should be treated with clindamycin and penicillin.⁷ **SOR A**
 - The rationale for clindamycin is based on in vitro studies demonstrating both toxin suppression and modulation of cytokine (i.e., TNF) production, on animal studies demonstrating superior efficacy versus that of penicillin, and on two observational studies demonstrating greater efficacy for clindamycin than for β -lactam antibiotics.⁷ **SOR A**
 - Metronidazole has the greatest anaerobic spectrum against the enteric Gram-negative anaerobes, but it is less effective against the Gram-positive anaerobic cocci. Gentamicin or a fluorinated quinolone, ticarcillin-clavulanate, or piperacillin-sulbactam is useful for coverage against resistant Gram-negative rods.⁷
 - The best choice of antibiotics for community-acquired mixed infections is a combination of ampicillin-sulbactam plus clindamycin plus ciprofloxacin.⁷ **SOR A**

- Another commonly used combination is a continuous infusion of penicillin G in combination with clindamycin and an aminoglycoside if renal function permits.¹⁰
- Empiric vancomycin should be considered during pending culture results to cover for the increasing incidence of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA).^{5,7}
- One preferred antimicrobial therapy for *V. vulnificus* is doxycycline in combination with ceftazidime and surgery for NSTI.⁶
- Hyperbaric oxygen (HBO₂) may have beneficial effects when used postoperatively in NSTIs. One recent study demonstrated decreased morbidity (amputations 50% vs. 0%) and mortality (34% vs. 11.9%) with the use of postoperative HBO₂.¹¹ **SOR B**
- Aggressive fluid resuscitation is often necessary because of massive capillary leak syndrome. Supplemental enteral nutrition is often necessary for patients with NSTIs.
- Vacuum-assisted closure devices may be helpful in secondary wound management after debridement of NSTIs.¹⁰
- A recommendation to use intravenous gammaglobulin (IVIG) to treat NF or toxic shock syndrome cannot be made with certainty.⁷ **SOR B**

PROGNOSIS AND FOLLOW-UP

- Overall case fatality rate remains 20% to 47% despite aggressive, modern therapy.^{5,6}
 - However, in a retrospective chart review of patients with NSTIs treated at six academic hospitals in Texas between 2004 and 2007 mortality rates varied between hospitals from 9% to 25% (n = 296).¹²
- Early diagnosis and treatment can reduce case fatality rate to 12%.⁵
- Carrying out the first fasciotomy and radical debridement within 24 hours of symptom onset is associated with significantly improved survival.⁸

PATIENT EDUCATION

The serious life-threatening nature of NF should be explained to the patient and family when informed consent is given prior to surgery. The risk of losing life and limb should be explained while giving hope for recovery. For those patients who survive but have lost a limb, counseling should be offered to help them deal with the psychological effects of the amputation.

SECTION 4 VIRAL

123 CHICKENPOX

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 12-year-old girl presents with a 3-day history of a body-wide pruritic vesicular rash (**Figure 123-1**). The episode started 24 hours before the rash with fever and malaise. The patient is diagnosed with varicella and no antiviral medications are given. Acetaminophen or ibuprofen are recommended for fever and comfort.

INTRODUCTION

Chickenpox is a highly contagious viral infection that can become reactivated in the form of zoster.

EPIDEMIOLOGY

- Varicella-zoster virus (VZV) is distributed worldwide.
- The rate of secondary household attack is more than 90% in susceptible individuals (**Figure 123-2**).¹
- Adults and immunocompromised patients generally develop more severe disease than normal children.
- Traditionally, primary infection with VZV occurred during childhood (**Figure 123-3**). In childhood, it is usually a benign, self-limited illness in immunocompetent hosts. It occurs throughout the year in temperate regions, but the incidence peaks in the late spring and summer months.
- Prior to the introduction of the varicella vaccine in 1995, the yearly incidence of chickenpox in the United States was approximately 4 million cases with approximately 11,000 hospital admissions and 100 deaths.²
- As the vaccination rates steadily increased in the United States, there has been a corresponding 4-fold decrease in the number of cases of chickenpox cases down to disease rates of from 0.3 to 1.0 per 1000 population in 2001.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Chickenpox is caused by a primary infection with the VZV, which is a double-stranded, linear DNA herpesvirus.
- Transmission occurs via contact with aerosolized droplets from nasopharyngeal secretions or by direct cutaneous contact with vesicle fluid from skin lesions.

FIGURE 123-1 Chickenpox in a child. Note lesions in various stages (papules, intact vesicles, pustules, and crusted papules) caused by multiple crops of lesions. The vesicles are on a red base. (Courtesy of Richard P. Usatine, MD.)

FIGURE 123-2 Chickenpox in sisters seen before the varicella vaccine was available. The girls are feeling better now that the disease is resolving. (Courtesy of Richard P. Usatine, MD.)

- The incubation period for VZV is approximately 15 days, during which the virus undergoes replication in regional lymph nodes, followed by two viremic phases, the second of which persists through the development of skin lesions generally by day 14.³
- The vesicular rash appears in crops for several days. The lesions start as vesicle on a red base, which is classically described as a dewdrop on a rose petal (**Figure 123-4**). The lesions gradually develop a pustular component (**Figure 123-5**) followed by the evolution of crusted papules (**Figure 123-6**). The period of infectivity is generally considered to last from 48 hours prior to the onset of rash until skin lesions have fully crusted.
- The most frequent complication in healthy children is bacterial skin superinfection (**Figure 123-7**). Less-common skin complications (seen more frequently in immunosuppressed hosts) include bullous varicella, purpura fulminans, and necrotizing fasciitis.
- Encephalitis is a serious potential complication of chickenpox that develops toward the end of the first week of the exanthema. One form, acute cerebellar ataxia, occurs mostly in children and is generally followed by complete recovery. A more diffuse encephalitis most often occurs in adults and may produce delirium, seizures, and focal neurologic signs. It has significant rates of long-term neurologic sequelae and death.
- Pneumonia is rare in healthy children but accounts for the majority of hospitalizations in adults, where it has up to a 30% mortality rate.⁴ It usually develops insidiously within a few days after the rash has appeared with progressive tachypnea, dyspnea, and dry cough. Chest X-rays reveal diffuse bilateral infiltrates. Treat with prompt administration of intravenous acyclovir. The use of adjunctive steroid therapy is controversial.
- Varicella hepatitis is rare, and typically only occurs in immunosuppressed individuals. It is frequently fatal.
- Reactivation of latent VZV results in herpes zoster or shingles.

DIAGNOSIS

CLINICAL FEATURES

- The typical clinical manifestations of chickenpox include a prodrome of fever, malaise, or pharyngitis, followed in 24 hours by the development of a generalized vesicular rash.
- The lesions are pruritic and appear as successive crops of vesicles more than 3 to 4 days.
- Coexisting lesions in different stages of development on the face, trunk, and extremities are common (**Figure 123-8**).
- New lesions stop forming in approximately 4 days, and most lesions have fully crusted by 7 days.

TYPICAL DISTRIBUTION

- Bodywide—No laboratory tests are needed unless the diagnosis is uncertain. For children or adults in which there is uncertainty about previous disease and it is important to establish a quick diagnosis, a direct fluorescent antibody test can be done on a scraping of a lesion. In many laboratories, a result can be obtained within 24 hours (**Figure 123-9**).

FIGURE 123-3 Chickenpox in a child. Note the widespread distribution of the lesions. The honey-crusted lesion on the eyebrow suggests a secondary bacterial infection (impetigo). (Courtesy of Richard P. Usatine, MD.)

FIGURE 123-4 Dewdrop on a rose petal is the classic description of a varicella vesicle on a red base. (Courtesy of Richard P. Usatine, MD.)

LABORATORY TESTING

- Diagnosis is usually based on classic presentation. Culture of vesicular fluid provides a definitive diagnosis, but is positive in less than 40% of cases. Direct immunofluorescence has good sensitivity and is more rapid than tissue culture. Latex agglutination blood testing may be used to determine exposure and immunity to VZV.

DIFFERENTIAL DIAGNOSIS

- Pemphigus and bullous pemphigoid are usually seen in adults, whereas varicella is a disease of children.
- Dermatitis herpetiformis is characterized by pruritic papulovesicles over the extremities and on the trunk, and granular immunoglobulin (Ig) A deposits on the basement membrane (see Chapter 186, Other Bullous Disease).
- Herpes simplex infection presents with similar lesions, but is generally restricted to the genital and oral areas. The vesicles of herpes simplex tend to be more clustered in a group rather than the wide distribution of varicella (see Chapter 129, Herpes Simplex).
- Impetigo can have bullous or crusted lesions anywhere on the body. The lesions often have mild erythema and a yellowish color to the crusts (see Chapter 116, Impetigo).
- Insect bites are often suspected by history and can occur on the entire body.

MANAGEMENT

NONPHARMACOLOGIC

- Pruritus can be treated with calamine lotion, pramoxine gel, or powdered oatmeal baths.
- Fingernails should be closely cropped to avoid significant excoriation and secondary bacterial infection.

MEDICATIONS

- Antihistamines are helpful in the symptomatic treatment of pruritus.
- Acetaminophen should be used to treat fever in children, as aspirin use is associated with Reye syndrome in the setting of viral infections.⁵ **SOR A**
- Superinfection may be treated with topical or oral antibiotics.
- Prophylactic use of varicella zoster immune globulin (125 U/10 kg, up to 625 U IM) in recently exposed susceptible individuals can prevent or attenuate the disease. However, the immune globulin is extremely hard to obtain at times.⁶
- Acyclovir (20 mg/kg PO 4 times daily) is U.S. Food and Drug Administration approved for treatment of varicella in healthy children. It should be given during the first 24 hours of rash.¹ However, the Committee on Infectious Disease of the American Academy of Pediatrics issued a statement saying they did not consider the routine administration of acyclovir to all healthy children with varicella to be justified.⁷ **SOR C**
- For adults, acyclovir 20 mg/kg PO 4 times daily (800 mg maximum) for 5 days may be used for treatment if started in the first 24 hours of the rash.⁶ **SOR A**

FIGURE 123-5 Pustules and crusted lesions on the face of a homeless man with varicella. Note how varicella has lesions simultaneously visible at different stages. (Courtesy of Richard P. Usatine, MD.)

FIGURE 123-6 Varicella on the leg of an infant after the lesions have crusted over. The patient is probably not contagious at this time. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

- Early treatment with intravenous acyclovir may be effective for treatment of varicella hepatitis and pneumonia, and may also be useful in the treatment of immunosuppressed patients. **SOR B**
- Adults who get varicella should be assessed for neurologic and pulmonary disease.

PREVENTION

- Varicella immunization (Varivax) can be used to prevent chickenpox. **SOR A** It is contraindicated in individuals allergic to gelatin or neomycin and in immunosuppressed individuals (it is a live vaccine). In 2006, and again in 2010, the Advisory Committee on Immunization Practices recommended that all children younger than 13 years of age should be routinely administered 2 doses of varicella-containing vaccine, with the first dose administered at 12 to 15 months of age and the second dose at 4 to 6 years of age (i.e., before first grade). The second dose can be administered at an earlier age provided the interval between the first and second dose is at least 3 months.⁸

FOLLOW-UP

- Follow-up is unnecessary for immunocompetent children and adults who are having no complications. All patients or parents should report any respiratory or neurologic problems immediately.

PATIENT EDUCATION

- Avoid scratching the blisters and keep fingernails short. Scratching may lead to superinfection.
- Calamine lotion and oatmeal (Aveeno) baths may help relieve itching.
- Do not use aspirin or aspirin-containing products to relieve fever. The use of aspirin is associated with development of Reye syndrome, which may cause death.

FIGURE 123-9 A 29-year-old woman with mild case of varicella. Her previous history of varicella in childhood was uncertain so a direct scraping of a lesion was performed and the varicella virus was identified quickly with a direct fluorescent antibody test. (Courtesy of Richard P. Usatine, MD.)

124 ZOSTER

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 14-year-old boy presents with deep burning pain and a vesicular eruption in a band starting at the left chest and ending just across the midline of the back (**Figure 124-1**). The varicella-zoster virus (VZV) leaves the dorsal root ganglion to travel down the spinal nerves to the cutaneous nerves of the skin. The vesicles do cross the midline by a few centimeters because the posterior primary ramus of the spinal nerve includes a small cutaneous medial branch that reaches across the midline.¹ The boy was treated with analgesics and an antiviral medication. The zoster healed with scarring.

INTRODUCTION

Herpes zoster (shingles) is a syndrome characterized by a painful, usually unilateral vesicular eruption that develops in a restricted dermatomal distribution (**Figures 124-1** and **124-2**).^{2,3}

SYNONYMS

Shingles.

EPIDEMIOLOGY

- According to the Centers for Disease Control and Prevention (CDC), 32% of persons in the United States will experience zoster during their lifetimes accounting for about 1 million cases annually.⁴ Older age groups account for the highest incidence of zoster. Approximately 4% of patients will experience a second episode of herpes zoster.⁵
- More zoster cases have been observed among women, even when controlling for age.⁶
- Herpes zoster occurs more frequently and more severely in immunosuppressed patients, including transplantation patients.

ETIOLOGY AND PATHOPHYSIOLOGY

- After primary infection with either chickenpox or vaccine-type VZV, a latent infection is established in the sensory dorsal root ganglia. Reactivation of this latent VZV infection results in herpes zoster (shingles).
- Both sensory ganglia neurons and satellite cells surrounding the neurons serve as sites of VZV latent infection. During latency, the virus only expresses a small number of viral proteins.

FIGURE 124-1 A 14-year-old boy with severe case of herpes zoster in a thoracic distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 124-2 Close-up of herpes zoster lesions. Note grouped vesicles on a red base. (Courtesy of Richard P. Usatine, MD.)

- How the virus emerges from latency is not clearly understood. Once reactivated, virus spreads to other cells within the ganglion. The dermatomal distribution of the rash corresponds to the sensory fields of the infected neurons within the specific ganglion.³
- Loss of VZV-specific cell-mediated immune response is responsible for reactivation.³
- The pain associated with zoster infections and postherpetic neuralgia (PHN) is thought to result from injury to the peripheral nerves and altered central nervous system processing.
- The most common complications are PHN and bacterial superinfection that can delay healing and cause scarring of the zoster lesions.
- Approximately 19% of patients develop complications that may include:⁷
 - PHN—The most common complication is seen in 10% at 90 days⁷ (see below).
 - Ocular complications, including uveitis and keratitis (seen in 4%)⁷ (see Chapter 125, Zoster Ophthalmicus).
 - Bell palsy and other motor nerve plastic (seen in 3%).⁷
 - Bacterial skin infection (seen in 2%).⁷
 - Meningitis caused by central extension of the infection.
 - Herpes zoster oticus (Ramsay Hunt syndrome) (**Figure 124-3**) includes the triad of ipsilateral facial paralysis, ear pain, and vesicles in the auditory canal and auricle.⁸ Disturbances in taste perception, hearing (tinnitus, hyperacusis), lacrimation, and vestibular function (vertigo) may occur.
 - Other rare complications may include acute retinal necrosis, transverse myelitis, encephalitis, leukoencephalitis, contralateral thrombotic stroke syndrome, and granulomatous vasculitis.⁹
- Immunosuppressed patients are at increased risk for complications, including severe complications such as broader dermatomal involvement (**Figure 124-4**), disseminated infection, visceral involvement, pneumonitis, and/or meningoencephalitis.
- PHN is the persistence of pain, numbness, and/or dysesthesias precipitated by movement or in response to nonnoxious stimuli in the affected dermatome for more than 1 month after the onset of zoster. The incidence of PHN in the general population is 1.38 per 1000 person-years, and it occurs more commonly in individuals older than age 60 years and in immunosuppressed individuals.³
- In a large study, rates of zoster-associated pain (PHN) persisting at least 90 days were:
 - Ten percent overall; 12% in women and 7% in men.
 - Ages 22 to 59 years—Five percent overall; 6% in women and 5% in men.
 - Ages 60 to 69 years—Ten percent overall; 14% in women and 5% in men.
 - Ages 70 to 79 years—Seventeen percent overall; 18% in women and 15% in men.
 - Age 80 years and older—Twenty percent overall; 23% in women and 13% in men.⁷

RISK FACTORS

ZOSTER³

- Older age.
- Underlying malignancy.

FIGURE 124-3 Herpes zoster oticus (Ramsay Hunt syndrome) with the classic presentation of vesicles on the auricle. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 124-4 Herpes zoster in a 4-year-old boy with HIV disease. Note multiple dermatomes are involved. (Courtesy of Richard P. Usatine, MD.)

- Disorders of cell-mediated immunity.
- Chronic lung or kidney disease.
- Autoimmune disease.

PHN

- Age older than 60 years.
- Negative vaccine status.

DIAGNOSIS

CLINICAL FEATURES

- A deep burning pain and sometimes redness in a dermatomal pattern is the most common first symptom and can precede the rash by days to weeks (**Figure 124-5**). A prodrome of fever, dysesthesias, malaise, and headache leads in several days to a dermatomal vesicular eruption. The rash starts as grouped vesicles or bullae which evolve into pustular or hemorrhagic lesions within 3 to 4 days (**Figures 124-1 to 124-8**). The lesions typically crust in approximately a week, with complete resolution within 3 to 4 weeks.⁵

TYPICAL DISTRIBUTION

- Generally limited to one dermatome in immunocompetent patients, but sometimes affects neighboring dermatomes. Rarely, a few scattered vesicles located away from the involved dermatome as a result of release of VZV from the infected ganglion into the bloodstream.³ If there are more than 20 lesions distributed outside the dermatome affected, the patient has disseminated zoster. The thoracic and lumbar dermatomes are the most commonly involved. Occasionally zoster will be seen on the extremities (**Figure 124-6**).

LABORATORY TESTING

- Meningitis associated with VZV infection can be diagnosed by cerebrospinal fluid showing pleocytosis.

DIFFERENTIAL DIAGNOSIS

- Pemphigus and other bullous diseases present with blisters, but not the classic dermatomal distribution (see Chapters 183, Overview of Bullous Disease and 185, Pemphigus).
- Molluscum contagiosum presents with white or yellow flat topped papules with central umbilication caused by a pox virus. The lesions are more firm and unless irritated do not have a red base as seen with zoster (see Chapter 130, Molluscum Contagiosum).
- Scabies may present as a pustular rash that is not confined to dermatomes and usually has characteristic lesions in the webs of the fingers (see Chapter 143, Scabies).
- Insect bites are often suspected by history and can occur over the entire body.

FIGURE 124-5 Herpes in the axilla of a young woman. Notice the redness in the dermatome that has started producing blisters. (Courtesy of Richard P. Usatine, MD.)

FIGURE 124-6 Herpes zoster on the arm that follows a dermatomal pattern. (Courtesy of E.J. Mayeaux, Jr., MD.)

FIGURE 124-7 Herpes zoster of the C4-C5 dermatomal distribution. (Courtesy of Richard P. Usatine, MD.)

- Folliculitis presents with characteristic pustules arising from hair shafts (see Chapter 117, Folliculitis).
- Zoster mimics coronary artery disease when it presents with chest pain before the vesicles are visible.
- Herpes simplex infection presents with similar lesions but is usually restricted to the perioral region, genital area, buttocks, and fingers (see Chapter 129, Herpes Simplex).

MANAGEMENT

NONPHARMACOLOGIC

- Calamine lotion and topically administered lidocaine may be used to reduce pain and itching. **SOR C**

MEDICATIONS

- The objectives of treatment of herpes zoster include (a) hastening the resolution of the acute viral infection, (b) treatment of the associated pain, and (c) prevention of PHN.
- Antiviral agents used in the treatment of herpes zoster include acyclovir (Zovirax), famciclovir (Famvir), and valacyclovir (Valtrex), all started within 72 hours of the onset of the rash (**Table 124-1**).¹⁰ **SOR A**
- Adding corticosteroids to acyclovir therapy may accelerate times to crusting and healing, return to uninterrupted sleep, resumption of full activity, and discontinuation of analgesic. Data is lacking for combining corticosteroids with other antivirals.
- Pain can be managed with nonprescription analgesics or narcotics. Pain should be treated aggressively. This may actually prevent or lessen the severity of PHN. Narcotic analgesics with hydrocodone are appropriate when needed. **SOR C**
- Treatment of herpes zoster with steroids does not reduce the prevalence of PHN.
- Treatment of herpes zoster early with valacyclovir, famciclovir, or amitriptyline does reduce pain of PHN at 6 months.
- Treatment of PHN includes tricyclic antidepressants, gabapentin (Neurontin), pregabalin (Lyrica), and/or opioid analgesics (**Table 124-2**).

PREVENTION

- Use of varicella (chickenpox) vaccine has not led to an increase in vaccine-associated herpes zoster in immunized patients or in the general population, and has led to an overall decrease in herpes zoster.⁸
- The herpes zoster vaccine contains a much higher dose of the live-attenuated virus than the varicella vaccine. In adults 60 years of age or older, immunization reduces the incidence of herpes zoster by 51% compared with placebo.³ In those who do develop zoster, the duration of pain and discomfort is shorter and the incidence of PHN is greatly reduced. It reduces the incidence of PHN from 1.38 to 0.46 per 1000 person-years.³

FIGURE 124-8 Herpes zoster in the thoracic distribution in an African child. (Courtesy of Richard P. Usatine, MD.)

TABLE 124-1 Treatments for Herpes Zoster

Medication	Dosage
Acyclovir (Zovirax)	800 mg orally 5 times daily for 7 to 10 days or 10 mg/kg intravenously every 8 hours for 7 to 10 days
Famciclovir (Famvir)	500 mg orally 3 times daily for 7 days
Valacyclovir (Valtrex)	1000 mg orally 3 times daily for 7 days
Prednisone (Deltasone)	30 mg orally twice daily for 1 week followed by a tapering dose for approximately 2 weeks

TABLE 124-2 Effective Treatments for Postherpetic Neuralgia

Treatment	Benefit/Risk	Risks	NNT for ≥50% Pain Reduction	Dose/Duration
Lidocaine patch 5%	Reduces pain and acts as mechanical barrier	Application site sensitivity	2	Apply up to 3 patches for up to 12 hours
Tricyclic antidepressants (including amitriptyline) (strongest evidence)	Reduce pain, better sleep, decreases anxiety and depression	Multiple side effects, including sedation and dry mouth	2.7	25 to 150 mg qhs
Gabapentin (Neurontin) (strongest evidence)	Reduces pain, improves sleep, mood, and quality of life	Somnolence, dizziness, decreased memory	2.8–5.3	300 to 600 mg tid (can go as high as 1200 mg tid)
Pregabalin (Lyrica)	May reduce pain	Peripheral edema and weight gain	5	75 mg bid
Opioids (morphine, oxycodone, methadone)	Reduce pain	Somnolence, constipation, tolerance	Variable	Start low and titrate to effective dose
Tramadol	Reduces pain and is not a true narcotic	Dizziness, nausea, somnolence, constipation	4.8	50 to 100 mg qid

Abbreviation: NNT, number needed to treat.

Adapted from Garroway N, Chhabra S, Landis S, Skolnik DC. Clinical inquiries: what measures relieve postherpetic neuralgia? *J Fam Pract.* 2009;58(7):384 and Tying SK. Management of herpes zoster and postherpetic neuralgia. *J Am Acad Dermatol.* 2007;57(6 Suppl):S136-142.

FOLLOW-UP

- Follow-up is based on the severity of the case and the immune status of the patient.

PATIENT EDUCATION

- Herpes zoster in an immunocompetent host is only contagious from contact with open lesions.
- Patients with disseminated zoster or with zoster and are immunocompromised should be isolated from nonimmune individuals with primary varicella infection (in which airborne spread is possible).
- Individuals who have not had varicella and are exposed to a patient with herpes zoster are only at risk of developing primary varicella and not herpes zoster.

125 ZOSTER OPHTHALMICUS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 44-year-old HIV-positive Hispanic man presented with painful herpes zoster of his right forehead (**Figure 125-1**). He was particularly worried because his right eye was red, painful, and very sensitive to light (**Figure 125-2**). On physical examination there was significant conjunctival injection, corneal punctate epithelial erosions, and clouding, and a small layer of blood in the anterior chamber (hyphema). The pupil was somewhat irregular. Along with the hyphema and ciliary flush, this indicated an anterior uveitis. The patient had a unilateral ptosis on the right side with limitations in elevation, depression, and adduction of the eye secondary to cranial nerve III palsy from the zoster. The patient was immediately referred to ophthalmology and the anterior uveitis, corneal involvement, and cranial nerve III palsy were confirmed. The ophthalmologist started the patient on topical ophthalmic preparations of erythromycin, moxifloxacin, prednisolone, and atropine. Oral acyclovir was also prescribed. Unfortunately, the patient did not return for follow up until 6 months later when he returned to the ophthalmologist with significant corneal scarring (**Figure 125-3**). The patient is currently on a waiting list for a corneal transplantation.

INTRODUCTION

Herpes zoster is a common infection caused by varicella-zoster virus, the same virus that causes chickenpox. Reactivation of the latent virus in neurosensory ganglia produces the characteristic manifestations of herpes zoster (shingles). Herpes zoster outbreaks may be precipitated by aging, poor nutrition, immunocompromised status, physical or emotional stress, and excessive fatigue. Although zoster most commonly involves the thoracic and lumbar dermatomes, reactivation of the latent virus in the trigeminal ganglia may result in herpes zoster ophthalmicus (HZO) (**Figures 125-1 to 125-6**).

SYNONYMS

Ocular herpes zoster.

EPIDEMIOLOGY

- Incidence rates of HZO complicating herpes zoster range from 8% to 56%.¹
- Ocular involvement is not correlated with age, gender, or severity of disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Serious sequelae may occur including chronic ocular inflammation, vision loss, and disabling pain. Early diagnosis is important

FIGURE 125-1 A 44-year-old HIV-positive Hispanic man with painful herpes zoster of his right forehead.

FIGURE 125-2 Acute zoster ophthalmicus of the same patient with conjunctival injection, corneal punctation (keratitis), and a small layer of blood in the anterior chamber (hyphema). A diagnosis of anterior uveitis was suspected based on the irregularly shaped pupil, the hyphema, and ciliary flush. A slit-lamp examination confirmed the anterior uveitis (iritis).

FIGURE 125-3 Corneal scarring and conjunctival injection of the same patient 6 months later after being lost to follow up.

to prevent progressive corneal involvement and potential loss of vision.²

- Because the nasociliary branch of the first (ophthalmic) division of the trigeminal (fifth cranial) nerve innervates the globe (**Figure 125-7**), the most serious ocular involvement develops if this branch is involved.
- Classically, involvement of the side of the tip of the nose (Hutchinson sign) has been thought to be a clinical predictor of ocular involvement via the external nasal nerve (**Figures 125-4** and **125-5**). The Hutchinson sign is a powerful predictor of ocular inflammation and corneal denervation with relative risks of 3.35 and 4.02, respectively. In one study, the manifestation of herpes zoster skin lesions at the dermatomes of both nasociliary branches (at the tip, the side, and the root of the nose) was invariably associated with the development of ocular inflammation.³
- Epithelial keratitis is the earliest potential corneal finding (**Figure 125-2**). On slit-lamp examination, it appears as multiple, focal, swollen spots on the cornea that stain with fluorescein dye. They may either resolve or progress to dendrite formation. Herpes zoster virus dendrites form branching or frond-like patterns that have tapered ends and stain with fluorescein dye. These lesions can lead to anterior stromal corneal infiltrates.
- Stromal keratitis occurs in 25% to 30% of patients with HZO, and is characterized by multiple fine granular infiltrates in the anterior corneal stroma. The infiltrates probably arise from antigen–antibody reaction and may be prolonged and recurrent.⁴
- Anterior uveitis evolves to inflammation of the iris and ciliary body and occurs frequently with HZO (**Figure 125-2**). The inflammation is usually mild, but may cause a mild intraocular pressure elevation. The course of disease may be prolonged, especially without timely treatment, and may lead to glaucoma and cataract formation.
- Herpes zoster virus is the most common cause of acute retinal necrosis. Symptoms include blurred vision and/or pain in one or both eyes and signs include peripheral patches of retinal necrosis that rapidly coalesce, occlusive vasculitis, and vitreous inflammation. It commonly causes retinal detachment. Bilateral involvement is observed in one-third of patients, but may be as high as 70% in patients with untreated disease. Treatment includes long courses of oral and intravenous acyclovir (Zovirax), and corticosteroids.⁵
- Varicella-zoster virus is a member of the same family (Herpesviridae) as herpes simplex virus, Epstein-Barr virus, and cytomegalovirus.
- The virus damages the eye and surrounding structures by neural and secondary perineural inflammation of the sensory nerves. This often results in corneal anesthesia.
- Conjunctivitis, usually with *Staphylococcus aureus*, is a common complication of HZO.

RISK FACTORS

- Immunocompromised persons, especially when caused by human immunodeficiency virus infection, have a much higher risk of developing zoster complications, including HZO.

FIGURE 125-4 This 5-year-old girl had herpes zoster involving the ophthalmic branch of the trigeminal nerve. Note the vesicles and bullae on the forehead and eyelid and the crust on the nasal tip (Hutchinson sign). Fortunately, she did not have ocular complications and her case of zoster fully healed with oral acyclovir and acyclovir eye ointment. (Courtesy of Amor Khachemoune, MD.)

FIGURE 125-5 Herpes zoster ophthalmicus involving the first and second branch of the trigeminal nerve and the eyelids. There is conjunctival hyperemia and purulent left eye discharge. The nasociliary branch of the ophthalmic branch of the trigeminal nerve is involved, producing the black crusting on the tip of the nose. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

- The syndrome usually begins with a prodrome of low-grade fever, headache, and malaise that may start up to 1 week before the rash appears.
- Unilateral pain or hypesthesia in the affected eye, forehead, top of the head, and/or nose may precede or follow the prodrome. The rash starts with erythematous macules along the involved dermatome, then rapidly progresses over several days to papules, vesicles and pustules (**Figures 125-4 to 125-6**). The lesions rupture and typically crust over, requiring several weeks to heal completely.
- With the onset of a vesicular rash along the trigeminal dermatome, hyperemic conjunctivitis, episcleritis, and lid droop (ptosis) can occur (**Figure 125-6**).
- Approximately two-thirds of patients with HZO develop corneal involvement (keratitis).¹ The epithelial keratitis may feature punctate or dendritiform lesions (**Figure 125-2**). Complications of corneal involvement can lead to corneal scarring (**Figure 125-3**).⁶
- Iritis (anterior uveitis) occurs in approximately 40% of patients and can be associated with hyphema and an irregular pupil (**Figure 125-2**).¹
- Rarely, zoster can be associated with cranial nerve palsies.

TYPICAL DISTRIBUTION

- The frontal branch of the first division of the trigeminal nerve (which includes the supraorbital, supratrochlear, and external nasal branch of the anterior ethmoidal nerve) is most frequently involved, and 50% to 72% of patients experience direct eye involvement (**Figure 125-7**).¹
- Although HZO most often produces a classic dermatomal rash in the trigeminal distribution, a minority of patients may have only cornea findings.

DIFFERENTIAL DIAGNOSIS

- Bacterial or viral conjunctivitis presents as eye pain and foreign body sensation associated with discharge but no rash (see Chapter 16, Conjunctivitis).
- Trigeminal neuralgia presents with facial pain but without the rash or conjunctival findings.
- Glaucoma that presents as inflammation, pain, and injection, but without the rash or conjunctival findings (see Chapter 19, Glaucoma).
- Traumatic abrasions usually present with a history of trauma and corneal findings but no other zoster findings (see Chapter 15, Corneal Foreign Body and Abrasion).
- Pemphigus and other bullous diseases present with blisters, but not in a dermatomal distribution (see Chapter 183, Overview of Bullous Disease).

FIGURE 125-7 Diagram demonstrating the sensory distribution of the trigeminal (fifth cranial) nerve, and major peripheral nerves of the first (ophthalmic) division that may be involved with herpes zoster ophthalmicus. The infraorbital nerve from the second division is also shown. (Courtesy of E.J. Mayeaux, Jr., MD.)

MANAGEMENT

MEDICATIONS

- The standard treatment for HZO is to initiate antiviral therapy with acyclovir (800 mg, 5 times daily for 7 to 10 days), valacyclovir (1000 mg 3 times daily for 7 or 14 days), or famciclovir (500 mg orally 3 times a day for 7 days), as soon as possible so as to decrease the incidence of dendritic and stromal keratitis as well as anterior uveitis.⁷ **SOR A**
- Oral acyclovir, valacyclovir, and famciclovir in patients with ophthalmic involvement have comparable outcomes. Treatment is most commonly oral acyclovir but intravenous acyclovir (10 mg/kg 3 times daily for 7 days) may be considered in immunocompromised patients or the rare patient who is extremely ill.⁸ **SOR A**
- Topical steroid ophthalmic drops are applied to the involved eye, after examination by the ophthalmologist, to reduce the inflammatory response and control immune keratitis and iritis.^{1,2} **SOR B**
- The ophthalmologist may prescribe a topical cycloplegic (such as atropine) to treat the ciliary muscle spasm that is painful in iritis. **SOR C**
- Topical ophthalmic antibiotics may also be prescribed to prevent secondary infection of the eye. **SOR C**
- As in all cases of zoster, pain should be treated effectively with oral analgesics and other appropriate medications. Early and effective treatment of pain may help to prevent postherpetic neuralgia (see Chapter 124, Zoster).
- Topical anesthetics should never be used with ocular involvement because of their corneal toxicity. **SOR B**
- Secondary infection, usually *S. aureus*, may develop and should be treated with broad-spectrum topical and/or systemic antibiotics.

REFERRAL OR HOSPITALIZATION

- Referral to an ophthalmologist urgently should be initiated when eye involvement is seen or suspected.
- Hospital admission should be considered for patients with loss of vision, severe symptoms, immunosuppression, involvement of multiple dermatomes, or with significant facial bacterial superinfection.

PREVENTION

- The herpes zoster vaccine reduces the incidence of herpes zoster by 51% compared with placebo.⁹ In those who do develop zoster, the duration of pain and discomfort is shorter and the incidence of postherpetic neuralgia (PHN) is greatly reduced. It reduces the incidence of PHN from 1.38 to 0.46 per 1000 person-years.⁹

PROGNOSIS

- HZO can become chronic or relapsing. Recurrence is a characteristic feature of HZO.

- Approximately 50% of patients with HZO develop complications. Systemic antiviral therapy can lower the emergence of complications.^{10,11}

FOLLOW-UP

- Early diagnosis is critical to prevent progressive corneal involvement and potential loss of vision. Patients with herpes zoster should be informed that they should present for medical care with any zoster involving the first (ophthalmic) division of the trigeminal nerve or the eye itself.

PATIENT EDUCATION

- Zoster of the eye is a very serious vision-threatening illness that requires strict adherence to medical therapy and close follow-up.
- Viral transmission to nonimmune individuals from patients with herpes zoster can occur, but it is less frequent than with chickenpox. Virus can be transmitted through contact with secretions.

126 MEASLES

E.J. Mayeaux, Jr., MD
Luke M. Baudoin, MD

PATIENT STORY

An 18-month-old boy, who is visiting family in San Antonio with his parents from Central America, presents with a 3-day history of fever, malaise, conjunctivitis, coryza, and cough. He had been exposed to a child with similar symptoms approximately 2 weeks prior. A day before, he developed a maculopapular rash that blanches under pressure (**Figures 126-1** and **126-2**). His shot records are unavailable but his mother states that his last vaccine was before age 1 year. He is diagnosed with measles and supportive care is provided.

INTRODUCTION

Measles is a highly communicable, acute, viral illness that is still one of the most serious infectious diseases in human history. Until the introduction of the measles vaccination, it was responsible for millions of deaths worldwide annually. Although the epidemiology of this disease makes eradication a possibility, the ease of transmission and the low percentage of nonimmunized population that is required for disease survival have made eradication of measles extremely difficult.

EPIDEMIOLOGY

- Last major outbreak in the United States was during 1989 to 1990 and prompted a change in immunization policy in 1991, so that all children are to have two measles, mumps, rubella (MMR) vaccines before starting kindergarten.
- This practice interrupted the transmission of indigenous measles in the United States by 1993 and reduced incidence of measles to a historic low (<0.5 cases per 1 million persons) by 1997 to 1999.¹
- After an all-time low of 34 cases were reported in 2004, the annual incidence began to increase with most cases linked to international travel of inadequately vaccinated Americans to endemic areas. Incomplete vaccination rates facilitate the spread once the virus is imported to the United States causing clusters of periodic outbreaks.¹
- The worldwide incidence of death from measles was effectively reduced from an estimated 873,000 in 1999 to 164,000 by 2008 with mass vaccination campaigns by the member countries of the World Health Assembly.² In 2008, approximately 83% of the world's children received one dose of measles vaccine by their first birthday through routine health services—up from 72% in 2000.³

ETIOLOGY AND PATHOPHYSIOLOGY

- Measles is caused by the measles virus, a member of the family paramyxoviridae, genus *Morbillivirus* (hence the name, morbilliform rash).

FIGURE 126-1 Typical measles rash that began on the face and became confluent. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 126-2 The typical measles rash on the trunk. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

- It is highly contagious, transmitted by airborne droplets, and commonly causes outbreaks.
- Classic measles infection starts with the incubation phase that is usually asymptomatic and lasts for 10 to 14 days. It starts after entry of the virus into the respiratory mucosa with local viral replication. The infection then spreads to regional lymphatic tissues, and then throughout the body through the bloodstream.
- The prodrome phase starts with the appearance of systemic symptoms including fever, malaise, anorexia, conjunctivitis, coryza, and cough (**Figure 126-3**). The respiratory symptoms are caused by mucosal inflammation from viral infection of epithelial cells. Patients may develop Koplik spots, which are small whitish, grayish, or bluish papules with erythematous bases that develop on the buccal mucosa usually near the molar teeth (**Figure 126-4**). The prodrome usually lasts for 2 to 3 days.
- The classic measles rash (**Figures 126-1, 126-2, and 126-5**) is maculopapular and blanches under pressure. Clinical improvement in symptoms typically ensues within 2 days. Three to 4 days after the rash first appears, it begins to fade to a brownish color, which is followed by fine flaking. The cough may persist for up to 2 weeks.
- Fever persisting beyond the third day of rash suggests a measles-associated complication.
- Immunity after measles infection is thought to be lifelong in most cases. Measles reinfection occasionally occurs, but it is extremely rare.
- Atypical measles is a measles variant that occurs in previously vaccinated persons. Patients develop high fever and headache 7 to 14 days after exposure, and often present with a dry cough and pleuritic chest pain. Two to 3 days later, a rash develops that spreads from the extremities to the trunk. The rash may be vesicular, petechial, purpuric, or urticarial. Patients may develop respiratory distress, peripheral edema, hepatosplenomegaly, paresthesias, or hyperesthesia.
- The measles virus can cause a variety of clinical syndromes, including the classic childhood illness and a less intense form in persons with suboptimal levels of antimeasles antibodies.
- Measles virus infection can also result in more severe illness, including lymphadenopathy, splenomegaly, laryngotracheobronchitis (croup), giant cell pneumonia, and measles inclusion body encephalitis in immunocompromised patients.² This form occurs in the very old and young, those with vitamin A deficiency, and in pregnant women.
- Postinfection neurologic syndromes can occur. Postinfectious encephalomyelitis is a demyelinating disease that presents during the recovery phase, and is thought to be caused by a postinfectious autoimmune response.³ The major manifestations include fever, headache, neck stiffness, ataxia, mental status changes, and seizures. Cerebrospinal fluid (CSF) analysis demonstrates lymphocytosis and elevated proteins. Postinfectious encephalomyelitis has a 10% to 20% mortality rate, and residual neurologic abnormalities are common.³
- Subacute sclerosing panencephalitis (SSPE) is a progressive, fatal, neurologic degenerative disease that may represent a persistent infection of the central nervous system with a variant of the virus. It usually occurs in patients younger than 20 years of age and 7 to 10 years after natural measles.⁴ Patients develop neurologic

FIGURE 126-3 Measles in an Ethiopian infant during a measles outbreak. The rash is faint but her cough is prominent and subcostal retractions are seen during this cough. She also has rhinorrhea and conjunctivitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 126-4 Koplik spots occur 1 to 2 days before to 1 to 2 days after the cutaneous rash. Their presence is considered to be pathognomonic for measles, and appear as punctate blue-white spots on the bright red background of the oral buccal (cheek) mucosa. (Courtesy of the Centers for Disease Control and Prevention.)

symptoms, myoclonus, dementia, and eventually flaccidity or decorticate rigidity.

- Measles in pregnancy is a rare entity in areas that practice vaccination. Premature births may be more common in gravid women with measles, but there is no clear evidence of teratogenicity.⁵

RISK FACTORS

For developing measles:

- Failure to receive immunization.
- Failure to receive second immunization dose.
- Travel to endemic areas.
- Exposure to travelers from endemic areas.

For developing severe measles or for developing complications:

- Immunodeficiency.
- Malnutrition.
- Pregnancy.
- Vitamin A deficiency.
- Age younger than 5 years or older than 20 years.

DIAGNOSIS

Measles is a distinct disease characterized by fever, malaise, conjunctivitis, coryza, cough, rash, and Koplik spots.

CLINICAL FEATURES

Koplik spots appear during the prodrome phase and are pathognomonic for measles infection; they occur approximately 48 hours before the characteristic measles exanthem. The classic blanching rash is usually adequate to make a tentative diagnosis. The most rapid and accurate test to confirm acute measles is a blood test for measles specific immunoglobulin (Ig) M antibodies. By waiting until the third day of the rash, a false-negative IgM result can be avoided.¹

TYPICAL DISTRIBUTION

The rash begins on the face and spreads centrifugally to involve the neck, trunk, and, finally, the extremities. The lesions may become confluent, especially on the face. This cranial-to-caudal rash progression is characteristic of measles.

DIFFERENTIAL DIAGNOSIS

- Upper respiratory tract infections—The prodrome stage of measles can be confused with an upper respiratory infection (URI) except that significant fever is typically present with measles infection.
- Fordyce spots—Tiny yellow-white granules on the buccal or lip mucosa caused by benign ectopic sebaceous glands that may be mistaken for Koplik spots. Fordyce spots do not have an erythematous base.

FIGURE 126-5 A South American child with a measles exanthem that has spread down the trunk. (Courtesy of Eric Kraus, MD.)

- Alternative diagnoses that may be confused with the measles rash include Rocky Mountain spotted fever, infectious mononucleosis, scarlet fever, Kawasaki disease, toxic shock syndrome, dengue fever, and simple drug eruption (see Chapter 203, Cutaneous Drug Reactions).
- Measles can usually be distinguished clinically from rubella, erythema infectiosum (parvovirus B19 infection), roseola, and enteroviral infection by the intensity of the measles rash, its subsequent brownish coloration, and the disease course.

MANAGEMENT

NONPHARMACOLOGIC

- The treatment of measles is mostly supportive. Suspected cases of measles should be immediately reported to the local or state department of health.

MEDICATIONS

- Measures to control spread of infection should not be delayed for laboratory confirmation. Vaccine should be promptly administered to all susceptible persons, or they should be removed from the outbreak setting for a minimum of 3 weeks. **SOR C**
- Giving serum immune globulin 0.25 mL/kg of body weight to a maximum dose of 15 mL to a susceptible person within 6 days of exposure to measles can prevent or modify disease. This is especially important in patients in whom the risk of complications of measles is higher, such as pregnant women, children younger than 1 year of age, and immunocompromised patients. **SOR C**
- Vitamin A reduces morbidity and mortality and is recommended by the World Health Organization (WHO) for children in areas where vitamin A deficiency is prevalent or where the mortality from measles exceeds 1%.⁵ **SOR B**

REFERRAL OR HOSPITALIZATION

Consider hospitalization in the following scenarios:

- Difficulty breathing or noisy breathing—Bronchopneumonia occurs in 5% to 10% of patients.
- Changes in behavior, confusion—May be a harbinger of acute disseminated encephalomyelitis.
- There is dehydration, which can be the result of diarrhea, vomiting, and poor oral intake.

Refer to ophthalmology if there are changes in vision as measles keratitis can lead to permanent scarring and blindness.

PREVENTION

- Measures to control spread of infection should not be delayed for laboratory confirmation. Vaccine should be promptly administered to all susceptible persons, or they should be removed from the outbreak setting for a minimum of 3 weeks.
- Initial and booster immunization.

- Avoidance of endemic areas without being fully immunized.
- Adequate nutrition and hand washing.

PROGNOSIS

- The disease is typically self-limited. Measles typically lasts approximately 10 to 14 days from the beginning of the prodrome to the fading of the eruption.
- Approximately 30% of measles cases have one or more complications. Complications of measles are more common among patients younger than 5 years of age and adults 20 years of age and older. Centers for Disease Control and Prevention (CDC)-reported measles complications include:⁶
 - Diarrhea—8%.
 - Otitis media—7%.
 - Pneumonia—6%.
 - Encephalitis—0.1%.
 - Seizures—0.6% to 0.7%.
 - Death—0.2%.

FOLLOW-UP

- Have patients watched for changes that indicate more severe disease or complications and follow-up if these occur.
- Make sure return appointments for full vaccination are scheduled.

PATIENT EDUCATION

- Drink plenty of fluids to avoid dehydration. Use antipyretics/analgesics to control fever and discomfort. Avoid aspirin to prevent Reye syndrome.
- Avoid exposure to other individuals, particularly unimmunized children and adults, pregnant women, and immunocompromised persons, until at least 4 days after rash onset.

127 FIFTH DISEASE

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 2-year-old boy presents with mild flu-like symptoms and a rash. He had erythematous malar rash and a “lace-like” erythematous rash on the trunk and extremities (**Figures 127-1** and **127-2**). The “slapped cheek” appearance made the diagnosis easy for fifth disease. The parents were reassured that this would go away on its own. The child returned to daycare the next day.

INTRODUCTION

Fifth disease is also commonly referred to as erythema infectiosum. The name derives from the fact that it represents the fifth of the six common childhood viral exanthems described. Transmission occurs through respiratory secretions, possibly through fomites, and parenterally via vertical transmission from mother to fetus and by transfusion of blood or blood products.

SYNONYMS

Erythema infectiosum, parvovirus B19 infections, slapped cheek disease.

EPIDEMIOLOGY

- Fifth disease is common throughout the world. Antiparvovirus B19 immunoglobulin (Ig) G is found equally among Americans, Asians, and Europeans.¹ The only known host for B19 is humans.
- Most individuals become infected during their school years.
- Fifth disease is very contagious via the respiratory route and occurs more frequently between late winter and early summer. Up to 60% of the population is seropositive for antiparvovirus B19 IgG by age 20 years.² In some communities, there are cycles of local epidemics every 4 to 10 years.³
- Thirty percent to 40% of pregnant women lack measurable IgG to the infecting agent and are, therefore, presumed to be susceptible to infection. Infection during pregnancy can in some cases lead to fetal death.

ETIOLOGY AND PATHOPHYSIOLOGY

- Fifth disease is a mild viral febrile illness with an associated rash caused by parvovirus B19 (**Figure 127-3**).
- Most persons with parvovirus B19 infection never develop the clinical picture of fifth disease.

FIGURE 127-1 Classic erythematous malar rash with “slapped cheek” appearance of fifth disease (erythema infectiosum). (Courtesy of Richard P. Usatine, MD.)

FIGURE 127-2 Classic fifth disease “lace-like” erythematous rash on the trunk and extremities. (Courtesy of Richard P. Usatine, MD.)

- Parvovirus B19 infects rapidly dividing cells and is cytotoxic for erythroid progenitor cells.
- After initial infection, a viremia occurs with an associated precipitous drop in the reticulocyte count and anemia. The anemia is rarely clinically apparent in healthy patients, but can cause serious anemia if the red blood cell count is already low. Patients with a chronic anemia such as sickle cell or thalassemia may experience a transient aplastic crisis.⁴
- Vertical transmission can result in congenital infection if a woman becomes infected during her pregnancy.⁵ The risk of a fetal loss or hydrops fetalis is greatest (loss rate of 11%) when the infection occurs within the first 20 weeks of gestation.⁶

RISK FACTORS

- Exposure to infected children.
- Reception of blood products.

DIAGNOSIS

CLINICAL FEATURES

- Fifth disease is usually a biphasic illness, starting with upper respiratory tract symptoms that may include headache, fever, sore throat, pruritus, coryza, abdominal pain, diarrhea, and/or arthralgias. These constitutional symptoms coincide with onset of viremia and they usually resolve for about a week before the next stage begins.
- The second stage is characterized by a classic erythematous malar rash with relative circumoral pallor or “slapped cheek” appearance in children (**Figures 127-1 and 127-4**) followed by a “lace-like” erythematous rash on the trunk and extremities (**Figures 127-2 and 127-5**). Arthropathy affecting the hands, wrists, knees, and ankles may precede the development of a rash in adults. The course is usually self-limited.

TYPICAL DISTRIBUTION

- The rash starts with the classic slapped cheek appearance (**Figures 127-1 and 127-4**). Then an erythematous macular rash occurs on the extremities. After several days, the extremities rash fades into a lacy pattern (**Figures 127-2 and 127-5**). The exanthem may recur over several weeks in association with exercise, sun exposure, bathing in hot water, or stress.

LABORATORY TESTING

- Laboratory studies are not usually needed as the diagnosis can be made by history and physical exam. Serum B19-specific IgM may be ordered in pregnant women exposed to fifth disease. After 3 weeks, infection is also indicated by a four-fold or greater rise in serum B19-specific IgG antibody titers.
- Patients with symptoms of anemia, a history of increased red blood cell (RBC) destruction (e.g., sickle cell disease, hereditary spherocytosis), or with decreased RBC production (e.g., iron-deficiency anemia) should be tested for anemia.
- Pregnant women who are exposed to or have symptoms of parvovirus infection should have serologic testing. **SOR C** Prior to

FIGURE 127-3 Transmission electron microscopy of parvovirus B19. (Courtesy of the Centers for Disease Control and Prevention.)

FIGURE 127-4 Classic erythematous malar rash with “slapped cheek” appearance of fifth disease in an 18-month-old child. (Courtesy of Richard P. Usatine, MD.)

20 weeks' gestation, women testing positive for acute infection (i.e., positive IgM and negative IgG) should be counseled concerning the low risk of fetal loss and congenital anomalies.

IMAGING

- If serologic testing in pregnant women is positive, some experts recommend that the patient should receive ultrasounds to look for signs of fetal hydrops. **SOR C** Intrauterine transfusion is currently the only effective treatment to alleviate fetal anemia.⁷

DIFFERENTIAL DIAGNOSIS

- Acute rheumatic fever presents as a fine papular (sandpaper) rash in association with a *Streptococcus* infection (see Chapter 34, Scarlet Fever and Strawberry Tongue).
- Allergic-hypersensitivity reactions (erythema multiforme, erythema nodosum, and cutaneous vasculitis) often involve the arms and legs but rarely affect the face (see Section 14, Hypersensitivity Syndromes).
- Lyme disease presents with an expanding rash with central clearing (see Chapter 218, Lyme Disease).
- Measles produces a blanching rash that begins on the face and spreads centrifugally to involve the neck, trunk, and finally the extremities. It tends to become more confluent instead of lacy with time (see Chapter 126, Measles).

MANAGEMENT

NONPHARMACOLOGIC

- Fifth disease is usually self-limited and requires no specific therapy.
- See “Patient Education” below for further information about parvovirus B19 infections in pregnancy.

MEDICATIONS

- NSAID or acetaminophen therapy may alleviate fevers and arthralgias. **SOR C**
- Transient aplastic anemia is very rare but may be severe enough to require transfusion until the patient's red cell production recovers. **SOR C**

PREVENTION

- Because it is spread through respiratory secretions and possibly through fomites, good hand sanitation and infection-control techniques are recommended.
- Infected individuals should avoid excessive heat or sunlight, which can cause rash flare-ups.

PROGNOSIS

- The rash of erythema infectiosum usually is self-limiting, but may last weeks to months with exacerbations.
- Aplastic anemia usually lasts up to 2 weeks but may become chronic. The onset of erythema infectiosum rash usually indicates that reticulocytosis has returned and aplastic crisis will not occur.

FIGURE 127-5 Classic reticular eruption on the extremities. (Courtesy of Jeffrey Meffert, MD.)

PATIENT EDUCATION

- Explain to parents that the disease is usually self-limited. Normal activities may be pursued as tolerated with sun protection or avoidance.
- Children who present with the classic findings of fifth disease are past the infectious state and can attend school and daycare.
- During pregnancy, a woman who has an acute infection prior to 20 weeks' gestation should be counseled concerning the low risks of fetal loss and congenital anomalies. Beyond 20 weeks' gestation, some physicians recommend repeated ultrasounds to look for signs of fetal hydrops.

128 HAND, FOOT, AND MOUTH DISEASE

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 4-year-old boy presents to a free clinic for homeless families with a low-grade fever and lesions on his hands and feet (**Figures 128-1** and **128-2**). The mother notes that two other kids in the transitional living center also have a similar rash. Upon further investigation, the mouth lesions are noted (**Figure 128-3**). The mother is reassured that this is nothing more than hand, foot, and mouth disease and will go away on its own. Treatment includes fluids and antipyretics as needed.

INTRODUCTION

Hand, foot, and mouth disease (HFMD) is a viral illness that may affect humans and some animals, and presents with a distinct clinical presentation. The disease occurs worldwide.

SYNONYMS

Hand, foot, mouth syndrome.

EPIDEMIOLOGY

- Epidemics tend to occur every 3 years worldwide. In temperate climates, the peak incidence is in late summer and early fall.
- HFMD generally has a mild course, but it may be more severe in infants and young children.^{1,2}
- There is no racial or gender predilection. Most cases affect children younger than 10-year-old.³

ETIOLOGY AND PATHOPHYSIOLOGY

- HFMD is most commonly caused by members of the enterovirus genus, especially coxsackie viruses. Epidemic infections are usually caused by coxsackievirus A16, and less commonly by other coxsackievirus A, coxsackievirus B, or enterovirus 71.^{2,3} Sporadic cases occur caused by other coxsackie viruses.
- Coxsackievirus infections are highly contagious. Transmission occurs via aerosolized droplets of nasal and/or oral secretions via the fecal-oral route, or from contact with skin lesions. During epidemics, the virus is spread from child to child and from mother to fetus.
- The incubation period averages 3 to 6 days. Initial viral implantation is in the GI tract mucosa, and it then spreads to lymph nodes within 24 hours. Viremia rapidly ensues, with spread to the oral mucosa and skin. Rarely, aseptic meningitis may occur. Usually by

FIGURE 128-1 Typical flat vesicular lesions on the hand of a 4-year-old boy with hand, foot, and mouth disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 128-2 Foot of the boy in Figure 128-1 with hand, foot, and mouth disease. Lesions tend to be on palms and soles, fingers, and toes. (Courtesy of Richard P. Usatine, MD.)

day 7, a neutralizing antibody response develops, and the virus is cleared from the body.

- When HFMD is caused by enteroviruses, it may also result in neurologic problems such as a polio-like syndrome, aseptic meningitis, encephalitis, acute cerebellar ataxia, acute transverse myelitis, Guillain-Barré syndrome, and benign intracranial hypertension. Rarely, cardiopulmonary complications such as myocarditis, interstitial pneumonitis, and pulmonary edema may occur.^{4,5} Rarely death may occur.⁶
- Infection in the first trimester of pregnancy may lead to spontaneous abortion or intrauterine growth retardation.

RISK FACTORS

- Attendance at child care centers.
- Contact with HFMD.
- Large family.
- Rural residence.

DIAGNOSIS

CLINICAL FEATURES

- A prodrome lasting 12 to 36 hours is usually the first sign of HFMD, and it usually consists of typical general viral infection symptoms with anorexia, abdominal pain, and sore mouth. Lesions are present for 5 to 10 days, and heal spontaneously in 5 to 7 days.
- Each lesion begins as a 2- to 10-mm erythematous macule, which develops a gray, oval vesicle that parallels the skin tension lines in its long axis (**Figures 128-1** and **128-2**). The oral lesions (**Figure 128-3**) begin as erythematous macules, evolve into 2- to 3-mm vesicles on an erythematous base, and then rapidly become ulcerated. The vesicles are painful and may interfere with eating. They are not generally pruritic.
- Cervical or submandibular lymphadenopathy may be present.

TYPICAL DISTRIBUTION

- Skin lesions develop on the hands, feet, and/or buttocks and oral lesions may involve the palate, buccal mucosa, gingiva, and/or tongue.

LABORATORY TESTING

- Laboratory tests are not needed.

DIFFERENTIAL DIAGNOSIS

- Aphthous stomatitis presents as single or multiple painful ulcers in the mouth without skin eruptions (see Chapter 41, Aphthous Ulcer).
- Chickenpox presents with body-wide vesicular lesions in multiple crops (see Chapter 123, Chickenpox).

FIGURE 128-3 Mouth lesions in same boy with hand, foot, and mouth disease appear as small ulcers on the lips and oral mucosa. (Courtesy of Richard P. Usatine, MD.)

- Erythema multiforme demonstrates body-wide target lesions that also involve the skin of the palms and soles (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal).
- Herpes simplex presents with painful recurrent ulcerations of the lips or genitals without simultaneous hand or foot lesions unless there is herpetic whitlow on the hand (see Chapter 129, Herpes Simplex).

MANAGEMENT

NONPHARMACOLOGIC

- The treatment of HFMD is usually supportive. Usually the mouth lesions are not as painful as in herpes gingivostomatitis. If there is a lot of mouth pain leading to poor oral intake, the following medications may be considered. Topical oral anesthetics such as 2% viscous lidocaine by prescription or 20% topical benzocaine (Orabase) nonprescription may be used to treat painful oral ulcers. **SOR C**
- A solution combining aluminum and magnesium hydroxide (liquid antacid) and 2% viscous lidocaine has been reported as helpful when swished and spit out several times a day as needed for pain. **SOR C**

MEDICATIONS

- Acetaminophen or NSAIDs/cyclooxygenase (COX)-2's may be used to manage fever, and analgesics may be used to treat arthralgias. **SOR C** Aspirin should not be used in viral illnesses in children younger than 12 years of age, to prevent Reye syndrome. **SOR C**
- A case report of enterovirus HFMD in an immunocompromised patient reported a faster resolution of symptoms and lesions with oral acyclovir. **SOR C**

REFERRAL OR HOSPITALIZATION

- Patients with central nervous system (CNS) manifestations may require hospitalization.

PREVENTION

- Good hand washing should be encouraged to reduce the spread of disease.

PROGNOSIS

- HFMD caused by coxsackieviruses is generally a mild self-limited illness that resolves in around 7 to 10 days. HFMD may rarely recur, persist, or cause serious complications.

PATIENT EDUCATION

- Educate parents of young children to watch for signs of dehydration owing to decreased oral intake secondary to mouth pain.

- To reduce viral spreading, do not rupture blisters.
- The patient may attend school once symptoms subside.
- The virus that causes hand, foot, and mouth disease may be present in the patient's stool for 1 month.
- Report any neurologic symptoms to healthcare providers immediately.

129 HERPES SIMPLEX

E.J. Mayeaux, Jr., MD
Kevin J. Carter, MD

PATIENT STORY

A 32-year-old man presents with complaints of a 1-week history of multiple painful vesicles on the shaft of his penis associated with tender groin adenopathy (**Figure 129-1**). The vesicles broke 2 days ago and the pain has increased. He had similar lesions 1 year ago but never went for healthcare examination at that time. He has had 3 different female sexual partners in the last 2 years but has no knowledge of them having any sores or diseases. He was given the presumptive diagnosis of genital herpes and a course of acyclovir. His herpes culture came back positive and his rapid plasma reagin (RPR) and HIV tests were negative.

INTRODUCTION

Herpes simplex virus (HSV) infection can involve the skin, mucosa, eyes and central nervous system. HSV establishes a latent state followed by viral reactivation and recurrent local disease. Perinatal transmission of HSV can lead to significant fetal morbidity and mortality.

EPIDEMIOLOGY

HSV affects more than one-third of the world's population, with the 2 most common cutaneous manifestations being genital (**Figures 129-1 to 129-4**) and orolabial herpes (**Figures 129-5 to 129-7**).¹

The Centers for Disease Control and Prevention (CDC) reports that at least 50 million persons in the United States have genital HSV-2 infection. Over the past decade, the percentage of Americans with genital herpes infection in the United States has remained stable. Most persons infected with HSV-2 have not been diagnosed with genital herpes.²

Genital HSV-2 infection is more common in women (approximately 1 out of 5 women 14 to 49 years of age) than in men (approximately 1 out of 9 men 14 to 49 years of age). Transmission from an infected male to his female partner is believed to be more likely than from an infected female to her male partner.

Orolabial herpes is the most prevalent form of herpes infection and often affects children younger than 5 years of age (**Figure 121-7**). The duration of the illness is 2 to 3 weeks, and oral shedding of virus may continue for as long as 23 days.¹

Herpetic whitlow is an intense painful infection of the hand involving the terminal phalanx of one or more digits. In the United States, the estimated annual incidence is 2.4 cases per 100,000 persons.³

ETIOLOGY AND PATHOPHYSIOLOGY

- HSV belongs to the family Herpesviridae and is a double-stranded DNA virus.

FIGURE 129-1 Recurrent genital herpes simplex virus on the penis showing grouped ulcers (deroofed vesicles). (Courtesy of Richard P. Usatine, MD.)

FIGURE 129-2 Herpes simplex on the penis with intact vesicles and visible crusts. (Courtesy of Jack Reznick, Sr., MD.)

- HSV exists as 2 separate types (types 1 and 2), which have affinities for different epithelia.³ Ninety percent of HSV-2 infections are genital, whereas 90% of those caused by HSV-1 are oral–labial.
- HSV enters through abraded skin or intact mucous membranes. Once infected, the epithelial cells die, forming vesicles and creating multinucleated giant cells.
- Retrograde transport into sensory ganglia leads to lifelong latent infection.¹ Reactivation of the virus may be triggered by immunodeficiency, trauma, fever, and UV light.
- Genital HSV infection is usually transmitted through sexual contact. When it occurs in a preadolescent, the possibility of abuse must be considered.
- Evidence indicates that 21.9% of all persons in the United States, 12 years or older, have serologic evidence of HSV-2 infection, which is more commonly associated with genital infections.⁴
- As many as 90% of those infected are unaware that they have herpes infection and may unknowingly shed virus and transmit infection.⁵
- Primary genital herpes has an average incubation period of 4 days, followed by a prodrome of itching, burning, or erythema.
- With both types, systemic symptoms are common in primary disease and include fever, headache, malaise, abdominal pain, and myalgia.⁶ Recurrences are usually less severe and shorter in duration than the initial outbreak.^{1,6}
- Maternal–fetal transmission of HSV is associated with significant morbidity and mortality. Manifestations of neonatal HSV include localized infection of the skin, eyes, and mouth, central nervous system (CNS) disease, or disseminated multiple organ disease (**Figure 129-8**). The CDC and the American College of Obstetricians and Gynecologists recommend that cesarean delivery should be offered as soon as possible to women who have active HSV lesions or, in those with a history of genital herpes, symptoms of vulvar pain or burning at the time of delivery.
- Herpetic whitlow occurs as a complication of oral or genital HSV infection and in medical personnel who have contact with oral secretions (**Figures 129-9 and 129-10**).
- Toddlers and preschool children are susceptible to herpetic whitlow if they have herpes labialis and engage in thumb-sucking or finger-sucking behavior.
- Like all HSV infections, herpetic whitlow usually has a primary infection, which may be followed by subsequent recurrences. The virus migrates to the peripheral ganglia and Schwann cells where it lies dormant. Recurrences observed in 20% to 50% of cases are usually milder and shorter in duration.

RISK FACTORS

- Multiple sexual partners.
- Female gender.
- Low socioeconomic status.
- HIV infection.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of HSV infection may be made by clinical appearance. Many patients have systemic symptoms, including fever, headache, malaise, and myalgias.
- Orolabial herpes typically takes the form of painful vesicles and ulcerative erosions on the tongue, palate, gingiva, buccal mucosa, and lips (**Figures 129-5 to 129-7**).
- Genital herpes presents with multiple transient, painful vesicles that appear on the penis (**Figures 129-1 and 129-2**), vulva (**Figure 129-3**), buttocks (**Figures 129-4 and 129-11**), perineum, vagina or cervix, and tender inguinal lymphadenopathy.⁶ The vesicles break down and become ulcers that develop crusts while these are healing.
- Recurrences typically occur 2 to 3 times a year. The duration is shorter and less painful than in primary infections. The lesions are often single and the vesicles heal completely by 8 to 10 days.
- UV radiation in the form of sunlight may trigger outbreaks. Another reason to use sun protection when outdoors triggers recurrence of orolabial HSV-1, an effect which is not fully suppressed by acyclovir.

LABORATORY STUDIES

- The gold standard of diagnosis is viral isolation by tissue culture and polymerase chain reaction (PCR) testing.²
 - The culture sensitivity rate is only 70% to 80% and depends upon the stage at which the specimen is collected. The sensitivity is highest at first in the vesicular stage and declines with ulceration and crusting. The tissue culture assay can be positive within 48 hours but may take longer.
 - PCR is extremely sensitive (96%) and specific (99%). PCR testing is generally used for cerebrospinal fluid (CSF) testing in suspected HSV encephalitis or meningitis.²
- Older type-specific HSV serologic assays that do not accurately distinguish HSV-1 from HSV-2 antibody are still on the market. Both laboratory-based assays and point-of-care tests that provide results for HSV-2 antibodies from capillary blood or serum with sensitivities of 80% to 98% are available. Because nearly all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. Type-specific HSV serologic assays might be useful in patients with recurrent symptoms and negative HSV cultures and an asymptomatic patient with a partner with genital herpes. Screening for HSV-1 and HSV-2 in the general population is not indicated.²
- The Tzanck test and antigen detection tests have lower sensitivity rates than viral culture and should not be relied on for diagnosis.²
- The CDC does not currently recommend routine type 2 HSV testing in someone with no symptoms suggestive of herpes infection (i.e., for the general population).⁷
- If the herpes was acquired by sexual contact, screening should be performed for other sexually transmitted diseases (STDs), such as syphilis and HIV.

FIGURE 129-11 Recurrent herpes simplex virus on the buttocks of a woman. Note the vesicles and crusts in a unilateral cluster. (Courtesy of Richard P. Usatine, MD.)

- Biopsy is usually unnecessary unless no infectious etiology is found for a genital lesion and a malignancy is suspected.

DIFFERENTIAL DIAGNOSIS

- Syphilis produces a painless or mildly painful, indurated, clean-based ulcer (chancre) at the site of exposure. It is best to investigate for syphilis or coexisting syphilis in any patient presenting for the first time with a genital ulcer of unproven etiology (see Chapter 216, Syphilis).
- Chancroid produces a painful deep, undermined, purulent ulcer that may be associated with painful inguinal lymphadenitis (see Chapter 216, Syphilis).
- Drug eruptions produce pruritic papules or blisters without associated viral symptoms (see Chapter 203, Cutaneous Drug Reactions).
- Behçet disease produces ulcerative disease around the mouth and genitals, possibly before onset of sexual activity (**Figure 129-12**).
- Acute paronychia which presents as a localized abscess in a nail fold and is the main differential diagnosis in the consideration of herpetic whitlow (see Chapter 194, Paronychia).
- Felon—A red, painful infection, usually bacterial, of the fingertip pulp. It is important to distinguish whitlow from a felon (where the pulp space usually is tensely swollen) as incision and drainage of a felon is needed, but should be avoided in herpetic whitlow because it may lead to an unnecessary secondary bacterial infection.

MANAGEMENT

NONPHARMACOLOGIC

- Women with active primary or recurrent genital herpetic lesions at the onset of labor should deliver by cesarean section to lower the chance of neonatal HSV infection.² **SOR A**

MEDICATIONS

- Acyclovir is a guanosine analog that acts as a DNA chain terminator which, when incorporated, ends viral DNA replication. Valacyclovir is the *L*-valine ester prodrug of acyclovir that has enhanced absorption after oral administration and high oral bioavailability. Famciclovir is the oral form of penciclovir, a purine analog similar to acyclovir. They must be administered early in the outbreak to be effective, but are safe and extremely well-tolerated.⁶ **SOR A**

Genital herpes:

- Antiviral therapy is recommended for an initial genital herpes outbreak. **Table 129-1** shows the dosages for antiherpes drugs. Although systemic antiviral drugs can partially control the signs and symptoms of herpes episodes, they do not eradicate latent virus.
- Acyclovir, famciclovir, and valacyclovir are equally effective for episodic treatment of genital herpes, but famciclovir appears somewhat less effective for suppression of viral shedding.² **SOR B**
- Effective episodic treatment of herpes requires initiation of therapy during the prodrome period or within 1 day of lesion onset.

FIGURE 129-12 Young man with Behçet syndrome presenting with a painful penile ulcer and aphthous ulcers in his mouth. (Courtesy of Richard P. Usatine, MD.)

TABLE 129-1 Dosages of Treatments for Genital Herpes Infection²

Drug	Primary Infection Dosage	Recurrent Infection Dosage	Chronic Suppressive Therapy
Acyclovir (Zovirax)	400 mg 3 times daily for 7 to 10 days or 200 mg 5 times daily	400 mg 3 times daily for 5 days or 800 mg twice daily for 5 days or 800 mg 3 times daily for 2 days	400 mg twice daily
Famciclovir (Famvir)	250 mg 3 times daily for 10 days*	125 mg twice daily for 5 days or 1 g twice daily for 1 day or 500 mg once, followed by 250 mg twice daily for 2 days	250 mg PO twice daily
Valacyclovir (Valtrex)	1 g twice daily for 10 days	500 mg twice daily for 3 days or 1 g daily for 5 days	500 mg to 1 g once daily

*Famciclovir is not FDA-labeled for this indication.

Providing the patient with a prescription for the medication with instructions to initiate treatment immediately when symptoms begin improves efficacy.² **SOR B**

- IV acyclovir therapy at 5 to 10 mg/kg IV every 8 hours for 2 to 7 days followed by oral antiviral therapy to complete at least 10 days of total therapy should be provided for patients who have severe HSV disease or complications.² **SOR C**
- HSV strains resistant to acyclovir have been detected in immunocompromised patients so that other antivirals (e.g., famciclovir) need to be considered in these patients. **SOR C**
- Topical medication for HSV infection is generally not effective. Topical penciclovir applied every 2 hours for 4 days, reduces clinical healing time by approximately 1 day.^{1,2}
- All patients with a first episode of genital herpes should receive antiviral therapy as even with mild clinical manifestations initially, they can develop severe or prolonged symptoms.
- Toxicity of these 3 antiviral drugs is rare, but in patients who are dehydrated or who have poor renal function, the drug can crystallize in the renal tubules, leading to a reversible creatinine elevation or, rarely, acute tubular necrosis. Adverse effects, usually mild, include nausea, vomiting, rash, and headache. Lethargy, tremulousness, seizures and delirium have been reported rarely in studies of renally impaired patients.⁹

Oral herpes:

Table 129-2 provides an overview of treatments for herpes labialis.

- In the treatment of primary orolabial herpes, oral acyclovir (200 mg 5 times daily for 5 days) accelerates healing by 1 day and can reduce the mean duration of pain by 36%.⁸ **SOR A**
- The oral lesions in primary herpes gingivostomatitis can lead to poor oral intake especially in children (**Figures 129-5** and **129-13**). To prevent dehydration, the following medications may be considered. Topical oral anesthetics such as 2% viscous lidocaine by prescription or 20% topical benzocaine OTC may be used to treat painful oral ulcers. **SOR C** A solution combining aluminum and magnesium hydroxide (liquid antacid) and 2% viscous lidocaine

FIGURE 129-13 Primary herpes gingivostomatitis in a 4-year-old girl. Note the cluster of ulcers inside the lower lip typical of herpes simplex virus. The patient also had involvement of her gingiva, which were swollen and painful. (Courtesy of Richard P. Usatine, MD.)

TABLE 129-2 Treatments for Herpes Labialis

Drug	Dose or Dosage	Evidence Rating [†]	References
Episodic oral treatment for recurrences[‡]			
Acyclovir (Zovirax)	200 mg 5 times per day or 400 mg 3 times per day for 5 days	A	12,13
Famciclovir (Famvir)	1500 mg once for 1 day	B	14
Valacyclovir (Valtrex)	2 g twice for 1 day	B	15
Episodic topical treatment for recurrences[‡]			
Acyclovir cream	Apply 5 times per day for 4 days	B	18
Docosanol cream (Abreva)	Apply 5 times per day until healed	B	17
Penciclovir cream (Denavir)	Apply every 2 hours while awake for 4 days	B	16
Treatment to prevent recurrences			
Acyclovir	400 mg twice per day (ongoing)	A	13,19
Valacyclovir	500 mg once per day (ongoing)	B	20

Abbreviation: NA, not available.

[†]A, Consistent, good-quality, patient-oriented evidence; B, inconsistent or limited-quality, patient-oriented evidence; C, consensus, disease-oriented evidence, usual practice, expert opinion, or case series.

[‡] Most effective if treatment is started at the onset of symptoms.

Source: Reprinted with permission from Usatine RP, Tinitigan R. Nongenital herpes simplex virus. *Am Fam Physician*. 2010;82(9):1075-1082.

has been reported as helpful when swished and spit out several times a day as needed for pain. **SOR C**

- Docosanol cream (Abreva) is available without prescription for oral herpes. One randomized controlled trial (RCT) of 743 patients with herpes labialis showed a faster healing time in patients treated with docosanol 10% cream compared with placebo cream (4.1 vs. 4.8 days), as well as reduced duration of pain symptoms (2.2 vs. 2.7 days).¹¹ More than 90% of patients in both groups healed completely within 10 days.¹¹ Treatment with docosanol cream, when applied 5 times per day and within 12 hours of episode onset, is safe and somewhat effective.¹²

PREVENTION

- Barrier protection using latex condoms is recommended to minimize exposure to genital HSV infections (see “Patient Education” below).
- Suppressive therapy with antiviral drugs reduces the frequency of genital herpes recurrences by 70% to 80% in patients with frequent recurrences.² **SOR A** Traditionally this is reserved for use in patients who have more than 4 to 6 outbreaks per year (see **Table 129-1**).

- Short-term prophylactic therapy with acyclovir for orolabial HSV may be used in patients who anticipate intense exposure to UV light. Early treatment of recurrent orolabial HSV infection with Famciclovir 250 mg 3 times daily for 5 days can markedly decrease the size and duration of lesions.¹⁰ **SOR A**

FOLLOW-UP

The patient should return for follow-up if pain is uncontrolled or superinfection is suspected. The patient should be periodically evaluated for the need for suppressive therapy based on the number of recurrences per year.

PATIENT EDUCATION

Measures to prevent genital HSV infection:

- Abstain from sexual activity or limit number of sexual partners to prevent exposure to the disease.
- Use condoms to protect against transmission, but this is not foolproof as ulcers can occur on areas not covered by condoms.
- Prevent autoinoculation by patting dry affected areas, not rubbing with towel.
- Studies show that patients may shed virus when they are otherwise asymptomatic. A link between HSV genital ulcer disease and sexual transmission of HIV has been established. Safer sex practices should be strongly encouraged to prevent transmission of HSV to others and acquiring HIV by the patient.

130 MOLLUSCUM CONTAGIOSUM

E.J. Mayeaux, Jr., MD

PATIENT STORIES

An 8-year-old girl is brought to the office because of an outbreak of bumps on her face for the past 3 months (**Figure 130-1**). Occasionally she scratches them, but she is otherwise asymptomatic. The mother and child are unhappy with the appearance of the molluscum contagiosum and chose to try topical imiquimod 5% cream. Fortunately, her health insurance covered this expensive treatment. A topical treatment was chosen to avoid the risk of hypopigmentation that can occur in dark-skinned individuals with cryotherapy.

An 11-year-old girl was also seen with molluscum on her face. The child and her mother decided to try cryotherapy as her treatment. She very bravely tolerated the treatment with liquid nitrogen in a Cryogun (**Figure 130-2**). The molluscum disappeared without scarring or hypopigmentation after two treatments.

INTRODUCTION

Molluscum contagiosum is a viral skin infection that produces pearly papules that often have a central umbilication. It is seen most commonly in children, but can also be transmitted sexually among adults.

EPIDEMIOLOGY

- Molluscum contagiosum infection has been reported worldwide. An Australian seroepidemiology study found a seropositivity rate of 23%.¹
- Up to 5% of children in the United States have clinical evidence of molluscum contagiosum infection.² It is a common, nonsexually transmitted condition in children (**Figures 130-1** to **130-4**).
- The number of cases in U.S. adults increased in the 1980s, probably as a result of the HIV/AIDS epidemic. Since the introduction of highly active antiretroviral therapy (HAART), the number of molluscum contagiosum cases in HIV/AIDS patients has decreased substantially.³ However, the prevalence of molluscum contagiosum in patients who are HIV-positive may still be as high as 5% to 18% (**Figures 130-5** and **130-6**).^{4,5}
- In adults, molluscum occurs most commonly in the genital region (**Figure 130-7**). In this case, it is considered a sexually transmitted disease. Subclinical cases may occur and may be more common in the general community than is generally recognized.

ETIOLOGY AND PATHOPHYSIOLOGY

- Molluscum contagiosum is a benign condition that is often transmitted through close contact in children and through sexual contact in adults.

FIGURE 130-1 Molluscum contagiosum on the face of an 8-year-old girl. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-2 Cryotherapy of molluscum on the face of an 11-year-old girl. The central umbilication is easily seen in the two papules that were just frozen. (Courtesy of Richard P. Usatine, MD.)

- It is a large DNA virus of the *Poxviridae* family of poxvirus. It is related to the orthopoxviruses (variola, vaccinia, smallpox, and monkeypox viruses).
- Molluscum replicates in the cytoplasm of epithelial cells. It causes a chronic localized skin infection consisting of dome-shaped pearly papules on the skin. Like most of the viruses in the poxvirus family, molluscum is spread by direct skin-to-skin contact. It can also spread by autoinoculation when scratching, touching, or treating lesions.
- Any one single lesion is usually present for approximately 2 months, but autoinoculation often causes continuous crops of lesions.

RISK FACTORS

- Common childhood disease.
- Molluscum contagiosum may be more common in patients with atopic dermatitis (**Figure 130-8**).²
- The disease also may be spread by participation in contact sports.²
- It is also associated with immunodeficient states such as in HIV infection (**Figures 130-5** and **130-6**) and with immunosuppressive drug treatment.

DIAGNOSIS

CLINICAL FEATURES

- Firm, multiple, 2- to 5-mm dome-shaped papules with a characteristic shiny surface and umbilicated center (**Figure 130-9**). Not all the papules have a central umbilication, so it helps to take a moment and look for a papule that has this characteristic morphology. If all features point to molluscum and no single lesion has central umbilication, do not rule out molluscum as the diagnosis.
- The lesions range in color from pearly white, to flesh-colored, to pink or yellow.
- Pruritus may be present or absent.

TYPICAL DISTRIBUTION

- The lesions may appear anywhere on the body except the palms and soles. The number of lesions may be greater in an HIV-infected individual. In adults, they are often found around the genitalia, inguinal area, buttocks, or inner thighs (**Figure 130-7**). In children, the lesions are often on the trunk or face.
- If a child is found to have molluscum contagiosum in the genital area, a history and physical examination should be directed at looking for other clues that might indicate sexual abuse (see Chapter 9, Child Sexual Abuse). Not all cases of molluscum in this area will be secondary to sexual abuse (**Figure 130-10**).

LABORATORY TESTING

- Laboratory testing is not typically indicated.
- Sexually active adolescents and adults with genital lesions should be evaluated for other sexually transmitted diseases, including for HIV infection.

FIGURE 130-3 A group of molluscum contagiosum lesions on the abdomen of a 4-year-old boy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-4 Molluscum contagiosum under the eye of a young girl with central umbilication. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-5 Molluscum contagiosum on the face of a woman with human immunodeficiency virus. Note the large molluscum on the scalp. (Courtesy of Richard P. Usatine, MD.)

BIOPSY

- If confirmation is needed, smears of the caseous material expressed from the lesions can be examined directly under the microscope looking for molluscum bodies (enlarged keratinocytes that are engorged with viral inclusion bodies). Hematoxylin and eosin (H&E) staining from a shave biopsy usually reveals keratinocytes that contain eosinophilic cytoplasmic inclusion bodies.⁵ If a single lesion is suspicious for basal cell carcinoma (BCC), perform a shave biopsy.

DIFFERENTIAL DIAGNOSIS

- Scabies is caused by *Sarcoptes scabiei* mite and can be transmitted through close or sexual contact. Early lesions are flesh-colored to red papules that produce significant itching. The itching and excoriations are greater than seen with molluscum. Scabies lesions also usually appear in the finger webs, ventral wrist fold, and underneath the breasts in women (see Chapter 143, Scabies).
- Dermatofibromas—Firm to hard nodules ranging in color from flesh to black that typically dimple downward when compressed laterally. Usually not seen in crops as in molluscum. These nodules are deeper in the dermis and don't appear stuck on like molluscum (see Chapter 160, Dermatofibroma).
- BCCs are also pearly and raised. Usually not seen in crops as in molluscum. If a single lesion could be a BCC or molluscum, a biopsy is warranted (see Chapter 170, Basal Cell Carcinoma).
- Genital warts may be flat and grossly resemble molluscum but they lack the characteristic shiny surface and central umbilication (see Chapter 133, Genital Warts).

MANAGEMENT**NONPHARMACOLOGIC**

- Treatment of nongenital lesions is usually not medically necessary as the infection is usually self-limited and spontaneously resolves after a few months. Treatment may be performed in an attempt to decrease autoinoculation. Patients and parents of children often want treatment for cosmetic reasons and when watchful waiting fails.
- A 2009 Cochrane Database systematic review investigated the efficacy of treatments for nongenital molluscum contagiosum in healthy individuals and found insufficient evidence to conclude that any treatment was definitively effective.⁶ **SOR A**
- In the HIV-infected patient, molluscum may resolve after control of HIV disease with HAART.³ **SOR B**

MEDICATIONS

- Podophyllotoxin 0.5% (Condylox) is an antimetabolic agent that is indicated for the treatment of genital warts. The efficacy of podophyllotoxin was established in a randomized trial of lesions located on the thighs or genitalia. **SOR B** Local erythema, burning, pruritus, inflammation, and erosions can occur with the use of this agent. The safety and efficacy of this drug has not been established in young children.⁷

FIGURE 130-6 Extensive molluscum contagiosum on the face of a young girl who has been human immunodeficiency virus-positive from birth. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-7 Molluscum contagiosum on and around the penis. His girlfriend has them on the buttocks. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-8 Molluscum contagiosum in the antecubital fossa of a 6-year-old girl with atopic dermatitis. (Courtesy of Richard P. Usatine, MD.)

- Topical imiquimod 5% (Aldara) cream has been shown (not FDA approved) to be better than vehicle alone to treat molluscum. ^{8,9} **SOR B** It can be well tolerated, although application site irritation can be uncomfortable and lead to discontinuation of therapy. It has been shown not to have systemic or toxic effects in children. ⁹ In one study, 23 children ranging in age from 1 to 9 years with molluscum contagiosum infection were randomized to either imiquimod cream 5% (12 patients) or vehicle (11 patients). Parents applied the study drug to the patient's lesions 3 times a week for 12 weeks. Complete clearance at week 12 was noted in 33.3% (4/12) of imiquimod patients and in 9.1% (1/11) of vehicle patients. ¹⁰
- Tretinoin cream ¹¹ 0.1% or gel 0.025% applied daily are commonly used but not FDA-approved for this indication. **SOR B**
- Cantharidin ¹² and trichloroacetic acid ¹³ are topical chemicals that can be applied by the physician in the office (**Figure 130-11**). **SOR B** Many children will fear treatment with a curette or with any form of cryotherapy.

SURGICAL

- Curettage and cryotherapy are physical methods used to eradicate molluscum. ^{14,15} **SOR B**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- ZymaDermis a nonprescription, topical, homeopathic agent that is marketed for the treatment of molluscum contagiosum, but no published studies have evaluated its efficacy or safety.

PREVENTION

- Molluscum contagiosum is a common childhood disease.
- Limiting sexual exposure or number of sexual contact may help prevent exposure.
- Genital lesions should be treated to prevent spread by sexual contact.

PROGNOSIS

- In immunocompetent patients, lesions usually spontaneously resolve within several months. In a minority of cases, disease persists for a few years. ¹⁶

FOLLOW-UP

- Have patients watch for complications that may include irritation, inflammation, and secondary infections. Lesions on eyelids may be associated with follicular or papillary conjunctivitis, so eye irritation should prompt a visit to an eye care specialist.

PATIENT EDUCATION

- Instruct patients to avoid scratching to prevent autoinoculation.

FIGURE 130-9 Close-up of a molluscum lesion on the back of a child showing a dome-shaped pearly papule with a characteristic umbilicated center. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-10 Molluscum contagiosum on and around the penis of a young boy. There was no evidence for sexual abuse. (Courtesy of Richard P. Usatine, MD.)

FIGURE 130-11 Blisters that formed the next day after treating molluscum contagiosum with cantharidin. The blisters are not always so large but are supposed to form as the cantharidin is derived from the blister beetle. The blistering helps eradicate the molluscum. (Courtesy of Richard P. Usatine, MD.)

131 COMMON WARTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

An 11-year-old girl presents with warts on her fingers that have not responded to nonprescription wart medications (**Figure 131-1**). It causes her and her mother some social embarrassment and they would like to be rid of them. Her mother is also worried that it is affecting her daughter's nails. The girl was able to tolerate the discomfort of liquid nitrogen treatment and wanted all her warts treated. The mother was instructed to purchase 40% salicylic acid to continue treatment of any residual warts at home.

INTRODUCTION

Human papillomaviruses (HPVs) are DNA viruses that infect skin and mucous membranes. Infection is usually confined to the epidermis and does not result in disseminated systemic infection. The most common clinical manifestation of these viruses is warts (verrucae). There are more than 100 distinct HPV subtypes based on DNA testing. Some tend to infect specific body sites or types of epithelium. Some HPV types have a potential to cause malignant change but transformation is rare on keratinized skin.

SYNONYMS

Verrucae, verruca vulgaris, common warts.

EPIDEMIOLOGY

- Nongenital cutaneous warts are widespread worldwide and are more common in children, with a peak incidence in the teenage years and a sharp decline thereafter.¹
- They are most commonly caused by HPV types 1 to 5, 7, 27, 29.¹
- Common warts account for approximately 70% of nongenital cutaneous warts.²
- Common warts occur most commonly in children and young adults (**Figures 131-1** and **131-2**).³

ETIOLOGY AND PATHOPHYSIOLOGY

- Infection with HPV occurs by skin-to-skin contact. It starts with a break in the integrity of the epithelium caused by maceration or trauma that allows the virus to infect the basal layers.
- Warts may infect the skin on opposing digits causing "kissing warts" (**Figure 131-3**).
- Individuals with subclinical infection may serve as a reservoir for HPVs.

FIGURE 131-1 Common warts on the hands of an 11-year-old girl. These periungual warts are particularly difficult to eradicate. (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-2 Many common warts on the hand of a human immunodeficiency virus-negative young adult. (Courtesy of Richard P. Usatine, MD.)

- An incubation period following inoculation lasts for approximately 2 to 6 months.

RISK FACTORS¹

- Young age.
- Disruption to the normal epithelial barrier.
- More common among meat handlers.
- Atopic dermatitis.
- Nail biters more commonly have multiple periungual warts.
- Conditions that decrease cell-mediated immunity such as HIV (**Figure 131-4**) and immunosuppressant drugs (**Figure 131-5**).

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of warts is based upon clinical appearance. The wart will obscure normal skin markings.
- Common warts are well-demarcated, rough, hard papules with irregular papillary surface. They are usually asymptomatic unless located on a pressure point.
- Warts may form cylindrical or filiform projections (**Figure 131-6**).

TYPICAL DISTRIBUTION

- Common anatomic locations include the dorsum of the hand, between the fingers, flexor surfaces, and adjacent to the nails (periungual) (**Figures 131-1 and 131-2**).

LABORATORY TESTING

- HPV testing is not useful for this condition.⁴
- HIV testing may be useful if the warts are severe and there are risk factors present (**Figure 131-4**).

BIOPSY

- Paring the surface with a surgical blade may expose punctate hemorrhagic capillaries, or black dots, which are thrombosed capillaries. If the diagnosis is in doubt, a shave biopsy is indicated to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Seborrheic keratosis are usually more darkly pigmented, have a stuck-on appearance, and “horn cysts” may be visible on close examination. They also have a wide distribution on the body (see Chapter 158, Seborrheic Keratosis). Typical dermoscopic patterns include comedo-like openings and milium-like cysts (see Appendix C, Dermoscopy)
- Acrochordon (skin tags) are pedunculated flesh-colored papules that are more common in obese persons. They lack the surface roughness of common warts. Filiform warts also may be pedunculated, but typically have a characteristic filiform appearance (see Chapter 157, Skin Tag).

FIGURE 131-3 Warts may infect the skin on opposing digits causing “kissing warts.” (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-4 Large cluster of warts on the foot of a child in Africa suspected of being human immunodeficiency virus-positive. (Courtesy of Richard P. Usatine, MD.)

- Squamous cell carcinoma (SCC) should be considered when lesions have irregular growth, pigmentation, ulceration, or resist therapy, particularly in sun-exposed areas and in immunosuppressed patients (see Chapter 171, Squamous Cell Carcinoma). The patient in **Figure 131-7** had a wart that was not going away and a biopsy demonstrated SCC in situ with in an HPV-induced lesion.
- Amelanotic melanoma—Although rare, lesions that are treatment resistant or atypical should be monitored closely or biopsied to establish the diagnosis (see Chapter 172, Melanoma).
- Early warts may appear similar to actinic keratosis in sun-exposed areas (see Chapter 166, Actinic Keratosis and Bowen Disease)
- Advanced warts may appear similar to a keratoacanthoma to casual inspection. The characteristic findings of the keratoacanthoma and biopsy will separate the two conditions. (see Chapter 167, Keratoacanthoma)

MANAGEMENT

NONPHARMACOLOGIC

- Because spontaneous regression occurs in two-thirds of warts within 2 years, observation without treatment is always an option. In 17 trials, the average reported cure rate was 30% within 10 weeks.⁵ Observational studies show that one-half of cutaneous warts resolve spontaneously within 1 year, and about two-thirds within 2 years.⁶
- Treatment does not decrease transmissibility of the virus.⁷

MEDICATIONS

- Therapies for common warts do not specifically treat the HPV virus. They work by destruction of virus-containing skin while preserving uninvolved tissue. This usually exposes the blood and its immune cells to the virus, which may promote an immune response against the virus.
- The least-painful methods should be used first, especially in children. **SOR C**
- A Cochrane review found that there is a considerable lack of evidence on which to base the rational use of the local treatments for common warts.⁵ The trials are highly variable in method and quality. There is evidence that simple topical treatments containing salicylic acid have a therapeutic effect.⁵ **SOR A** There is less evidence for the efficacy of cryotherapy and no convincing evidence that it is any more effective than simple topical treatments.
- Seventeen percent salicylic acid is a useful first-line agent, especially for thick or multiple warts.⁵ **SOR A** It is safe in children. Combined results from 5 randomized controlled trials (RCTs) showed a 73% cure rate with 6 to 12 weeks of salicylic acid treatment, compared with a 48% cure rate with placebo (number needed to treat [NNT] = 4).⁵ A number of preparations are available without a prescription. Topical 17% salicylic acid is applied overnight and is now the most commonly used form for this type of wart. Soak the wart area with warm water for 5 minutes, then gently file down any thick skin with a pumice stone or emery board. The salicylic acid product should be applied to the wart. Repeat the first two steps daily with liquid or gel preparations, or

FIGURE 131-5 Biopsy-proven warts on the neck and chest of a woman on azathioprine after a renal transplantation. Human papillomaviruses lesions can proliferate as a result of immunosuppressive medications. This patient is also being monitored for squamous cell carcinoma, as this is a more significant risk in posttransplantation patients. (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-6 Filiform warts are identified by their multiple projections as opposed to a unified papule. This wart was on the face of an elderly woman and was removed by shave excision and sent for pathology. It was proven to be a wart and not squamous cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

every other day with the patch. Tape may be used to cover the wart after application of salicylic acid liquid. Repeat treatment until the wart has cleared, or for up to 12 weeks. Discontinue the treatment if severe redness or pain occurs in the treated area. Do not use salicylic acid on the face because of an increased risk of hypopigmentation.¹

- Forty percent salicylic acid plasters (Mediplast) are available over the counter for larger and thicker warts. The plasters are cut to fit and then applied a few millimeters beyond the wart for 48 hours. Then the patch is removed; the wart pared down with a nail file, pumice stone, or scalpel; and the process repeated as needed.
- Imiquimod 5% is an expensive topical immunomodulator that is indicated for treatment of anogenital warts but is also used on nongenital warts.⁸⁻¹⁰ **SOR B** It is nonscarring and painless, although local irritation is common. Debriding heavily keratinized warts may enhance penetration of the medication. The cream is applied in a thin layer to the lesions three times a week (every other night) and covered with an adhesive bandage or tape. The medication is removed with soap and water in the morning. It can also be used as adjunctive therapy. A lower concentration of imiquimod (3.75% cream) is also available, but data for common warts is lacking.
- Intralesional injections with *Candida* antigen induces a localized, cell-mediated, and HPV-specific response that may target the injected wart as well as more distant warts (**Figure 131-8**). This method has moderate effectiveness (60% cure rates) for treatment of recalcitrant warts in patients with a positive skin antigen pretest.¹ **SOR B** The *Candida* antigen must be diluted before used (see **Table 132-1**). Inject 0.1 to 0.3 mL into the largest warts using a 30-gauge needle and up to 1 mL per treatment. Warn the patient to expect itching in the area, burning, or peeling. Repeat every 4 weeks, up to 3 treatments or until warts are gone.
- Photodynamic therapy with aminolevulinic acid plus topical salicylic acid is a moderately effective option for treatment of recalcitrant warts.¹ **SOR B** Although it is likely to be beneficial, it is expensive and often requires referral.
- Cantharidin 0.7% is an extract of the blister beetle that is applied to the wart, after which blistering occurs on the following day. It may be used in resistant cases. It is also useful in young children because application is painless in the office. However, painful blisters often occur within a day after application. Be careful not to overtreat with cantharidin because the blistering can be quite severe. Carefully apply to multiple lesions using the wooden end of a cotton-tipped applicator (**Figure 131-9**). **SOR C**
- Contact immunotherapy using dinitrochlorobenzene, squaric acid dibutylester, and diphenylcyclopropanone may be applied to the skin to sensitize the patient and then to the lesion to induce an immune response. **SOR C**
- Intralesional injection with bleomycin can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.¹ **SOR B**
- Early open-label, uncontrolled studies indicate cimetidine might be useful in treating warts. However, three placebo-controlled, double-blind studies and two open-label comparative trials demonstrate that its efficacy is equal to placebo.¹¹ **SOR A**

FIGURE 131-7 Squamous cell carcinoma in situ that started from an human papillomavirus-positive lesion. When cryotherapy is not working on what appears to be a wart, consider performing a biopsy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-8 *Candida* antigen is being injected into a cluster of warts on the knee of a teenage boy. His warts did not respond to multiple therapies, including topical salicylic acid and cryotherapy. (Courtesy of Richard P. Usatine, MD.)

SURGICAL

- Cryotherapy, most commonly with liquid nitrogen, is useful but is somewhat painful for younger children.⁵ **SOR B** Chemical cryogenes are now available over the counter but are not as cold or effective as liquid nitrogen. Most trials comparing cryotherapy with salicylic acid found similar effectiveness, with overall cure rates of 50% to 70% after 3 or 4 treatments.¹ Aggressive cryotherapy (10 to 30 seconds) is more effective than less-aggressive cryotherapy, but may increase complications.¹ **SOR B** Anesthesia is usually unnecessary but may be achieved with 1% lidocaine or EMLA (eutectic mixture of local anesthetics) cream. Liquid nitrogen is applied for 10 to 20 seconds via a Cryogun or a cotton swab so that the freeze ball extends 2 mm beyond the lesion (**Figure 131-10**). Two freeze cycles may improve resolution, but it is better to underfreeze than overfreeze as overfreezing may lead to permanent scarring or hypopigmentation. Best results of cryotherapy can be achieved when the patient is treated every 2 or 3 weeks. There is no therapeutic benefit beyond 3 months.¹ **SOR B** Because HPV can survive in liquid nitrogen, cotton swabs and residual liquid nitrogen should be properly discarded to avoid spreading the virus to other patients or contaminating the liquid nitrogen reservoir.¹³ After cryotherapy, the skin shows erythema and may progress to hemorrhagic blistering. Healing occurs in approximately a week and hypopigmentation may occur. Ring warts may result from an inadequate margin of treatment of a common wart (**Figure 131-11**). Common adverse effects of cryotherapy include pain, blistering, and hypo- or hyperpigmentation. Cryotherapy must be used cautiously where nerves are located superficially (such as on the fingers) to prevent pain and neuropathy. Overfreezing in the periungual region can result in permanent nail dystrophy.
- Simple excision is used for small or filiform warts (**Figure 131-7**). The area is injected with lidocaine and the wart is excised with sharp scissors or a scalpel blade. **SOR C**
- Pulsed-dye laser can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.¹ **SOR B**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Although preliminary studies were promising, duct tape is of uncertain efficacy for wart treatment.¹ A randomized controlled trial in adults showed it to be no better than moleskin and both groups only had a 21% to 22% success rate.¹² **SOR B**

PREVENTION

- Tools used for paring down warts, such as nail files and pumice stones, should not be used on normal skin or by other people.
- Hair-bearing areas with warts should be shaved with depilatories, electric razors, or not at all to help limit spread of warts.

PROGNOSIS

- Sixty percent to 70% of cutaneous warts resolve in 3 to 24 months without treatment.^{14,15}

FIGURE 131-9 Cantharidin is being applied to periungual warts on the fingers of a 5-year-old child. Note the use of the wooden stick of a cotton-tipped applicator. If the cotton tip is used, the cantharidin stays within the cotton and the application is insufficient. (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-10 Cryotherapy showing an adequate free zone (halo) around the wart. (Courtesy of Richard P. Usatine, MD.)

FIGURE 131-11 Ring wart that resulted from inadequate cryotherapy of a common wart. (Courtesy of Richard P. Usatine, MD.)

- New warts may appear while others are regressing. This is not a treatment failure but part of the natural disease process with HPV.

FOLLOW-UP

- Schedule patients for return visits after treatment to limit loss of follow-up and to assess therapy.
- Follow-up visits can be left to the patient's discretion when self-applied therapy is being used.

PATIENT EDUCATION

- Therapy often takes weeks to months, so patience and perseverance are essential for successful therapy.

132 FLAT WARTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 16-year-old girl presents with multiple flat lesions on her forehead (**Figure 132-1**). It started with just a few lesions but has spread over the past 3 months. She is diagnosed with flat warts and topical imiquimod is prescribed as the initial treatment.

INTRODUCTION

Flat warts are characterized as flat or slightly elevated flesh-colored papules. They may be smooth or slightly hyperkeratotic. They range in size from 1 to 5 mm or more, and numbers range from a few to hundreds of lesions, which may become grouped or confluent. They occur most commonly on the face, hands, and shins. They may appear in a linear distribution as a result of scratching, shaving, or trauma (Koebner phenomenon) (**Figure 132-2**).

SYNONYMS

Plane warts, verruca plana, verruca plana juvenilis.

EPIDEMIOLOGY

- Flat warts (verruca plana) are most commonly found in children and young adults (**Figures 132-1 to 132-?**).
- Flat warts are the least common variety of wart, but are generally numerous on an individual.¹
- Flat warts are usually caused by human papillomavirus (HPV) types 3, 10, 28, and 29.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Like all warts, flat warts are caused by HPV.²
- Flat warts may spread in a linear pattern secondary to spread by scratching or trauma, such as shaving.
- Flat warts present a special treatment problem because they persist for a long time, they are generally located in cosmetically important areas, and they are resistant to therapy.

RISK FACTORS

- Shaving next to infected areas (**Figures 132-2 and 132-3**).
- HIV infection or other types of immunosuppression (**Figure 132-3**).

FIGURE 132-1 Flat warts on a patient's forehead. (Courtesy of Richard P. Usatine, MD.)

FIGURE 132-2 Flat warts just above the knee of a young woman. Probably spread by shaving. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

- Multiple small, flat-topped papules that may be pink, light brown, or light yellow colored. They may be polygonal in shape (**Figure 132-4**).

TYPICAL DISTRIBUTION

- Flat warts typically appear on the forehead (**Figure 132-1**), around the mouth (**Figure 132-5**), the backs of the hands, and shaved areas, such as the lower face and neck in men (**Figure 132-3**) and the lower legs in women (**Figure 132-2**).

LABORATORY TESTING

- HPV testing is not useful for this condition.³

BIOPSY

- Although usually not necessary, a shave biopsy can confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Lichen planus produces flat-topped papules that may be confused with flat warts. Look for characteristic signs of lichen planus such as the symmetric distribution, purplish coloration, and oral lacy lesions. (Wickham striae are white, fine, reticular scale seen on the lesions.) The distribution of lichen planus is different, with the most common sites being the ankles, wrists, and back (see Chapter 154, Lichen Planus).
- Seborrheic keratoses are often more darkly pigmented and have a stuck-on appearance; “horn cysts” may be visible on close examination (see Chapter 158, Seborrheic Keratosis).
- Squamous cell carcinoma should be considered when lesions have irregular growth or pigmentation, ulceration, or resist therapy, particularly in sun-exposed areas and in immunosuppressed patients (see Chapter 171, Squamous Cell Carcinoma).

MANAGEMENT

NONPHARMACOLOGIC

- Regression of these lesions may occur, which usually is heralded by inflammation.
- There are no current therapies for HPV that are virus specific.

MEDICATIONS

- Topical salicylic acid treatments by topical liquid or patch are the most effective treatment for all types of warts with a success rate average of 73% from five pooled placebo-controlled trials.⁴ Number needed to treat (NNT) = 4. **SOR A** Salicylic acid may be more acceptable on the legs than the face.² Often, 17% salicylic acid topicals are applied overnight daily until the warts resolve.

FIGURE 132-3 Flat warts on the neck of an HIV-positive man. The warts have been spread by shaving. Cryotherapy and imiquimod were not successful but intralesional Candida antigen injections cleared all the warts. (Courtesy of Richard P. Usatine, MD.)

FIGURE 132-4 Close-up of a flat wart. Note typical small, flat-topped papule. (Courtesy of Richard P. Usatine, MD.)

FIGURE 132-5 Flat warts on the upper lip and nose of a young girl. (Courtesy of Richard P. Usatine, MD.)

- Fluorouracil (Efudex 5% cream, Fluoroplex 1%) may be used to treat flat warts. Apply the cream to affected areas twice daily for 3 to 4 weeks. Sun protection is essential because the drug is photosensitizing. Persistent hypo- or hyperpigmentation may occur following use, but applying it with a cotton-tipped applicator to individual lesions instead of to the area may minimize this adverse reaction.^{5,6} **SOR B**
- Imiquimod 5% cream is an expensive topical immunomodulator that has shown some efficacy in treating flat warts.^{7,8} It is nonscarring and painless to apply. There are rare reports of systemic side effects. The cream is applied to the lesions 3 times a week (every other day). The cream may be applied to the affected area, not strictly to the lesion itself.⁹ It can be used on all external HPV-infected sites, but not on occluded mucous membranes. Therapy can be temporarily halted if symptoms become problematic. Imiquimod has the advantage of having almost no risk of scarring.^{7,8} **SOR B** A lower concentration of imiquimod (3.75% cream) is also available, but data for its use with flat or common warts is lacking.
- Tretinoin cream, 0.025%, 0.05%, or 0.1%, applied at bedtime over the entire involved area is one accepted treatment. The frequency of application is then adjusted so as to produce a mild, fine scaling and erythema. Sun protection is important. Treatment may be required for weeks or months and may not be effective. No published studies were found to support this treatment. **SOR C**
- Intralesional injections with *Candida* antigen induces a localized, cell-mediated, and HPV-specific response that may target the injected wart as well as more distant warts. This method has moderate effectiveness (60% cure rates) for treatment of recalcitrant warts (**Figure 132-3**).² The *Candida* antigen must be diluted before used (see **Table 132-1**). Inject 0.1 to 0.3 mL into the largest warts using a 30-gauge needle and up to 1 mL per treatment. Warn the patient to expect itching in the area, burning, or peeling. Repeat every 4 weeks, up to three treatments or until warts are gone.¹⁰ **SOR B**
- Photodynamic therapy with aminolevulinic acid plus topical salicylic acid is a moderately effective option for treatment of recalcitrant warts. Although it is likely to be beneficial, it is expensive and often requires dermatologic referral.² **SOR B**
- Cantharidin 0.7% is an extract of the blister beetle that is applied to the wart after which blistering occurs. It may be used in resistant cases.¹¹ It is also useful in young children because application is painless in the office. However, painful blisters often occur within a day after application. Be careful not to overtreat with cantharidin because the blistering can be quite severe. Carefully apply to multiple lesions using the wooden end of a cotton-tipped applicator. **SOR C**

SURGICAL

- Cryotherapy, most commonly with liquid nitrogen, is useful but is somewhat painful for younger children.⁶ **SOR B** Chemical cryogenics are now available over the counter but are not as cold or effective as liquid nitrogen. Most trials comparing cryotherapy with salicylic acid found similar effectiveness.² Liquid nitrogen is applied for 5 to 10 seconds via a Cryogun or a cotton swab so that the freeze ball extends 1 to 2 mm beyond the lesion. Because flat warts are thinner than common warts, the freeze times needed are shorter. Two freeze cycles may improve resolution, but it is better

TABLE 132-1 Candida Dilutions

Creating 1.0 mL for Injection	Candida Antigen (mL)	2% Lidocaine (no Epinephrine) (mL)
Generic 1:1000	0.25	0.75
Candin 1:500	0.5	0.5

Reprinted with permission from: Usatine R, Pfenninger J, Stulberg D, Small R. *Dermatologic and Cosmetic Procedures in Office Practice*. Elsevier, Inc., Philadelphia. 2012.

to underfreeze than overfreeze since overfreezing may lead to permanent scarring or hypopigmentation. Best results of cryotherapy can be achieved when the patient is treated every 2 or 3 weeks. There is no therapeutic benefit beyond 3 months.² **SOR B** Because HPV can survive in liquid nitrogen, cotton swabs and residual liquid nitrogen should be properly discarded to avoid spreading the virus to other patients or contaminating the liquid nitrogen reservoir.¹² After cryotherapy, the skin shows erythema and may progress to hemorrhagic blistering. Healing occurs in approximately a week and hypopigmentation may occur. Common adverse effects of cryotherapy include pain, blistering, and hypo- or hyperpigmentation.

- Pulsed-dye laser can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.² **SOR B**

PREVENTION

- Hair-bearing areas with warts should be shaved with depilatories, electric razors, or not at all to help limit spread of warts.

FOLLOW-UP

- Schedule patients for a return visit in 2 to 3 weeks after therapy to assess efficacy.

PATIENT EDUCATION

- To help avoid spreading warts, patients should avoid touching or scratching the lesions.
- Razors that are used in areas where warts are located should not be used on normal skin or by other people to prevent spread.

133 GENITAL WARTS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

An 18-year-old woman presents with a concern that she might have genital warts (**Figure 133-1**). She has never had a sexually transmitted disease (STD) but admits to two new sexual partners in the last 6 months. She has not been vaccinated against human papillomavirus (HPV). The patient is told that her concern is accurate and she has condyloma caused by HPV (an STD). The treatment options are discussed and she chooses to have cryotherapy with liquid nitrogen followed by imiquimod self-applied beginning 2 weeks after cryotherapy. A urine test for gonorrhea and *Chlamydia* is performed and the patient is sent to the lab to have blood tests for syphilis and HIV. Fortunately, all the additional tests are negative. Further patient education is performed and follow-up is arranged.

INTRODUCTION

More than 100 types of HPV exist, with more than 40 that can infect the human genital area. Most HPV infections are asymptomatic, unrecognized, or subclinical. Low-risk HPV types (e.g., HPV types 6 and 11) cause genital warts, although coinfection with HPV types associated with squamous intraepithelial neoplasia can occur. Asymptomatic genital HPV infection is common and usually self-limited.¹

SYNONYMS

Condyloma acuminata.

EPIDEMIOLOGY

- Anogenital warts are the most common viral STD in the United States. There are approximately 1 million new cases of genital warts per year in the United States.²
- Most infections are transient and cleared within 2 years.²
- Some infections persist and recur and cause much distress for the patients.

ETIOLOGY AND PATHOPHYSIOLOGY

- Genital warts are caused by HPV infection. HPV encompasses a family of primarily sexually transmitted double-stranded DNA viruses. The incubation period after exposure ranges from 3 weeks to 8 months.

FIGURE 133-1 Multiple vulvar exophytic condyloma in an 18-year-old woman. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS³

- Sexual intercourse and oral sex.
- Other types of sexual activity including digital–anal, oral–anal, and digital–vaginal contact.
- Immunosuppression, especially HIV (**Figure 133-2**).

DIAGNOSIS**CLINICAL FEATURES**

- Diagnosis of genital warts is usually clinical based on visual inspection.¹
- Genital warts are usually asymptomatic, and typically present as flesh-colored, exophytic lesions on the genitalia, including the penis, vulva, vagina, scrotum, perineum, and perianal skin.
- External warts can appear as small bumps, or they may be flat, verrucous, or pedunculated (**Figures 133-2 to 133-4**).
- Less commonly, warts can appear as reddish or brown, smooth, raised papules, or as dome-shaped lesions on keratinized skin.

TYPICAL DISTRIBUTION

- In women, the most common sites of infection are the vulva (85%) (**Figure 133-1**), perianal area (58%), and the vagina (42%) (**Figure 133-3**).
- In men, the most common sites of infection are the penis (**Figures 133-4 to 133-5**) and scrotum.
- Perianal warts (**Figure 133-6**) can occur in men or women who have a history of anal intercourse, and in those who do not have any such history (**Figure 133-7**).¹
- Condyloma acuminata may be seen on the abdomen or upper thighs in conjunction with genital warts (**Figure 133-8**).
- Condyloma caused by HPV can be seen in obese individuals within the folds of the pannus (**Figure 133-9**).
- An RPR or VDRL should be ordered to screen for syphilis and a HIV test should be ordered as well. Genital warts are a sexually transmitted disease and patients who have one STD should be screened for others.

LABORATORY TESTING

- HPV viral typing is not recommended because test results would not alter clinical management of the condition. The application of 3% to 5% acetic acid to detect mucosal changes attributed to HPV infection is not recommended.¹

BIOPSY

- Diagnosis may be confirmed by shave or punch biopsy if necessary.¹ Biopsy is indicated if:
 - The diagnosis is uncertain.
 - The patient has a poor response to appropriate therapy.
 - Warts are atypical in appearance (unusually pigmented, indurated, fixed, or ulcerated).
 - The patient has compromised immunity and squamous cell carcinoma is suspected (one type of HPV-related malignancy).

FIGURE 133-6 Perianal warts in a gay man with history of anal-receptive intercourse. These lesions responded to cryotherapy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 133-5 Smooth-topped condyloma on the well-keratinized skin of a circumcised man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 133-7 Extensive perianal warts in a 17-year-old boy who denies sexual abuse and anal intercourse. Patient failed imiquimod therapy and was referred to surgery. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Pearly penile papules, which are small papules around the edge of the glans penis (**Figure 133-10**).
- Common skin lesions, such as seborrheic keratoses and nevi—These are rare in the genital area (**Figure 133-11**) (see Chapters 158, Seborrheic Keratosis and 162, Nevus).
- Giant condyloma or Buschke-Lowenstein tumor is a low-grade, locally invasive malignancy that can appear as a fungating condyloma (**Figure 133-12**). Persons with HIV/AIDS have a higher risk of giant condyloma and malignant transformation (**Figure 133-13**).
- Molluscum contagiosum—Waxy umbilicated papules around the genitals and lower abdomen (see Chapter 130, Molluscum Contagiosum).
- Malignant neoplasms, such as basal cell carcinoma and squamous cell carcinomas (see Chapters 170, Basal Cell Carcinoma and 171, Squamous Cell Carcinoma).
- Condyloma lata is caused by secondary syphilis infection; lesions appear flat and velvety (see Chapter 216, Syphilis). A full work-up for other STDs, including syphilis, should be done for any patient with genital warts (**Figure 133-14**).
- Micropapillomatosis of the vulva is a normal variant and appears as distinct individual papillary projections from the labia in a symmetrical pattern.

MANAGEMENT

- The primary reason for treating genital warts is the amelioration of symptoms and ultimately removal of the warts.¹
- The choice of therapy is based on the number, size, site, and morphology of lesions, as well as patient preference, treatment cost, convenience, adverse effects, and physician experience.
- Although available therapies for genital warts are likely to reduce HPV infectivity, they probably do not eradicate transmission.¹

MEDICATIONS AND SURGICAL METHODS

- Treatments for external genital warts include topical medications, cryotherapy (**Figure 133-15**), and surgical methods, and are shown in **Table 133-1**.
- Cryotherapy is best applied with a bent-tipped spray applicator that allows for precise application with a less painful attenuated flow (**Figure 133-15**).⁸ Application may be repeated every 2 weeks if necessary.
- Treatment with 5% fluorouracil cream (Efudex) is no longer recommended because of severe local side effects and teratogenicity.¹

REFERRAL OR HOSPITALIZATION

- Consider consultation for patients with very large or recalcitrant lesions.

PREVENTION

- A bivalent vaccine (Cervarix) containing HPV types 16 and 18 and a quadrivalent vaccine (Gardasil) vaccine containing HPV types 6, 11, 16, and 18 are licensed in the United States. The quadrivalent

FIGURE 133-8 Condyloma that started on the penis and spread up the abdomen and on to the thighs. Note how these warts are hyperpigmented in this Latino man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 133-9 Panus condyloma from HPV growing between the folds of heavy adipose tissue in this obese woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 133-13 Giant condylomata acuminata in a man with AIDS. (Courtesy of Jack Resneck, Sr., MD.)

FIGURE 133-11 Two large condylomas that resemble seborrheic keratoses. Shave biopsy was positive for HPV. (Courtesy of Richard P. Usatine, MD.)

FIGURE 133-12 Buschke-Lowenstein tumor (giant condylomata acuminata) at the base of the penis. This was treated with surgical resection. The margins were clear and there was no squamous cell carcinoma found. (Courtesy of Suraj Reddy, MD.)

FIGURE 133-14 This 22-year-old IV heroine addict presented with many condyloma in the anogenital region. An RPR was positive for syphilis. The patient was treated with penicillin as well as cryotherapy. The visible condyloma in this image are most likely HPV and not condyloma lata based on their verrucous morphology. (Courtesy of Richard P. Usatine, MD.)

TABLE 133-1 Treatments for External Genital Warts

Treatment	Possible Adverse Effects	Clearance (%)	Recurrence (%)
Patient-Applied Therapy			
Imiquimod (Aldara) is applied at bedtime for 3 days, then rest 4 days; alternatively, apply every other day for 3 applications; may repeat weekly cycles for up to 16 weeks ⁵ SOR A	Erythema, irritation, ulceration, pain, and pigmentary changes; minimal systemic absorption	30 to 50	15
Sinecatechins 15% ointment—Apply a 0.5-cm strand of ointment to each wart 3 times daily ⁶ SOR A	Erythema, pruritus/burning, pain, ulceration, edema, induration, and vesicular rash	53 to 57	3.7
Podofilox (Condylox) is applied twice daily for 3 days, then rest 4 days; may repeat for 4 cycles ⁷ SOR A	Burning, pain, inflammation; low risk for systemic toxicity unless applied to occluded membranes	45 to 80	5 to 30
Provider-Applied Therapy			
Cryotherapy performed with liquid nitrogen or a cryoprobe ⁶ SOR B	Pain or blisters at application site, scarring	60 to 90	20 to 40
Podophyllin resin is applied to each wart and allowed to dry, and is repeated weekly as needed ^{6,7} SOR A	Local irritation, erythema, burning, and soreness at application site; neurotoxic and oncogenic if absorbed	30 to 80	20 to 65
Surgical treatment for warts involves removal to the dermal–epidermal junction; options include scissor excision, shave excision, laser vaporization, and loop electrosurgical excision procedure (LEEP) excision ⁶ SOR B	Pain, bleeding, scarring; risk for burning and allergic reaction from local anesthetic; laser and LEEP have risk for spreading HPV in plume	35 to 70	5 to 50
Trichloroacetic acid (TCA) and bichloroacetic acid (BCA) are applied to each wart and allowed to dry; repeated weekly ⁶ SOR B	Local pain and irritation; no systemic side effects	50 to 80	35

HPV vaccine protects against the HPV types that cause 90% of genital warts (i.e., types 6 and 11) in males and females when given prophylactically. Both vaccines offer protection against the HPV types that cause 70% of cervical cancers (i.e., types 16 and 18). In the United States, the quadrivalent (Gardasil) HPV vaccine can also be used in males and females ages 9 to 26 years to prevent genital warts.⁴

PROGNOSIS

- Many genital warts will eventually resolve without treatment. Resolution can usually be hastened with therapy (see **Table 133-1**).

FOLLOW-UP

- Patients should be offered a follow-up evaluation 2 to 3 months after treatment to check for new lesions.¹ **SOR C**

PATIENT EDUCATION

- HPV is transmitted mainly by skin-to-skin contact. Although condoms may decrease the levels of transmission, they are imperfect

barriers at best as they can fail, and they do not cover the scrotum or vulva, where infection may reside.

134 PLANTAR WARTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 15-year-old boy presents with painful growths on his right heel for approximately 6 months (**Figure 134-1**). It is painful to walk on and he would like it treated. He was diagnosed with multiple large plantar warts called *mosaic warts*. The lesions were treated with gentle paring with a #15 blade scalpel and liquid nitrogen therapy over a number of sessions. He and his mom were instructed on how to use salicylic acid plasters on the remaining warts.

INTRODUCTION

Plantar warts (*verruca plantaris*) are human papilloma virus (HPV) lesions that occur on the soles of the feet (**Figures 134-1 to 134-5**) and palms of the hands (**Figure 134-6**).

SYNONYMS

Palmoplantar warts, myrmecia.

EPIDEMIOLOGY

- Plantar warts affect mostly adolescents and young adults, affecting up to 10% of people in these age groups.¹
- Prevalence studies demonstrate a wide range of values, from 0.84% in the United States² to 3.3% to 4.7% in the United Kingdom,³ to 24% in 16- to 18-year-olds in Australia.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Plantar warts are caused by HPV.
- They usually occur at points of maximum pressure, such as on the heels (**Figures 134-1 to 134-4**) or over the heads of the metatarsal bones (**Figure 134-5**), but may appear anywhere on the plantar surface including the tips of the fingers (**Figure 134-7**).
- A thick, painful callus forms in response to the pressure that is induced as the size of the lesion increases. Even a minor wart can cause a lot of pain.
- A cluster of many warts that appear to fuse is referred to as a *mosaic wart* (**Figures 134-1 and 134-4**).

RISK FACTORS

- Young age.
- Decreased immunity.

FIGURE 134-1 Plantar warts. Note small black dots in the warts that represent thrombosed vessels. Large plantar warts such as these are called *mosaic warts*. (Courtesy of Richard P. Usatine, MD.)

FIGURE 134-2 Close-up of plantar wart on the side of the heel. Note the disruption of skin lines and black dots. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

Plantar warts present as thick, painful endophytic plaques located on the soles and/or palms. Warts have the following features:

- Begin as small shiny papules.
- Lack skin lines crossing their surface (**Figure 134-3**).
- Have a highly organized mosaic pattern on the surface when examined with a hand lens.
- Have a rough keratotic surface surrounded by a smooth collar of callused skin
- Painful when compressed laterally.
- May have centrally located black dots (thrombosed vessels) that may bleed with paring (**Figures 134-1 to 134-7**).

TYPICAL DISTRIBUTION

- They occur on the palms of the hands and soles of the feet. They are more commonly found on weight-bearing areas, such as under the metatarsal heads or on the heel.⁵

BIOPSY

- If the diagnosis is doubtful, a shave biopsy is indicated to confirm the diagnosis.⁶

DIFFERENTIAL DIAGNOSIS

- Corns and calluses are pressure-induced skin thickenings that occur on the feet and can be mistaken for plantar warts. Calluses are generally found on the sole and corns are usually found on the toes. Calluses and corns have skin lines crossing the surface, and are painless with lateral pressure (see Chapter 207, Corn and Callus).
- Black heel presents as a cluster of blue-black dots that result from ruptured capillaries. They appear on the plantar surface of the heel following the shearing trauma of sports that involve sudden stops or position changes. Examination reveals normal skin lines, and paring does not cause additional bleeding. The condition resolves spontaneously in a few weeks.
- Black warts are plantar warts undergoing spontaneous resolution, which may turn black and feel soft when pared with a blade.⁷
- Squamous cell carcinoma should be considered when lesions have irregular growth or pigmentation, ulceration, or resist therapy, particularly in immunosuppressed patients (see Chapter 171, Squamous Cell Carcinoma).
- Amelanotic melanoma, although extremely rare, can look similar to HPV lesions. Lesions that are treatment resistant or atypical, particularly on the palms or soles, should be monitored closely. A biopsy is required to establish the diagnosis (see Chapter 172, Melanoma).
- Palmoplantar keratoderma describes a rare heterogeneous group of disorders characterized by thickening of the palms and the soles that can also be an associated feature of different syndromes. They can be classified as having uniform involvement versus

FIGURE 134-3 Close-up of a plantar wart demonstrating disruption of normal skin lines. Corns and callus do not disrupt normal skin lines. The black dots are thrombosed vessels, which are frequently seen in plantar warts. (Courtesy of Richard P. Usatine, MD.)

FIGURE 134-4 A mosaic wart is formed when several plantar warts become confluent. (Courtesy of Richard P. Usatine, MD.)

FIGURE 134-5 Multiple plantar warts on the ball of the foot and toes. The thrombosed vessels within the warts appear as black dots. (Courtesy of Richard P. Usatine, MD.)

focal hyperkeratosis located mainly on pressure points and sites of recurrent friction (**Figure 134-8**). This latter type can be differentiated from plantar warts by the more diffuse locations on the pal-moplantar surfaces, the mainly epidermal involvement, and biopsy, if necessary (**Figure 134-9**).

MANAGEMENT

NONPHARMACOLOGIC

- Painless plantar warts do not require therapy. Minimal discomfort can be relieved by periodically removing the hyperkeratosis with a blade or pumice stone.
- Painful warts should be treated using a technique that causes minimal scarring as scars on the soles of the feet are usually permanent and painful.
- Patients with diabetes must be treated with the utmost care to minimize complications.

MEDICATIONS

- Topical salicylic acid solutions are available in nonprescription form and provide conservative keratolytic therapy. These preparations are nonscarring, minimally painful, and relatively effective, but require persistent application of medication once each day for weeks to months. The wart is first pared with a blade, pumice stone, or emery board, and the area soaked in warm water. The solution is then applied, allowed to dry, reapplied, and occluded with adhesive tape.⁸ White, pliable, keratin forms and should be pared away carefully until pink skin is exposed.⁹ **SOR B**
- Seventeen percent to 50% salicylic acid solution and plasters are available in nonprescription and prescription forms. However, the 17% solutions are more prevalent and easier to find in nonprescription form. The treatment is similar to the previous process, except that with plasters the salicylic acid has been incorporated into a pad. They are particularly useful in treating mosaic warts covering a large area. Pain is quickly relieved in plantar warts, because a large amount of keratin is removed during the first few days of treatment.⁹ **SOR B** A recent multicenter, open-label, randomized, controlled trial found that 50% salicylic acid and the cryotherapy were equally effective for clearance of plantar warts.¹⁰ **SOR A**
- Acid chemotherapy with trichloroacetic acid (TCA) or bichloroacetic acid (BCA) is commonly employed to treat plantar warts in the office. They are considered safe during pregnancy for external lesions. The excess keratin is first pared with a scalpel, then the entire lesion is coated with acid, and the acid is worked into the wart with a sharp toothpick. The process is repeated every 7 to 10 days. **SOR C**
- Cryotherapy with liquid nitrogen therapy is commonly used, but plantar warts are more resistant than other HPV lesions. The liquid nitrogen is applied to form a freeze ball that covers the lesion and 2 mm of surrounding normal tissue, usually 10 to 20 seconds per freeze. **SOR C** There is no evidence that two freezing episodes are better than one, other than it allows for more freeze time in a way that is more acceptable to the patient. It is always better to under-freeze than to overfreeze in areas where scarring can produce permanent disability.

FIGURE 134-6 Multiple plantar warts on the palms of an HIV-positive man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 134-7 Close up of plantar wart on a finger that also shows disruption of skin lines and black dots. (Courtesy of Richard P. Usatine, MD.)

- Treatments for resistant lesions are often carried out in referral practices that have a high enough volume to use more expensive or specialized therapy. Cantharidin is an extract of the blister beetle that is applied to the wart after which blistering occurs. Intralesional immunotherapy with skin-test antigens (i.e., mumps, *Candida*, or *Trichophyton* antigens) may lead to the resolution both of the injected wart and other warts that were not injected. Contact immunotherapy using dinitrochlorobenzene, squaric acid dibutylester, and diphenylcyclopropenone may be applied to the skin to sensitize the patient and then to the lesion to induce an immune response. Intralesional bleomycin or laser therapy are also useful for recalcitrant warts. **SOR C**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Although many complementary and alternative therapies are promoted for wart therapy, there is no significant data supporting their use in the treatment of plantar warts.

PREVENTION

- Tools used for paring down warts, such as nail files and pumice stones, should not be used on normal skin or by other people.

PROGNOSIS

Most plantar warts will spontaneously disappear without treatment. Treatment often hastens resolution of lesions.

FOLLOW-UP

- Regular follow-up to assess treatment efficacy, adverse reactions, and patient tolerance are recommended to minimize treatment dropouts.

PATIENT EDUCATION

- Because spontaneous regression occurs, observation of painless lesions without treatment is preferable.
- Therapy often takes weeks to months, so patience and perseverance are essential for successful therapy.

SECTION 5 FUNGAL

135 FUNGAL OVERVIEW

Richard P. Usatine, MD

PATIENT STORY

A 55-year-old woman presents with a red pruritic area on her face for 3 months (**Figure 135-1**). The annular distribution immediately is suspicious for a dermatophyte infection. Further investigation demonstrates that the patient has severe tinea pedis in a moccasin distribution. The patient is treated with an oral antifungal agent and her fungal infection clears over the coming month.

INTRODUCTION

Fungal infections of the skin and mucous membranes are ubiquitous and common. There are many types of fungus that grow on humans but they all share a predilection for warm and moist areas. Consequently, hot and humid climates promote fungal infections, but many areas of the skin can get warm and sweaty even in cold climates, such as the feet and groin.

SYNONYMS

Pityriasis versicolor equals tinea versicolor.

PATHOPHYSIOLOGY

Mucocutaneous fungal infections are caused by:

- Dermatophytes in three genera: *Microsporum*, *Epidermophyton*, and *Trichophyton*. There are approximately 40 species in the three genera and these fungi cause tinea pedis and manus, tinea capitis, tinea corporis, tinea cruris, tinea faciei, and onychomycosis (**Figures 135-1** to **135-6**).
- Yeasts in the genera of *Candida* and *Pityrosporum* (*Malassezia*)—There are also multiple types of species and the *Pityrosporum* that cause seborrhea and tinea versicolor (**Figures 135-7** and **135-8**). Although tinea versicolor has the name tinea in it, it is not a true dermatophyte and may be best called pityriasis versicolor.

DIAGNOSIS

CLINICAL FEATURES OF TINEA INFECTIONS

Scaling, erythema, pruritus, central clearing, concentric rings, and maceration (**Table 135-1**). Changes in pigmentation are not uncommon in various types of tinea especially tinea versicolor.

FIGURE 135-1 Tinea faciei on the face of a 55-year-old woman with typical scaling and ringlike pattern (ringworm). Note the well-demarcated raised border and central clearing. (Courtesy of Richard P. Usatine, MD.)

FIGURE 135-2 Annular pruritic lesion with concentric rings in the axilla of a young woman caused by tinea corporis. The concentric rings have a high specificity for tinea infections. (Courtesy of Richard P. Usatine, MD.)

- **Figure 135-1** shows tinea faciei on the face with typical scaling and ring-like pattern, hence, the name ringworm. There is also erythema and central clearing. The patient was experiencing pruritus.
- **Figure 135-2** shows annular pruritic lesion with concentric rings in the axilla of a young woman caused by tinea corporis. The concentric rings have a high specificity (80%) for tinea infections.
- Note that tinea infections will not show central clearing in 58% of cases, as in **Figure 135-3** in which tinea cruris has no central clearing.
- Post-inflammatory hyperpigmentation is common in skin of color, as seen in **Figure 135-4**. Note the hyperpigmentation is seen within the area affected by the tinea corporis.
- Hypopigmentation is frequently seen in tinea versicolor (**Figure 135-8**).

TYPICAL DISTRIBUTION

Literally found from head to toes:

- **Figure 135-5** shows tinea capitis in a 5-year-old black girl with hair loss and an inflammatory response. Her kerion is healing after initiating oral griseofulvin.
- The two-foot, one-hand syndrome is a curious phenomenon with tinea manus of one hand and tinea pedis of both feet (**Figure 135-6**). It is not clear why only one hand is involved in these cases. In this case, it was the nondominant hand.

LABORATORY STUDIES

Creating a KOH Prep:

- Scrape the leading edge of the lesion on to a slide using the side of a #15 scalpel or another microscope slide (**Figure 135-9**).
- Use your coverslip to push the scale into the center of the slide.
- Add two drops of KOH (or fungal stain) to the slide and place coverslip on top.
- Gently heat with flame from an alcohol lamp or lighter if you are using plain KOH without dimethyl sulfoxide (DMSO). Avoid boiling.
- DMSO acts as a surfactant that helps to break up the cell membranes of the epithelial cells without heating. Fungal stains that come with KOH and a surfactant in the solution are very simple to use. These inexpensive stains come conveniently in small plastic squeeze bottles that have a shelf life of 1 to 3 years. Two useful stains that can make it easier to identify fungus are chlorazol and Swartz-Lamkins stains. Swartz-Lamkins stain has a longer shelf life and is my preferred stain.
- Examine with microscope starting with 10 power to look for the cells and hyphae and then switch to 40 power to confirm your findings (**Figures 135-10 to 135-13**). The fungal stain helps the hyphae to stand out among the epithelial cells.
- It helps to start with 10 power to find the clumps of cells and look for groups of cells that appear to have fungal elements within them (**Figure 135-10**).
- Do not be fooled by cell borders that look linear and branching. True fungal morphology at 40 power should confirm that you are looking at real fungus and not artifact. The fungal stains bring out

FIGURE 135-3 Tinea cruris with well-demarcated raised border and no central clearing. (Courtesy of Richard P. Usatine, MD.)

these characteristics including cell walls, nuclei, and Arthroconidia (Figures 135-11 to 135-13).

- KOH test characteristics¹ (without fungal stains)—Sensitivity 77% to 88%, specificity 62% to 95% (Table 135-2). The sensitivity and specificity should be higher with fungal stains and the experience of the person performing the test.

OTHER LABORATORY STUDIES

- Fungal culture—Send skin scrapings, hair, or nail clippings to the laboratory in a sterile container such as a urine cup. These will be plated out on fungal agar and the laboratory can report the species if positive.
- Biopsy specimens can be sent in formalin for periodic acid-Schiff (PAS) staining when KOH and fungal cultures seem to be falsely negative.
- UV light (Woods lamp), looking for fluorescence. The *Microsporum* species are most likely to fluoresce. However, the majority of tinea infections are caused by *Trichophyton* species that do not fluoresce.

MANAGEMENT

There is a wide variety of topical antifungal medications (Table 135-3). A Cochrane systematic review of 70 trials of topical antifungals for tinea pedis showed good evidence for efficacy compared to placebo² for:

- Allylamines (naftifine, terbinafine, butenafine).
- Azoles (clotrimazole, miconazole, econazole).
- Allylamines cure slightly more infections than azoles but are more expensive.²
- No differences in efficacy found between individual topical allylamines or individual azoles.² **SOR A**

Evidence for the management onychomycosis by topical treatments is sparse. There is some evidence that ciclopiroxolamine and

FIGURE 135-12 Arthroconidia visible from tinea cruris using Swartz-Lamkins fungal stain at 40 power. (Courtesy of Richard P. Usatine, MD.)

FIGURE 135-13 *Trichophyton rubrum* from tinea cruris using chlorazol black fungal stain at 40 power. (Courtesy of Richard P. Usatine, MD.)

TABLE 135-2 Diagnostic Value of Clinical Diagnosis and KOH Prep in Tinea Infection

Test	Sensitivity (%)	Specificity (%)	PV+ (%)	PV- (%)	LR+	LR-
Clinical diagnosis*	81	45	24	92	1.47	0.42
KOH prep (study one) [†]	88	95	73	98	17.6	0.13
KOH prep (study two) [†]	77	62	59	79	2.02	0.37

*The clinical diagnosis set was compiled by 27 general practitioners prior to submission of skin for fungal culture. Specimens were taken from consecutive patients with erythrosquamous lesions. Culture results were considered the gold standard; study quality = 2b.

[†]Both studies of KOH preps were open analyses of patients with suspicious lesions. Paired fungal culture was initiated simultaneously with KOH prep and was considered the gold standard; study quality = 2b.

LR-, Negative likelihood ratio; LR+, positive likelihood ratio; PV-, negative predictive value; PV+, positive predictive value.

TABLE 135-3 Topical Antifungal Preparations

Generic Name	Brand Name	OTC or R _x	Class
Butenafine	Mentax	R _x	Allylamine
	Lotrimin Ultra	OTC	
Ciclopirox	Loprox	R _x	Pyridone
Clotrimazole	Lotrimin AF Cream	OTC	Azole
	Lotrimin AF Spray		
Econazole	Spectazole	R _x	Azole
Ketoconazole	Nizoral	2% R _x	Azole
Miconazole	Micatin	OTC	Azole
	Generic		
Naftifine	Naftin	R _x	Allylamine
Oxiconazole	Oxistat	R _x	Azole
Sertaconazole	Ertaczo	R _x	Azole
Terbinafine	Lamisil AT	OTC	Allylamine
Tolnaftate*	Tinactin cream	OTC	Miscellaneous
	Lamisil AF defense and Tinactin powder spray		
	Generic cream		

*All the above antifungals will treat dermatophytes and *Candida*. Tolnaftate is effective only for dermatophytes and not *Candida*. Nystatin is effective only for *Candida* and not the dermatophytes. OTC, over-the-counter.

butenafine are both effective, but they both need to be applied daily for at least 1 year.³

Oral antifungals are needed for all tinea capitis infections and for more severe infections of the rest of the body.⁴ True dermatophyte infections that do not respond to topical antifungals may need an oral agent.

- A Cochrane systematic review of 12 trials of oral antifungals for tinea pedis showed oral terbinafine for 2 weeks cures 52% more patients than oral griseofulvin.⁵ **SOR A**

- Terbinafine is equal to itraconazole in patient outcomes.⁵
- No significant differences in comparisons between a number of other oral agents.⁵

Oral antifungals used for fungal infections of the skin, nails, or mucous membranes:

- Itraconazole (Sporanox).
- Fluconazole (Diflucan).
- Griseofulvin.
- Ketoconazole (Nizoral).
- Terbinafine (Lamisil).

One metaanalysis suggests that terbinafine is more efficacious than griseofulvin in treating tinea capitis caused by *Trichophyton* species, whereas griseofulvin is more efficacious than terbinafine in treating tinea capitis caused by *Microsporum* species.⁶ **SOR A**

136 CANDIDIASIS

Richard P. Usatine, MD

PATIENT STORY

The 42-year-old man (**Figure 136-1**) was admitted to the hospital for community-acquired pneumonia and type 2 diabetes out of control. On the second day of admission, when he was feeling a bit better, he asked about the itching he was having on his penis. Physical examination revealed an uncircumcised penis with white discharge on the glans and inside the foreskin consistent with *Candida* balanitis. KOH prep was positive for the pseudohyphae of *Candida*. The patient was treated with a topical azole and the balanitis resolved.

INTRODUCTION

Cutaneous and mucosal *Candida* infections are seen commonly in persons with obesity, diabetes, hyperhidrosis, and/or immunodeficiency.

SYNONYMS

Perlèche = angular cheilitis.

EPIDEMIOLOGY

Candida thrush is common in normal infants and in adults may be a sign of immunosuppression (**Figure 136-2**).

Candida balanitis is more common in uncircumcised men than in those that have been circumcised (**Figure 136-1**).

ETIOLOGY AND PATHOPHYSIOLOGY

- Infections caused by *Candida* species are primarily *Candida albicans*.¹
- *C. albicans* has the ability to exist in both hyphal and yeast forms (termed *dimorphism*). If pinched cells do not separate, a chain of cells is produced and is termed *pseudohyphae*.¹

RISK FACTORS

Obesity, diabetes, hyperhidrosis, immunodeficiency, HIV, heat, use of oral antibiotics, and use of inhaled or systemic steroids.¹

DIAGNOSIS

CLINICAL FEATURES

- Typical distribution—Groin, glans penis, vulva, inframammary, under abdominal pannus, between fingers, in the creases of the neck, corners of mouth, nailfolds in chronic paronychia.

FIGURE 136-1 *Candida* balanitis in a man with uncontrolled diabetes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-2 Thrush in an otherwise healthy infant. (Courtesy of Richard P. Usatine, MD.)

- Morphology—Macules, patches, plaques that are pink to bright red with small peripheral satellite lesions.
- Candidiasis of the nipple in the nursing mother is associated with infantile thrush (**Figures 136-2 and 136-3**). Nipple candidiasis is almost always bilateral, with the nipples appearing bright red and inflamed. In this case, the inflammation was made worse by the application of a topical antibiotic that caused a secondary contact dermatitis.
- The *Candida* infection in the corners of the mouth are called perlèche or angular cheilitis (**Figure 136-4**). When accompanied by thrush it may be a sign of HIV/AIDS.
- Thrush can be caused by *Candida* growing on the upper plate of a denture and the roof of the mouth (**Figure 136-5**).
- Ask about recent antibiotic use if there is a new onset of a rash with satellite lesions. In **Figure 136-6**, the man with diabetes had a course of antibiotics before he developed a *Candida* infection in his groin.

LABORATORY STUDIES

Scrape involved area and add to a slide with KOH (DMSO optional). *C. albicans* exist in both hyphal and yeast forms (dimorphism). Look for pseudohyphae and/or budding yeast (**Figure 136-7**).

DIFFERENTIAL DIAGNOSIS

- Intertrigo is a nonspecific inflammatory condition of the skin folds. It is induced or aggravated by heat, moisture, maceration, and friction. The condition frequently is worsened by infection with *Candida* or dermatophytes (**Figures 136-8 and 136-9**). In **Figure 136-8** there is significant hyperpigmentation secondary to the inflammation.
- Tinea corporis or cruris—Can be distinguished from *Candida* when you see an annular pattern or concentric circles in the tinea (**Figure 136-9**). There is no scrotal involvement in tinea cruris. *Candida* intertrigo may have scrotal involvement (see Chapters 138, Tinea Corporis and 139, Tinea Cruris).
- Erythrasma—May be brown and glows a coral red with UV light (see Chapter 119, Erythrasma).
- Inverse psoriasis—Psoriasis in the intertriginous areas as seen in **Figure 136-10** (see Chapter 152, Psoriasis).
- Seborrhea—Inflammation related to overgrowth of *Pityrosporum*, a yeast-like organism (see Chapter 151, Seborrheic Dermatitis).

MANAGEMENT

PRIMARY CANDIDAL SKIN INFECTIONS

- Topical azoles, including clotrimazole, miconazole, and nystatin (polyenes), are effective.³ **SOR B**
- Keeping the infected area dry is important.² **SOR C**
- For more details of the topical antifungals, see Table 135-3 in Chapter 135, Fungal Overview.

FIGURE 136-3 *Candida* rash with superimposed contact dermatitis in a breastfeeding woman. Her baby has thrush and both need treatment to eradicate the infection. The contact dermatitis was to the neomycin-containing topical antibiotic she applied to her sore breasts. (Courtesy of Jack Resneck, Sr., MD.)

FIGURE 136-4 Thrush and perlèche in a man with AIDS. The *Candida* infection in the corners of the mouth are called perlèche or angular cheilitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-5 *Candida* on the roof of the mouth in an elderly woman using dentures. This is a common complication of denture use and should be suspected if a patient presents with new onset pain under the dentures. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-7 The branching pseudohyphae and budding yeast of *Candida* under high power. **A.** *Candida* from thrush. **B.** *Candida* from vaginitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-6 *Candida* inguinal eruption in a 61-year-old man after a course of antibiotics for bronchitis. Note the satellite lesions. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-8 *Candida* under the breasts of an overweight Hispanic woman showing hyperpigmentation. The border is not well-demarcated and there are satellite lesions. (Courtesy of Richard P. Usatine, MD.)

- In one study, miconazole ointment was well tolerated and significantly more effective than the zinc oxide/petrolatum vehicle control for treatment of diaper dermatitis complicated by candidiasis.³
- Do not use tolnaftate, which is active against dermatophytes but not *Candida*.
- If recurrent or recalcitrant, consider fluconazole 150 mg qwk × 2 or ketoconazole 200 mg qd for 1 to 2 weeks.

OROPHARYNGEAL CANDIDIASIS

- Treat initial episodes with clotrimazole troches (one 10-mg troche 5 times per day for adults) or nystatin (available as a suspension of 100,000 U/mL [dosage, 4 to 6 mL qid] or as flavored 200,000 U pastilles [dosage, 1 or 2 pastilles 4 to 5 times per day for 7 to 14 days]).² **SOR B**
- Oral fluconazole (100 mg/day for 7 to 14 days) is as effective as—and, in some studies, superior to—topical therapy.² **SOR A**
- Itraconazole solution (200 mg/day for 7 to 14 days) is as effective as fluconazole.² **SOR A**
- Ketoconazole and itraconazole capsules are less effective than fluconazole, because of variable absorption.² **SOR A**
- Fluconazole-refractory oropharyngeal candidiasis will respond to oral itraconazole therapy (>200 mg/day, preferably in solution form) approximately two thirds of the time.² **SOR A**
- Children with thrush are usually treated with oral nystatin suspension.² **SOR B**
- HIV/AIDS patients with oral candidiasis may be treated with clotrimazole troches. If unresponsive to topical therapy, fluconazole may be needed.² **SOR A**
- Denture-related disease may require extensive and aggressive disinfection of the denture for definitive cure.² **SOR C**

MAMMARY CANDIDIASIS IN BREASTFEEDING

- Most mammary candidiasis does not present with the red breasts seen in **Figure 136-3**.
- Nipple pain and discomfort along with thrush are adequate data to treat the mother and child.
- Topical nystatin and oral fluconazole are safe for infants and the mother.²

CHRONIC MUCOCUTANEOUS CANDIDIASIS

- Chronic mucocutaneous candidiasis (**Figure 136-11**) requires a long-term approach that is analogous to that used in patients with AIDS.²
- Systemic therapy is needed, and azole antifungal agents (ketoconazole, fluconazole, and itraconazole) have been used successfully.²
- As with HIV-infected patients, development of resistance to these agents has been described.²

PATIENT EDUCATION

Keep the infected area clean and dry. For thrush in a baby, treat sources of infection such as the mother's breasts and bottle nipples. If the baby is bottle fed, boil the nipples between uses.

FIGURE 136-9 Tinea corporis under the breasts of a 55-year-old woman. Note the annular pattern with well-demarcated borders. KOH was positive for dermatophytes and not *Candida*. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-10 Inverse psoriasis that closely resembles *Candida* intertrigo in the submammary folds. This patient did not improve with topical antifungals and finally a biopsy showed that this was inverse psoriasis. Inverse psoriasis is often mistaken for a fungal infection unless the physician is aware of this condition. Frequently there are other clues to the diagnosis of psoriasis in the skin and nails so that a biopsy is not needed. (Courtesy of Richard P. Usatine, MD.)

FIGURE 136-11 Severe chronic cutaneous candidiasis in a 22-year-old man with immunosuppression. (Courtesy of Richard P. Usatine, MD.)

137 TINEA CAPITIS

Richard P. Usatine, MD
Congjun Yao, MD, PhD

PATIENT STORY

An 11-year-old boy has a history of 2 months of progressive patchy hair loss (**Figure 137-1**). He has some itching of the scalp but his mother is worried about his hair loss. Physical examination reveals alopecia with scaling of the scalp and broken hairs looking like black dots in the areas of hair loss. A KOH preparation is created by scraping an area of alopecia onto a slide. A few loose hairs are added to the slide before the KOH and cover slip are placed. Fungal elements are seen under the microscope. After 6 weeks of griseofulvin, the tinea capitis is fully resolved.

INTRODUCTION

Tinea capitis is a fungal infection involving the scalp and hair. It is the most common type of dermatophytoses in children younger than 10 years of age. Common signs include hair loss, scaling, erythema, and impetigo-like plaques.

SYNONYMS

Ringworm of the scalp and tinea tonsurans.

EPIDEMIOLOGY

- Tinea capitis is more common in young, black boys.
- Tinea capitis is the most common type of dermatophytoses in children younger than 10 years (**Figures 137-1 to 137-5**). It rarely occurs after puberty or in adults.¹ The infection has a worldwide distribution.
- Combs, brushes, couches, and sheets may harbor the live dermatophyte for a long period of time.
- Spread from person to person with direct contact or through fomites.
- Occasionally spread from cats and dogs to humans.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tinea capitis is a superficial fungal infection affecting hair shafts and follicles on the scalp but could involve the eyebrows and eyelashes.
- Caused by *Trichophyton* and *Microsporum* dermatophytes. The most common organism in the United States is *Trichophyton tonsurans*, which is associated with black dot alopecia. *Microsporum canis* is less common now than decades ago. *M. canis* is still highly prevalent in developing countries. The natural reservoir of *M. canis* is dogs and cats.

FIGURE 137-1 Tinea capitis in a young black boy. The most likely organism is *Trichophyton tonsurans*. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-2 Tinea capitis with patchy hair loss and scaling of the scalp in a young boy. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Lack of access to clean water and soap.
- Poverty and living in rural areas.
- African descent as the dermatophytes grow well in the follicles of short curly hairs.
- Crowded living arrangements in which infected individuals spread the tinea to others.
- Sharing combs, brushes, and hair ornaments.

DIAGNOSIS

- The clinical appearance is often adequate to make the diagnosis.
- Confirm the diagnosis by scraping the scaling areas on the scalp and placing a few loose hairs on a microscope slide with KOH. (DMSO and a fungal stain will help.) Look for hyphae and spores (**Figure 137-6**). Look for endoectothrix invasion of the hair shaft with fungus.

CLINICAL FEATURES

- Alopecia and scaling of the scalp (**Figures 137-1** and **137-2**).
- A kerion occurs when there is an inflammatory response to the tinea. The scalp gets red, swollen, and boggy. There may be serosanguineous discharge and some crusting as this dries (**Figure 137-3**).
- There may be broken hairs that look like black dots in the areas of hair loss (**Figure 137-4**).
- Cervical lymphadenopathy is common from the tinea capitis (**Figure 137-5**).
- Tinea capitis can even be annular and have the rings of ringworm (**Figure 137-6**).

TYPICAL DISTRIBUTION

By definition it occurs on the head, but usually is found on the scalp. Rarely involves the eyebrows and eyelashes.

LABORATORY STUDIES

Whenever possible it is very important to confirm or dispel ones' clinical suspicion with mycologic evidence before starting weeks of oral antifungal medicines.

- KOH preparation—Scrape the scale and infected hairs using a #15 blade. Then use KOH or a fungal stain to dissolve the keratin. Use the microscope to look for septate, branching hyphae under 10 and 40 power (**Figure 137-7**). The hyphae of *Microsporum* may also be found on the exterior of the hair (exothrix) as in **Figure 137-8**. The hyphae of *Trichophyton* is found in the interior of the hair (endothrix).
- If the diagnosis is uncertain, send a few loose hairs and a scraping of the scalp scale for a fungal culture.
- You may look at the scalp with a UV light (Woods lamp), looking for fluorescence, but the yield is low. Only the *Microsporum* species

FIGURE 137-3 A kerion resulting from inflammation of the tinea capitis on this young boy. The kerion looks superinfected but it is nothing more than an exuberant inflammatory response to the dermatophyte. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-4 Close-up of black dot alopecia in a 7-year-old girl showing the black dots where infected hairs have broken off. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-5 Lymphadenopathy visible in the neck of this young boy with tinea capitis. The fungal infection shows more scaling and crusting than actual hair loss. The lymphadenopathy is a reaction to the tinea and not a bacterial superinfection. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-6 Tinea capitis with an annular configuration. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-7 *T. tonsurans* from tinea capitis visible among skin cells at 40 power after adding Swartz-Lamkins fungal stain. (Courtesy of Richard P. Usatine, MD.)

FIGURE 137-8 *M. canis* showing hyphae on the exterior of the hair (exothrix) at 40 power after adding Swartz-Lamkins fungal stain. (Courtesy of Eric Kraus, MD.)

will fluoresce (**Figure 137-9**) and this organism is the involved dermatophyte less than 30% of the time.

DIFFERENTIAL DIAGNOSIS

- Alopecia areata—Produces areas of hair loss with no scaling, inflammation, or scarring in the underlying scalp. It is an autoimmune process in which the immune system attacks the person's own hair follicles (see Chapter 187, Alopecia Areata).
- Seborrhea of the scalp (dandruff)—Is caused by the *Pityrosporum* yeast, resulting in scaling and inflammation but rarely causing hair loss. The scalp involvement tends to be more widespread than patchy and localized as seen in tinea capitis (see Chapter 151, Seborrheic Dermatitis).
- Scalp psoriasis—Rarely causes alopecia. There are mild cases with slight, fine scaling on the scalp, or severe cases with silvery, thick, crusted plaques covering the majority of the scalp. Often psoriatic plaques are seen elsewhere on the body and nail changes are visible.
- Trichotillomania—Self-inflicted alopecia caused when the patient pulls and twists her/his own hair (see Chapter 188, Traction Alopecia and a Trichotillomania).
- Traction alopecia—Alopecia that occurs when the patient or parent pulls the hair to style it into braids or ponytails. There should be no scaling of the scalp (unless there is coexisting seborrhea) and the pattern of hair loss should match the hairstyle (**Figure 137-10**) (see Chapter 188, Traction Alopecia and Trichotillomania).
- Scarring alopecia—Seen with systemic lupus erythematosus (SLE) and discoid lupus. Scarring and hypopigmentation should differentiate this from tinea capitis (see Chapter 189, Scarring Alopecia).
- Tinea barbae (**Figure 137-11**) is a type of tinea infection of the hair follicles of the beard.

MANAGEMENT

- Topical antifungal therapy is not adequate and oral treatment is needed.
- Griseofulvin remains the treatment of choice for tinea capitis even if it requires a somewhat longer course than the newer antifungal agents.²⁻⁵ **SOR B** Most importantly, it is less expensive and available in a liquid form for children. Prescribe a 6- to 8-week course or longer (12-week course) of griseofulvin for tinea capitis.
- A 2- to 4-week course of terbinafine, fluconazole, and itraconazole are at least as effective as a 6- to 8-week course of griseofulvin for the treatment of *Trichophyton* infections of the scalp. Griseofulvin is likely to be superior to terbinafine for the rare cases caused by *Microsporum* species; its efficacy is matched by itraconazole and fluconazole.⁵ **SOR B**
- Griseofulvin is available in many forms, including liquid (125 mg microsize/5 cc) for children. Taking the drug with fatty food increases absorption and aids bioavailability. The dose for microsize griseofulvin is 20 mg/kg per day and ultramicrosize griseofulvin is 10 mg/kg per day. Ultramicrosize preparations are stronger per mg

FIGURE 137-9 A. Tinea capitis in a young boy. B. Fluorescence with an ultraviolet light indicating that this is a *Microsporum* species causing the tinea capitis. (Courtesy of Jeff Meffert, MD.)

FIGURE 137-10 Traction alopecia that is related to the tight braids that put pressure on the hair follicle. The slight scaling was caused by seborrhea but tinea capitis must be in the differential diagnosis. (Courtesy of Richard P. Usatine, MD.)

than the microsize, but do not come in liquid form. The tablets are less expensive than the liquids and can be used for children that can swallow a pill. The standard course should be 6 to 12 weeks for tinea capitis to deal with increasing resistance patterns.

- Terbinafine is effective and offers a shorter course of therapy than griseofulvin. It is not available in liquid form. Recommended dosage for 10- to 20-kg children is 62.5 mg/day; for 20- to 40-kg children, 125 mg daily; and for children who weigh more than 40 kg, 250 mg daily. Treatment duration for *Trichophyton* is 2 to 4 weeks; it is 8 to 12 weeks for *Microsporum* infection.
- Fluconazole is available in liquid form and appears to be effective and safe to treat cutaneous fungal infections. Recommended dosage is 5 to 6 mg/kg per day. Treatment duration for *Trichophyton* is 3 to 6 weeks; 8 to 12 weeks for *Microsporum* infection.
- Itraconazole is also available in liquid form. The recommended dose is 3 mg/kg per day for liquid form. For capsules: 5 mg/kg per day. Treatment duration is 2 to 6 weeks.
- None of these agents require laboratory monitoring at the recommended lengths of treatment for tinea capitis.¹
- A kerion may resolve with oral antifungal treatment alone. If it is severe and painful, consider a short pulse of oral steroids to speed up resolution. **SOR C**
- Although oral therapy is still the recommended treatment for tinea capitis, topical treatment can be used as adjuvant therapy: 1% or 2.25% selenium sulfide, 1% ciclopirox, or 2% ketoconazole shampoo should be applied to the scalp and hair for 5 minutes 2 or 3 times a week for 8 weeks.⁶⁻⁷ **SOR B** Another use for antifungal shampoo is empirical treatment while waiting for a culture to come back in an equivocal case. **SOR C**

PREVENTION

Family members or playmates should be screened and asymptomatic carriers should be treated. Close physical contact and sharing of toys or combs/hairbrushes should be avoided.⁸ **SOR B**

PROGNOSIS

Severe hair loss and scarring alopecia can occur if tinea capitis is left untreated.

PATIENT EDUCATION

Patients and parents need to exercise care to avoid spreading the infection to others. Explain the importance of not sharing combs, brushes, and towels.

FOLLOW-UP

Follow-up may be scheduled to check for full resolution of the infection by negative culture or hair regrowth.

FIGURE 137-11 Tinea barbae involving the hair follicles of the beard in a 63-year-old man with cutaneous lupus. The annular eruption on the neck was initially confused for his lupus until a potassium hydroxide scraping confirmed a fungal infection. The tinea barbae became inflammatory like a kerion with swelling of the upper lip before it was cured with oral terbinafine. (Courtesy of Richard P. Usatine, MD.)

138 TINEA CORPORIS

Richard P. Usatine, MD
Adeliza Jimenez, MD

PATIENT STORY

A 6-year-old girl is brought to the office for a round, itchy rash on her body (**Figure 138-1**). It was first noted 2 weeks ago. The family cat does have some patches of hair loss. Note the concentric rings with scaling, erythema, and central sparing. UV light showed green fluorescence (*Microsporum* species) and the KOH is positive for branching and septate hyphae. The child was treated with a topical antifungal cream bid and the tinea resolves in 3 to 4 weeks. The family cat was taken to the veterinarian for treatment, too.

INTRODUCTION

Tinea corporis is a common superficial fungal infection of the body, characterized by well-demarcated, annular lesions with central clearing, erythema, and scaling of the periphery.

EPIDEMIOLOGY

Dermatophytes are the most prevalent agents causing fungal infections in the United States, with *Trichophyton rubrum* causing the majority of cases of tinea corporis, tinea cruris, tinea manuum, and tinea pedis.

- Excessive heat and humidity make a good environment for fungal growth.
- Dermatophytes are spread by exposure to infected animals or persons and contact with contaminated items.

ETIOLOGY AND PATHOPHYSIOLOGY

Tinea corporis is caused by fungal species from any one of the following three dermatophyte genus's: *Trichophyton*, *Microsporum*, and *Epidermophyton*. *T. rubrum* is the most common causative agent of tinea corporis.

- Dermatophytes produce enzymes such as keratinase that penetrate keratinized tissue. Their hyphae invade the stratum corneum and keratin and spread centrifugally outward.

RISK FACTORS

- Participation in daycare centers.
- Living in a nursing home.
- Poor personal hygiene.
- Living conditions with poor sanitation.
- Warm, humid environments.

FIGURE 138-1 Tinea corporis on the shoulder of this young girl. This is a very typical annular pattern and the cat on a sweatshirt might be a clue to an infected pet at home spreading a *Microsporum* dermatophyte to its owner. Note the concentric rings with scaling, erythema, and central sparing. (Courtesy of Richard P. Usatine, MD.)

- Conditions that cause weakening of the immune system (e.g., AIDS, cancer, organ transplantation, diabetes).

DIAGNOSIS

The diagnosis can be made from history, clinical presentation, culture, and direct microscopic observation of hyphae in infected tissue and hairs after KOH preparation.

CLINICAL FEATURES

- Pruritus of affected area.
- Well-demarcated, annular lesions with central clearing, erythema, and scaling of the periphery. Concentric rings are highly specific (80%) for tinea infections (**Figure 138-1**).
- Central clearing is not always present (**Figure 138-2**).
- Although scale is the most prominent morphologic characteristic, some tinea infections will actually cause pustules from the inflammatory response (**Figure 138-3**).

TYPICAL DISTRIBUTION

Any part of the body including the face and axilla (**Figures 138-1 to 138-4**).

Tinea incognito is a type of tinea infection that was previously not recognized by the physician or patient and topical steroids were used on the site. While applying the steroid, the dermatophyte continues to grow and form concentric rings (**Figures 138-5 and 138-6**).

Tinea corporis can cover large parts of the body as in **Figures 138-7 to 138-9**.

In some cases the infection may cause hyperpigmentation (**Figures 138-7 to 138-9**).

LABORATORY STUDIES

- KOH preparation of skin scraping can be very useful to confirm a clinical impression or when the diagnosis is not certain. Scrape the skin with the side of a slide or scalpel, making sure to scrape the periphery and the erythematous part. Scrape hard enough to get some stratum corneum without causing significant bleeding. False negatives can occur secondary to inadequate scraping, patient using topical antifungals, or an inexperienced microscopist.
- Use KOH (plain, with dimethyl sulfoxide [DMSO], or in a fungal stain) to break up the epithelial cells more rapidly without heating (**Figure 138-10**). It is easy to purchase a small bottle of Swartz-Lamkins fungal stain that includes KOH, a surfactant, and blue ink. The blue ink allows the hyphae to stand out, thereby saving time and decreasing the chance of a false-negative result (**Figure 138-11**). If the epithelial cells are not breaking up sufficiently, use a flame under the slide for approximately 5 seconds to speed up the process.
- Skin scraping and culture—Gold standard, but more costly and may take up to 2 weeks for the culture to grow. Consider culture if the KOH is negative but tinea is still suspected, or when a microscope is not available.
- Skin biopsy sent in formalin for periodic acid-Schiff (PAS) staining when the KOH and culture remain negative but the clinical picture is consistent with a fungal infection.

FIGURE 138-2 Tinea faciei in a young girl. There is no central clearing or annular pattern here but the KOH preparation was positive for branching hyphae. It resolved with a topical antifungal medicine. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-3 Tinea corporis with pustules and scale. KOH preparation was positive for branching hyphae. The pustules are a manifestation of an inflammatory response to the dermatophyte infection. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-4 Extensive tinea corporis in the axilla and arm of this older adult. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-6 Tinea incognito in the axillary region of a young man who was prescribed topical steroids. Although there is some hyperpigmentation, erythema is most prominent. (Courtesy of Chris Wenner, MD.)

FIGURE 138-5 Tinea incognito on the chest and arm of this black woman. This tinea infection continued to grow as the patient applied the topical steroids given to her by her physician. There is an extensive amount of postinflammatory hyperpigmentation. **A.** Tinea incognito on the arm with concentric rings as this dermatophyte infection continued to grow under the influence of the topical steroids. **B.** Tinea incognito on the chest. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-7 Tinea corporis covering the back and showing well-demarcated borders. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Granuloma annulare—Inflammatory, benign dermatosis of unknown cause, characterized by both dermal and annular papules (**Figure 138-12**) (see Chapter 173, Granuloma Annulare).
- Psoriasis—Plaque with scale on extensor surfaces and trunk. Occasionally, the plaques can have an annular appearance (**Figure 138-13**). Inverse psoriasis in intertriginous areas can also mimic tinea corporis (see Chapter 152, Psoriasis).
- Erythema annulare centrifugum (EAC)—Scaly red rings with normal skin in the center of the rings. The scale is trailing the erythema as the ring expands while the scale is leading in tinea corporis (**Figure 138-14**) (see Chapter 206, Erythema Annulare Centrifugum).
- Cutaneous larva migrans has serpiginous burrows made by the hookworm larvae, and these burrows can look annular and be confused with tinea corporis (see Chapter 144, Cutaneous Larva Migrans).
- Nummular eczema—Round coin-like red scaly plaques without central clearing (see Chapter 145, Atopic Dermatitis).
- Erythrasma—Found in the axilla and groin without an annular configuration and central clearing. Fluoresces coral red under UV lamp (see Chapter 119, Erythrasma).

MANAGEMENT

- Use topical antifungal medications for tinea corporis that involves small areas of the body such as seen in **Figures 138-1** and **138-2**.
- Although all the topical antifungal agents may be effective, the evidence supports the greater effectiveness of the allylamines (terbinafine) over the less-expensive azoles for tinea pedis and corporis. Allylamines cure slightly more infections than azoles and are now available over the counter.^{1,2} **SOR A**
- Studies show that terbinafine 1% cream or solution applied once daily for 7 days is highly effective for tinea corporis/cruris.^{3,4} The 1% cream (which is available over the counter as Lamisil AF) produced a mycologic cure of 84.2% versus 23.3% with placebo. Number needed to treat (NNT) = 1.6.³ **SOR A**
- Oral antifungal agents should be considered for first-line therapy for tinea corporis covering large areas of the body, as seen in **Figures 138-6** and **138-7**. However, it is not wrong to attempt topical treatment if the size of the area infected is on the borderline. The patient with tinea incognito in **Figures 138-4** and **138-5** did need oral therapy to resolve her infection. Unfortunately, the postinflammatory hyperpigmentation did not resolve well.
- One randomized controlled trial (RCT) showed that oral itraconazole 200 mg daily for 1 week is similarly effective, equally well tolerated, and at least as safe as itraconazole 100 mg for 2 weeks in the treatment of tinea corporis or cruris.⁵ **SOR B**
- In one study, patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks.⁶ **SOR B**

FIGURE 138-8 Tinea corporis on the back, shoulder, and arm with erythema and hyperpigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-9 Tinea corporis from the trunk down both legs with significant hyperpigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-10 Branching hyphae at 40x power from KOH preparation of tinea corporis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-11 Branching hyphae easily seen at 40x power using fungal stain (Swartz-Lamkins) from a scraping of tinea corporis. Note how the hyphae stand out with the blue ink color. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-12 Multiple annular lesions caused by granuloma annulare. No scale is visible. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-13 Widespread annular lesions caused by psoriasis. Not all lesions that are annular with scale are tinea corporis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 138-14 Erythema annulare centrifugum (EAC) in the axilla of a 28-year-old man. After multiple failed trials of antifungal medicines, a punch biopsy showed this to be EAC. Note the trailing scale rather than leading scale seen in tinea corporis. (Courtesy of Richard P. Usatine, MD.)

- In summary, if an oral agent is needed, the evidence is greatest for the use of:
 - Terbinafine 250 mg daily for 2 weeks.⁶ **SOR B** (Terbinafine is available as an inexpensive generic prescription on the \$4 and \$5 plans in the United States. It also has less drug interactions than itraconazole. For these reasons it is usually the preferred treatment when an oral agent is needed.)
 - Itraconazole 200 mg daily for 1 week.⁵ **SOR B** (More expensive with more drug interactions than terbinafine.)
 - Itraconazole 100 mg daily for 2 weeks.⁵ **SOR B**

PREVENTION

Tinea corporis and cruris are dermatophyte infections that are particularly common in areas of excessive heat and moisture. A dry, cool environment may play a role in reducing infection. In addition, avoiding contact with farm animals and other individuals infected with tinea corporis and cruris may help in preventing infection. Preventative measures for tinea infections include practicing good personal hygiene; keeping the skin dry and cool at all times; and avoiding sharing towels, clothing, or hair accessories with infected individuals.⁷

In individuals involved in contact sports such as wrestling, a comprehensive skin disease prevention protocol includes some combination of the following: washing of wrestling mats before and after each practice and competition; showers before and after each practice; use of clean clothing before each practice; and exclusion of infected athletes.⁸

PATIENT EDUCATION

Keep the skin clean and dry. Infected pets should be treated.

FOLLOW-UP

Consider follow-up appointments in 4 to 6 weeks for difficult and more widespread cases. If there are concerns about bacterial superinfection, follow-up should be sooner.

139 TINEA CRURIS

Richard P. Usatine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 59-year-old man presents with itching in the groin (**Figure 139-1**). On examination, he was found to have scaly erythematous plaques in the inguinal area. A skin scraping was treated with Swartz-Lamkins stain and the dermatophyte was highly visible under the microscope (**Figure 139-2**). He was treated with a topical antifungal medicine until his tinea cruris resolved.

INTRODUCTION

Tinea cruris is an intensely pruritic superficial fungal infection of the groin and adjacent skin.

SYNONYMS

Crotch rot and jock itch.

EPIDEMIOLOGY

- Using data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey (NHAMCS) (1995-2004), there were more than 4 million annual visits for dermatophytoses and 8.4% were for tinea cruris.¹
- Tinea cruris is more common in men than women (three-fold) and rare in children.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most commonly caused by the dermatophytes: *Trichophyton rubrum*, *Epidermophyton floccosum*, *Trichophyton mentagrophytes*, and *Trichophyton verrucosum*. *T. rubrum* is the most common organism.²
- Can be spread by fomites, such as contaminated towels.
- The fungal agents cause keratinases, which allow invasion of the cornified cell layer of the epidermis.²
- Autoinoculation can occur from fungus on the feet or hands.

RISK FACTORS

- Wearing tight-fitting or wet clothing or underwear has traditionally been suggested; however, in a study of Italian soldiers, none of the risk factors analyzed (e.g., hyperhidrosis, swimming pool attendance) were significantly associated with any fungal infection.³
- Obesity and diabetes mellitus may be risk factors.⁴

FIGURE 139-1 Tinea cruris in a 59-year-old Hispanic man present for 1 year. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-2 Microscopic view of the scraping of the groin in a man with tinea cruris. The hyphae are easy to see under 40 power with Swartz-Lamkins stain. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

The cardinal features are scale and signs of inflammation. In light-skinned persons inflammation often appears pink or red and in dark-skinned persons the inflammation often leads to hyperpigmentation (**Figures 139-3** and **139-4**). Occasionally, tinea cruris may show central sparing with an annular pattern as in **Figure 139-5**, but most often is homogeneously distributed as in **Figures 139-3** and **139-4**.

TYPICAL DISTRIBUTION

By definition tinea cruris is in the inguinal area. However, the fungus can grow outside of this area to involve the abdomen and thighs (**Figures 139-4** and **139-6**). Tinea can be present in multiple locations, as in the patient in **Figure 139-7** who had tinea in the groin, on her feet and face, and under her breasts.

LABORATORY STUDIES

Diagnosis is often made based on clinical presentation, but a skin scraping treated with KOH and a fungal stain analyzed under the microscope can be helpful (**Figure 139-2**). False negatives may occur if scraping is inadequate, patient is using topical antifungals, or the viewer is inexperienced.

Skin scraping and culture is definitive but expensive, and may take up to 2 weeks for the culture to grow.

UV lamp can be used to look for the coral red fluorescence of erythrasma (see Chapter 119, Erythrasma). Most tinea cruris is caused by *T. rubrum* so will not fluoresce.

DIFFERENTIAL DIAGNOSIS

- Cutaneous *Candida* in the groin can become red and have scaling that extends to the thigh and scrotum. Tinea cruris does not often involve the scrotum. *Candida* often has satellite lesions. However, tinea cruris can also have a few satellite lesions (see Chapter 136, Candidiasis).
- Erythrasma in the groin appears similar to tinea cruris. It is less common than tinea cruris and may show coral red fluorescence with a UV light (**Figure 139-8**) (see Chapter 119, Erythrasma).
- Contact dermatitis can occur anywhere on the body. If the contact is near the groin this can be mistaken for tinea cruris (see Chapter 146, Contact Dermatitis).
- Inverse psoriasis causes inflammation in the intertriginous areas of the body. It does not have the thick plaques of plaque psoriasis. Inverse psoriasis is frequently misdiagnosed as a fungal infection until an astute clinician recognizes the pattern or does a biopsy (**Figure 139-9**; see Chapter 152, Psoriasis).
- Intertrigo is an inflammatory condition of the skin folds. It induced or aggravated by heat, moisture, maceration, and friction.⁵ The condition frequently is worsened by infection with *Candida* or dermatophytes so there is some overlap with tinea cruris.

FIGURE 139-3 Tinea cruris in an older black man with hyperpigmentation secondary to the inflammatory response. A silvery scale is also seen and psoriasis should be considered in the differential diagnosis. In such a case, performing a potassium hydroxide preparation is crucial to making an accurate diagnosis as it is not possible to know the diagnosis by appearance only. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-4 Tinea cruris that has expanded beyond the inguinal area in this 35-year-old black man. Postinflammatory hyperpigmentation is visible throughout the infected area. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-5 An 18-year-old woman with tinea cruris showing erythema and scale in an annular pattern. Central clearing is less common in tinea cruris than tinea corporis but can occur. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-8 Erythrasma in the groin can be mistaken for tinea cruris. This erythrasma fluoresced coral red with a ultraviolet light. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-6 A 54-year-old man with tinea cruris and corporis for decades despite multiple treatments with oral antifungal medications. His cultures show *T. rubrum* sensitive to all the typical oral antifungal medications, but his tinea never completely clears. He does not have a known immunodeficiency but his immune system appears not to recognize the *T. rubrum* as foreign. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-7 A 55-year-old woman with tinea cruris showing erythema and scale. Although less common in women, women do get tinea cruris. This patient had tinea on her feet, face, and under her breasts. She was treated with oral terbinafine for 3 weeks. (Courtesy of Richard P. Usatine, MD.)

FIGURE 139-9 Inverse psoriasis in a man who also has the nail changes of psoriasis. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

- Tinea cruris is best treated with a topical allylamine or an azole antifungal (SOR A), based on multiple randomized controlled trials [RCTs].⁶ Differences in current comparison data are insufficient to stratify the two groups of topical antifungals.⁷ In one RCT, cure rates were higher at 1 week with butenafine (once daily for 2 weeks) versus clotrimazole (twice daily for 4 weeks) (26.5% vs. 2.9%, respectively), but were not significantly different at 4 or 8 weeks.⁸
- The fungicidal allylamines (naftifine and terbinafine) and butenafine (allylamine derivative) are a more costly group of topical tinea treatments, yet they are more convenient as they allow for a shorter duration of treatment compared with fungistatic azoles (clotrimazole, econazole, ketoconazole, oxiconazole, miconazole, and sulconazole).⁷
- Topical azoles should be continued for 4 weeks and topical allylamines for 2 weeks or until clinical cure.⁶⁻⁸ SOR A
- Fluconazole 150 mg once weekly for 2 to 4 weeks appears to be effective in the treatment of tinea cruris.⁹ SOR B
- One RCT showed that itraconazole 200 mg for 1 week is similarly effective, equally well tolerated, and at least as safe as itraconazole 100 mg for 2 weeks in the treatment of tinea corporis or cruris (clinical response: 73% and 80% at the end of follow-up, respectively).¹⁰ SOR B
- Patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks.¹¹ SOR B
- If there are multiple sites infected with fungus, treat all active areas of infection simultaneously to prevent reinfection of the groin from other body sites. If the tinea is widespread as in the patient in **Figure 139-5**, an oral agent is warranted.

FOLLOW-UP

As needed.

PATIENT EDUCATION

- Advise patients with tinea pedis to put on their socks before their undershorts to reduce the possibility of direct contamination. SOR C
- Dry the groin completely after bathing. SOR C

140 TINEA PEDIS

Richard P. Usatine, MD
Katie Reppa, MD

PATIENT STORY

A 38-year-old man presents with an itchy rash on his hands and blisters on his feet for 1 week duration (**Figure 140-1**). Vesicular tinea pedis with bullae were present. The papules and vesicles between the fingers were typical of an autoeczematization reaction (Id reaction) (**Figure 140-2**). The patient was treated with an oral antifungal medication and a short burst of oral prednisone for the autoeczematization reaction.

INTRODUCTION

Tinea pedis is a common cutaneous infection of the feet caused by dermatophyte fungus. The clinical manifestation presents in 1 of 3 major patterns: interdigital, moccasin, and inflammatory. Concurrent fungal infection of the nails (onychomycosis) occurs frequently.

SYNONYMS

Athlete's foot

EPIDEMIOLOGY

- Tinea pedis is thought to be the world's most common dermatophytosis.¹
- 70% of the population will be infected with tinea pedis at some time.¹
- More commonly affects males than females.¹
- Prevalence increases with age and it is rare before adolescence.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- A cutaneous fungal infection most commonly caused by *Trichophyton rubrum*.¹
- *Trichophyton mentagrophytes* and *Epidermophyton floccosum* follow in that order.
- *T. rubrum* causes most tinea pedis and onychomycosis.

RISK FACTORS

- Male gender.
- Use of public showers, baths or pools.²
- Household member with tinea pedis infection.²

FIGURE 140-1 Vesicular tinea pedis with bullae present. This is an inflammatory reaction to the tinea pedis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 140-2 The hand shows an autoeczematization reaction to the inflammatory tinea pedis in the previous figure. The vesicles between the fingers are typical of an autoeczematization reaction, also known as an Id reaction. (Courtesy of Richard P. Usatine, MD.)

- Certain occupations (miners, farmers, soldiers, meat factory workers, marathon runners).²
- Use of immunosuppressive drugs.

DIAGNOSIS

TYPICAL DISTRIBUTION AND MORPHOLOGY

Three types of tinea pedis

- Interdigital type—most common (**Figure 140-3**).
- Moccasin type (**Figure 140-4** and **140-5**).
- Inflammatory/vesicular type—least common (**Figure 140-1**).

Some authors describe an ulcerative type (**Figure 140-6**).

CLINICAL FEATURES

- Interdigital—white or green fungal growth between toes with erythema, maceration, cracks, and fissures—especially between fourth and fifth digits (**Figure 140-3**). The dry type has more scale and the moist type becomes macerated.
- Moccasin—scale on sides and soles of feet (**Figure 140-4** and **140-5**).
- Vesicular—vesicles and bullae on feet (**Figure 140-6**).
- Ulcerative tinea pedis is characterized by rapidly spreading vesiculopustular lesions, ulcers, and erosions, typically in the web spaces (**Figure 140-7**). It is accompanied by a secondary bacterial infection. This can lead to cellulitis or lymphangitis.
- Autosensitization (dermatophytid reaction; ID reaction) is a hypersensitivity response to the fungal infection causing papules on the hands (**Figure 140-2**).
- Examine nails for evidence of onychomycosis—fungal infections of nails may include subungual keratosis, yellow or white discolorations, dystrophic nails (Chapter 193, Onychomycosis).
- Examine to exclude cellulitis that may show erythema, swelling, tenderness with red streaks tracking up the foot and lower leg (Chapter 120, Cellulitis).

TYPICAL DISTRIBUTION

Between the toes, on the soles, and lateral aspects of the feet.

LABORATORY STUDIES

Diagnosis is often made based on clinical presentation but a skin scraping treated with KOH and a fungal stain analyzed under the microscope can be helpful (**Figure 140-8**).

In the patient with tinea incognito on his foot and lower leg, the physicians were set astray by his diagnosis of systemic lupus erythematosus (SLE) (**Figure 140-9**). It took a skin scraping to demonstrate that this was tinea and not lupus to get the patient the treatment he needed (**Figure 140-8**).

Skin scraping and culture is definitive but expensive, and may take up to 2 weeks for the culture to grow.

FIGURE 140-3 Tinea pedis seen in the interdigital space between the fourth and fifth digits. This is the most common area to see tinea pedis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 140-4 Tinea pedis in the moccasin distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 140-5 Tinea pedis in a moccasin distribution that has spread up the leg. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Pitted keratolysis: well-demarcated pits or erosions in the sole of the foot caused by bacteria (**Figure 140-10**) (Chapter 118, Pitted Keratolysis).
- Contact dermatitis: tends to be seen on the dorsum and sides of the foot (**Figure 140-11**) (Chapter 146, Contact Dermatitis).
- Keratoderma: thickening of the soles of the feet that can be caused by a number of etiologies, including menopause (**Figure 140-12**). This condition looks a lot like tinea pedis in the moccasin distribution.
- Dyshidrotic eczema is characterized by scale and tapioca-like vesicles on the hands and feet (**Figure 140-13**) (Chapter 147, Hand Eczema).
- Friction blisters: blisters on the feet of persons leading an active athletic lifestyle.
- Psoriasis: can mimic tinea pedis but will usually be present in other areas as well (**Figure 140-14**) (Chapter 152, Psoriasis).

MANAGEMENT

Table 140-1 discusses management of tinea pedis.

TOPICAL ANTIFUNGALS

- Systematic review of 70 trials of topical antifungals showed good evidence for efficacy compared to placebo for the following:
 - Allylamines (naftifine, terbinafine, butenafine)³ **SOR A**
 - Azoles (clotrimazole, miconazole, econazole)³ **SOR A**
 - Allylamines cure slightly more infections than azoles but are more expensive³ **SOR A**
 - No differences in efficacy found between individual allylamines or individual azoles (**Table 140-2**) **SOR A**
 - In one metaanalysis, topical terbinafine was found to be equally effective as other topical antifungals but the average duration of treatment was shorter. (1 week instead of 2 weeks). Additionally, terbinafine is effective as a single-application film-forming solution.⁴ **SOR A**

ORAL ANTIFUNGALS

- Systematic review of 12 trials, involving 700 participants: oral terbinafine for 2 weeks cures 52% more patients than oral griseofulvin.⁵ **SOR A**
- Terbinafine is equal to itraconazole in patient outcomes.⁵ **SOR A**
- No significant differences in comparisons between a number of oral agents.⁵ **SOR A**

Dosing for tinea pedis needing oral therapy:

- Itraconazole two 100 mg tablets daily for 1 week.⁶
- Terbinafine 250 mg PO daily for 1 to 2 weeks.⁶

Patients with onychomycosis may have recurrences of the skin infection related to the fungus that remains in the nails and, therefore, may need oral treatment for 3 months to achieve better results.

FIGURE 140-6 Vesicular tinea pedis with vesicles and bullae over the arch region of the foot. The arch is a typical location for vesiculobullous tinea pedis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 140-7 Ulcerative tinea pedis with spreading vesicles related to a bacterial superinfection. The patient was treated with antifungals and antibiotics. (Courtesy of Richard P. Usatine, MD.)

TABLE 140-2 Topical Antifungal Medications

Agent	Formulation	Frequency*	Duration* (weeks)	NNT [†]
Imidazoles				
Clotrimazole	1% cream 1% solution 1% swabs	Twice daily	2 to 4	2.9
Econazole	1% cream	Twice daily	2 to 4	2.6
Ketoconazole	2% cream	Once daily	2 to 4	No data available
Miconazole	2% cream 2% spray 2% powder	Twice daily	2 to 4	2.8 (at 8 weeks)
Oxiconazole	1% cream 1% lotion	Once to twice daily	2 to 4	2.9
Sulconazole	1% cream 1% solution	Once to twice daily	2 to 4	2.5
Allylamines				
Naftifine	1% cream 1% gel	Once to twice daily	1 to 4	1.9
Terbinafine	1% cream 1% solution	Once to twice daily	1 to 4	1.6 (1.7 for tinea cruris/tinea corporis at 8 weeks)
Benzylamine				
Butenafine	1% cream	Once to twice daily	1 to 4	1.9 (1.4 for tinea corporis and 1.5 for tinea cruris)
Other				
Ciclopirox	0.77% cream 0.77% lotion	Twice daily	2 to 4	2.1
Tolnaftate	1% powder 1% spray 1% swabs	Twice daily	4	3.6 (at 8 weeks)

*Manufacturer guidelines.

[†]NNT, number needed to treat. NNT is calculated from systematic review of all randomized controlled trials for tinea pedis at 6 weeks after the initiation of treatment except where otherwise noted.

Reprinted with permission from Thomas B. Clear choices in managing epidermal tinea infections. *J Fam Pract* 2003;52(11):857. Reproduced with permission from Frontline Medical Communications.

Topical urea (Carmol, Keralac), available in 10% to 40% concentrations, may be useful to decrease scaling in patients with hyperkeratotic soles.⁵

ALTERNATIVE THERAPY

One small pilot study with 56 participants showed significant improvement or resolution of symptoms in patients treated by wearing socks containing copper-oxide fibers daily for a minimum of 8 to 10 days.⁷ **SOR B**

PATIENT EDUCATION

- Do not go barefoot in public showers and locker rooms. **SOR C**
- Keep feet dry and clean, and use clean socks and shoes that allow the feet to get fresh air. **SOR C**
- Use the topical medication beyond the time in which the feet look clear to prevent relapse.

141 TINEA VERSICOLOR

Richard P. Usatine, MD
Melissa M. Chan, MD

PATIENT STORY

A young black man presents to the office with a 5-year history of white spots on his trunk (**Figure 141-1**). He denies any symptoms but worries if this could spread to his girlfriend. These spots get worse during the summer months but never go away completely. He was relieved to receive a treatment for his tinea versicolor and to find out that it is rarely spread to others through contact.

INTRODUCTION

Tinea versicolor is a common superficial skin infection caused by the dimorphic lipophilic yeast *Pityrosporum* (*Malassezia furfur*). The most typical presentation is a set of hypopigmented macules and patches with fine scale over the trunk in a cape-like distribution.

SYNONYMS

Pityriasis versicolor is actually a more accurate name as “tinea” implies a dermatophyte infection. Tinea versicolor is caused by *Pityrosporum* and not a dermatophyte.

EPIDEMIOLOGY

- Seen more commonly in men than in women.
- Seen more often during the summer, and is especially common in warm and humid climates.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tinea versicolor is caused by *Pityrosporum* (*M. furfur*), which is a lipophilic yeast that can be normal human cutaneous flora.
- *Pityrosporum* exists in two shapes—*Pityrosporum ovale* (oval) and *Pityrosporum orbiculare* (round).
- Tinea versicolor starts when the yeast that normally colonizes the skin changes from the round form to the pathologic mycelial form and then invades the stratum corneum.¹
- *Pityrosporum* is also associated with seborrhea and *Pityrosporum* folliculitis.
- The white and brown colors are secondary to damage caused by the *Pityrosporum* to the melanocytes, while the pink is an inflammatory reaction to the organism.
- *Pityrosporum* thrive on sebum and moisture; they tend to grow on the skin in areas where there are sebaceous follicles secreting sebum.

FIGURE 141-1 Tinea versicolor showing areas of hypopigmentation. (From the Usatine RP. What is in a name? *West J Med.* 2000;173(4): 231-232.)

DIAGNOSIS

CLINICAL FEATURES

Tinea versicolor consists of hypopigmented, hyperpigmented, or pink macules and patches on the trunk that are finely scaling and well-demarcated. Versicolor means a variety of or variation in colors; tinea versicolor tends to come in white, pink, and brown colors (**Figures 141-1 to 141-5**).

TYPICAL DISTRIBUTION

Tinea versicolor is found on the chest, abdomen, upper arms, and back, whereas seborrhea tends to be seen on the scalp, face, and anterior chest.

LABORATORY STUDIES

A scraping of the scaling portions of the skin may be placed onto a slide using the side of another slide or a scalpel. KOH with DMSO (DMSO helps the KOH dissolve the keratinocytes faster and reduces the need for heating the slide) is placed on the slide and covered with a coverslip. Microscopic examination reveals the typical “spaghetti-and-meatballs” pattern of tinea versicolor. The “spaghetti,” or more accurately “ziti,” is the short mycelial form and the “meatballs” are the round yeast form (**Figures 141-6 and 141-7**). Fungal stains such as the Swartz-Lamkins stain help make the identification of the fungal elements easier.

DIFFERENTIAL DIAGNOSIS

- Pityriasis rosea has a fine collarette scale around the border of the lesions and is frequently seen with a herald patch. Negative KOH (see Chapter 153, Pityriasis Rosea).
- Secondary syphilis is usually not scaling and tends to have macules on the palms and soles. Negative KOH (see Chapter 216, Syphilis).
- Tinea corporis is rarely as widespread as tinea versicolor and each individual lesion usually has central clearing and a well-defined, raised, scaling border. The KOH preparation in tinea corporis shows hyphae with multiple branch points and not the “ziti-and-meatballs” pattern of tinea versicolor (see Chapter 138, Tinea Corporis).
- Vitiligo—The degree of hypopigmentation is greater and the distribution is frequently different with vitiligo involving the hands and face (see Chapter 198, Vitiligo).
- Pityriasis alba—Lightly hypopigmented areas with slight scale that tend to be found on the face and trunk of children with atopy. These patches are frequently smaller and rounder than tinea versicolor (see Chapter 145, Atopic Dermatitis).
- *Pityrosporum* folliculitis is caused by the same organism but presents with pink or brown papules on the back. The patient complains of itchy rough skin and the KOH is positive (**Figure 141-8**).

MANAGEMENT

TOPICAL

- Because tinea versicolor is usually asymptomatic, the treatment is mostly for cosmetic reasons.

FIGURE 141-2 Patches of hypopigmentation across the back caused by tinea versicolor in a young Latino man. Vitiligo is on the differential diagnosis in this case. A KOH preparation confirmed tinea versicolor. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-3 Pink scaly patches caused by tinea versicolor. Seborrhea may be seen in this location, but tends to be worse in the presteral region. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-4 Large areas of pink tinea versicolor on the shoulder in a cape-like distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-5 Hyperpigmented variant of tinea versicolor in a Hispanic woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-7 Close-up of *Malassezia furfur* (*Pityrosporum*) showing the ziti-and-meatball appearance after Swartz-Lamkins stain was applied to the scraping of tinea versicolor in a young woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-6 Microscopic examination of scrapings done from previous patient showing short mycelial forms and round yeast forms suggestive of spaghetti and meatballs. Swartz-Lamkins stain was used. (Courtesy of Richard P. Usatine, MD.)

FIGURE 141-8 *Pityrosporum* folliculitis on the back of a man with pruritus. (Courtesy of Richard P. Usatine, MD.)

- The mainstay of treatment has been topical therapy using antidandruff shampoos, because the same *Pityrosporum* species that cause seborrhea and dandruff also cause tinea versicolor.^{1,2}
- Patients may apply selenium sulfide 2.5% lotion or shampoo, or zinc pyrithione shampoo to the involved areas daily for 1 to 2 weeks. Various amounts of time are suggested to allow the preparations to work, but there are no studies that show a minimum exposure time needed. A typical regimen involves applying the lotion or shampoo to the involved areas for 10 minutes and then washing it off in the shower. **SOR C**
- One study used ketoconazole 2% shampoo (Nizoral) as a single application or daily for 3 days and found it safe and highly effective in treating tinea versicolor.³ **SOR B**
- Topical antifungal creams for smaller areas of involvement can include ketoconazole and clotrimazole. **SOR C**

ORAL TREATMENT AND PREVENTION

- A single-dose 400-mg oral fluconazole provided the best clinical and mycologic cure rate, with no relapse during 12 months of follow-up.⁴ **SOR B**
- A single dose of 300 mg of oral fluconazole repeated weekly for 2 weeks was equal to 400 mg of ketoconazole in a single dose repeated weekly for 2 weeks. No significant differences in efficacy, safety, and tolerability between the two treatment regimens were found.⁵ **SOR B**
- A single-dose 400-mg oral ketoconazole to treat tinea versicolor is safe and cost-effective compared to using the newer, more expensive, oral antifungal agents, such as itraconazole.^{6,7} **SOR B**
- Oral itraconazole 200 mg given twice a day for 1 day a month has been shown to be safe and effective as a prophylactic treatment for tinea versicolor.⁸ **SOR B**
- There is no evidence that establishes the need to sweat after taking oral antifungals to treat tinea versicolor.

PATIENT EDUCATION

Patients should be told that the change in skin color will not reverse immediately. The first sign of successful treatment is the lack of scale. The yeast acts like a sunscreen in the hypopigmented macules. Sun exposure will hasten the normalization of the skin color in patients with hypopigmentation.

FOLLOW-UP

None needed unless it is a stubborn or recurrent case. Recurrent cases can be treated with monthly topical or oral therapy.

SECTION 6 INFESTATIONS

142 LICE

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 64-year-old homeless woman with schizophrenia presented to a homeless clinic for itching all over her body. She stated that she could see creatures feed on her and move in and out of her skin. The physical examination revealed that she was unwashed and had multiple excoriations over her body (**Figure 142-1**). Body lice and their progeny were visible along the seams of her pants (**Figure 142-2**). Treatment of this lousy infestation required giving her new clothes and a shower.¹

INTRODUCTION

Lice are ectoparasites that live on or near the body. They will die of starvation within 10 days of removal from their human host. Lice have coexisted with humans for at least 10,000 years.² Lice are ubiquitous and remain a major problem throughout the world.³

SYNONYMS

Pediculosis, crabs (pubic lice).

EPIDEMIOLOGY

- Human lice (pediculosis corporis, pediculosis pubis, and pediculosis capitis) are found in all countries and climates.³
- Head lice are most common among school-age children. Each year, approximately 6 to 12 million children, ages 3 to 12 years, are infested.⁴
- Head lice infestation is seen across all socioeconomic groups and is not a sign of poor hygiene.⁵
- In the United States, black children are affected less often as a result of their oval-shaped hair shafts that are difficult for lice to grasp.⁴
- Body lice infest the seams of clothing (**Figure 142-2**) and bed linen. Infestations are associated with poor hygiene and conditions of crowding.
- Pubic lice are most common in sexually active adolescents and adults. Young children with pubic lice typically have infestations of the eyelashes. Although infestations in this age group may be an indication of sexual abuse, children generally acquire the crab lice from their parents.⁶

FIGURE 142-1 Body lice in a 64-year-old homeless woman with schizophrenia. (Courtesy of Richard P. Usatine, MD and Usatine RP, Halem L. A terrible itch. *J Fam Pract.* 2003;52(5):377-379. Reproduced with permission from Frontline Medical Communications.)

FIGURE 142-2 Adult body lice and nymphs visible along the pant seams of the woman in **Figure 142-1**. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Lice are parasites that have six legs with terminal claws that enable them to attach to hair and clothing. There are three types of lice responsible for human infestation. All three kinds of lice must feed daily on human blood and can only survive 1 to 2 days away from the host. The three types of lice are as follows:
 - Head lice (*Pediculus humanus capitis*)—Measure 2 to 4 mm in length (**Figure 142-3**).
 - Body lice (*Pediculus humanus corporis*)—Body lice similarly measure 2 to 4 mm in length (**Figure 142-4**).
 - Pubic or crab lice (*Phthirus pubis*)—Pubic lice are shorter, with a broader body and have an average length of 1 to 2 mm (**Figure 142-5**).
- Female lice have a lifespan of approximately 30 days and can lay approximately 10 eggs (nits) a day.⁴
- Nits are firmly attached to the hair shaft or clothing seams by a glue-like substance produced by the louse (**Figures 142-6 to 142-8**).
- Nits are incubated by the host's body heat.
- The incubation period from laying eggs to hatching of the first nymph is 7 to 14 days.
- Mature adult lice capable of reproducing appear 2 to 3 weeks later.⁵
- Transmission of head lice occurs through direct contact with the hair of infested individuals. The role of fomites (e.g., hats, combs, brushes) in transmission is negligible.⁶ Head lice do not serve as vectors for transmission of disease among humans.
- Transmission of body lice occurs through direct human contact or contact with infested material. Unlike head lice, body lice are well-recognized vectors for transmission of the pathogens responsible for epidemic typhus, trench fever, and relapsing fever.⁵
- Pubic or crab lice are transmitted primarily through sexual contact. In addition to pubic hair (**Figure 142-9**), infestations of eyelashes, eyebrows, beard, upper thighs, abdominal, and axillary hairs may also occur.

RISK FACTORS

- Contact with an infected individual.
- Living in crowded quarters such as homeless shelters.
- Poor hygiene and mental illness.

DIAGNOSIS

CLINICAL FEATURES

- Nits can be seen in active disease or treated disease. Nits closer to the base of the hairs are generally newer and more likely to be live and unhatched. Unfortunately, nits that were not killed by pediculicides can hatch and start the infestation cycle over again. Note that nits are glued to the hairs and are hard to remove, whereas flakes of dandruff can be easily brushed off.

FIGURE 142-3 Adult head louse with elongated body. (Courtesy of Centers for Disease Control and Prevention and Dennis D. Juranek.)

FIGURE 142-4 A body louse feeding on the blood of the photographer. The dark mass inside the abdomen is a previously ingested blood meal. (Courtesy of Centers for Disease Control and Prevention and Frank Collins, PhD.)

FIGURE 142-5 The crab louse has a short body and its large claws are responsible for the "crab" in its name. (Courtesy of Centers for Disease Control and Prevention and World Health Organization.)

- Pruritus is the hallmark of lice infestation. It is the result of an allergic response to louse saliva.⁷ Head lice are associated with excoriated lesions that appear on the scalp, ears, neck, and back.
- Occipital and cervical adenopathy may develop, especially when lesions become superinfected.
- Body lice result in small maculopapular eruptions that are predominantly found on the trunk (**Figure 142-1**) and the clothing (**Figure 142-2**).
- Chronic infestations often result in hyperpigmented, lichenified plaques known as “vagabond’s skin.”⁸
- Pubic lice produce bluish-gray spots (macula cerulea) that can be found on the chest, abdomen, and thighs.⁸

TYPICAL DISTRIBUTION

- Head lice—Look for nits and lice in the hair especially above the ears, behind the ears, and at the nape of the neck. There are many more nits present than live adults. Finding nits without an adult louse does not mean that the infestation has resolved (**Figures 142-6** and **142-7**). Systematically combing wet or dry hair with a fine toothed nit comb (teeth of comb are 0.2 mm apart) better detects active louse infestation than visual inspection of the hair and scalp alone.⁹
- Body lice—Look for the lice and larvae in the seams of the clothing (**Figure 142-2**).
- Pubic lice—Look for nits and lice on the pubic hairs (**Figure 142-9**). These lice and their nits may also be seen on the hairs of the upper thighs, abdomen, axilla, beard, eyebrows, and eyelashes. Little specks of dried blood may be seen in the underwear as a clue to the infestation.

LABORATORY TESTING

- Direct visualization and identification of live lice or nits are sufficient to make a diagnosis (**Figures 142-2** to **142-7** and **142-9**).
- The use of a magnification lens may aid in the detection or confirmation of lice infestation.
- Under Wood light the head lice nits fluoresce a pale blue.
- If you find an adult louse put it on a slide with a cover slip loosely above it. Look at it under the microscope on the lowest power (**Figures 142-4** and **142-5**). You will see the internal workings of the live organs. If the louse was not found in a typical location, you can use the morphology of the body and legs to determine the type of louse causing the infestation.
- In cases of pubic lice infestations, individuals should be screened for other sexually transmitted diseases.⁵

DIFFERENTIAL DIAGNOSIS

- Dandruff, hair casts, and debris should be ruled out in cases of suspected lice infestations. Unlike nits, these particles are easily removed from the hair shaft. In addition, adult lice are absent.
- Scabies is also characterized by intense pruritus and papular eruptions. Unlike lice infestations, scabies may be associated with vesicles, and the presence of burrows is pathognomonic. Diagnosis is

FIGURE 142-6 Pearly nits on the hair of a schoolgirl. (Courtesy of Richard P. Usatine, MD.)

FIGURE 142-7 Massive infestation of head lice on a mentally ill homeless person. (Courtesy of Richard P. Usatine, MD.)

FIGURE 142-8 Microscopic view of a nit cemented to the hair and about to hatch. (Courtesy of Dan Stulberg, MD.)

confirmed by microscopic examination of the scrapings from lesions for the presence of mites or eggs (see Chapter 143, Scabies).

MANAGEMENT

NONPHARMACOLOGIC

- In young children or others who wish to avoid topical pediculicides for head lice, mechanical removal of lice by wet combing is an alternative therapy. A 1:1 vinegar: water rinse (left under a conditioning cap or towel for 15 to 20 minutes) or 8% formic acid crème rinse may enhance removal of tenacious nits.⁸ Combing is performed until no lice are found for 2 weeks. **SOR B**
 - Nits are also removed with a fine-toothed comb following the application of all treatments. This step is critical in achieving resolution.
 - Combs and hairbrushes should be discarded, soaked in hot water (at a temperature of at least 55°C [130°F]) for 5 minutes, or treated with pediculicides.¹⁰

MEDICATIONS

- *Pediculus humanus capitis* (head lice):
 - Nonprescription 1% permethrin cream rinse (Nix), pyrethrins with piperonyl butoxide (which inhibits pyrethrin catabolism; RID) shampoo, or permethrin 1% is applied to the hair and scalp and left on for 10 minutes then rinsed out.¹¹ **SOR A**
 - Pyrethrins are only pediculicidal, whereas permethrin is both pediculicidal and ovicidal. It is important to note that treatment failure is common with these agents owing to the emergence of resistant strains of lice.
 - After 7 to 10 days repeating the application is optional when permethrin is used, but is a necessary for pyrethrin. Lice persisting after treatment with a pyrethroid may be an indication of resistance.
 - Malathion 0.5% (Ovide) is available by prescription only, and is a highly effective pediculicidal and ovicidal agent for resistant lice. Malathion may have greater efficacy than pyrethrins.¹² It is approved for use in children age 6 years and older. The lotion is applied to dry hair for 8 to 12 hours and then washed. Repeat application is recommended after 7 to 10 days if live lice are still present. When used appropriately, malathion is 78% to 95% effective.¹² **SOR A**
 - Benzyl alcohol 5% lotion (Ulesfia) is a newer treatment option in patients 6 months of age and older. It works by asphyxiating the parasite. It is applied for 10 minutes with saturation of the scalp and hair, and then rinsed off with water. The treatment is repeated after 7 days.¹³ **SOR A**
 - Spinosad (Natroba) is a new topical prescription medication approved by the FDA in 2011 for the treatment of lice. Spinosad is a fermentation product of the soil bacterium *Saccharopolyspora spinosa* that compromises the central nervous system of lice. It is approximately 85% effective in lice eradication, usually after one application. It is applied to completely cover the dry scalp and hair, and rinsed off after 10 minutes. Treatment should be repeated if live lice remain 7 days after the initial application.¹⁴ **SOR A**
 - In February 2012, the U.S. FDA approved ivermectin 0.5% lotion for the treatment of head lice. It is applied as a single

FIGURE 142-9 Crab lice infesting pubic hair. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

10-minute topical application. The safety of ivermectin in infants younger than age 6 months has not been established.¹⁵ **SOR A**

- Hair conditioners should not be used prior to the application of pediculicides; these products may result in reduced efficacy.¹⁶
- A Cochrane review found no evidence that any one pediculicide was better than another; permethrin, synergized pyrethrin, and malathion were all effective in the treatment of head lice.¹⁷ **SOR A**
- Other therapeutic options include permethrin 5% cream and lindane 1% shampoo. Permethrin 5% is conventionally used to treat scabies; however, it is anecdotally recommended for treatment of recalcitrant head lice.⁵ **SOR C**
- Lindane is considered a second-line treatment option owing to the possibility of central nervous system toxicity, which is most severe in children.
- Oral therapy options include a 10-day course of trimethoprim-sulfamethoxazole or 2 doses of ivermectin (200 mcg/kg) 7 to 10 days apart. **SOR C** Trimethoprim-sulfamethoxazole is postulated to kill the symbiotic bacteria in the gut of the louse.⁴ Combination therapy with 1% permethrin and trimethoprim-sulfamethoxazole is recommended in cases of multiple treatment failure or suspected cases of resistance to therapy.^{5,10} **SOR C**
- *Pediculus humanus corporis* (body lice):
 - Improving hygiene, and laundering clothing and bed linen at temperatures of 65°C (149°F) for 15 to 30 minutes will eliminate body lice.⁸
 - In settings where individuals cannot change clothing (e.g., indigent population), a monthly application of 10% lindane powder can be used to dust the lining of all clothing.⁸
 - Additionally, lindane lotion or permethrin cream may be applied to the body for 8 to 12 hours to eradicate body lice.
- *Phthirus pubis* (pubic lice):
 - Pubic lice infestations are treated with a 10-minute application of the same topical pediculicides used to treat head lice.
 - Retreatment is recommended 7 to 10 days later.
 - Petroleum ointment applied 2 to 4 times a day for 8 to 10 days will eradicate eyelash infestations.
 - Clothing, towels, and bed linen should also be laundered to eliminate nit-bearing hairs.⁸

PREVENTION

- Washing clothing and linen used by the head or pubic lice-infested person during the 2 days prior to therapy in hot water and/or drying the items on a high-heat dryer cycle (54.5°C [130°F].) Items that cannot be washed may be dry cleaned or stored in a sealed plastic bag for 2 weeks.

FOLLOW-UP

- Patients should be reexamined upon completion of therapy to confirm eradication of lice.

PATIENT EDUCATION

- Patients should be instructed to wash potentially contaminated articles of clothing, bed linen, combs, brushes, and hats.
- Nit removal is important in preventing continued infestation as a result of new progeny. Careful examination of close contacts, with appropriate treatment for infested individuals is important in avoiding recurrence.
- In cases of pubic lice, all sexual contacts should be treated.

143 SCABIES

Richard P. Usatine, MD
Pierre Chanoine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 2-year-old boy is seen with severe itching and crusting of his hands (**Figures 143-1** and **143-2**). He also has a pruritic rash over the rest of his body. The child has had this problem since 2 months of age and has had a number of treatments for scabies. Other adults and children in the house have itching and rash. Various attempts at treatment have only included topical preparations. A scraping was done and scabies mites and scybala (feces) were seen (**Figures 143-3** and **143-4**). The child and all the family members were put on ivermectin simultaneously and the Norwegian scabies cleared from the child. The family cleared as well and the child was given a repeat dose of ivermectin to avoid relapse.

SYNONYMS

Seven-year itch.

EPIDEMIOLOGY

- Three hundred million cases per year are estimated worldwide.¹ In some tropical countries, scabies is endemic.
- The incidence of scabies in a study performed in general practices in England and Wales was 351 per 100,000 person-years in men and 437 per 100,000 person-years in women.²
- Data from the Royal Infirmary in Edinburgh show that 5% of patients with skin disease between 1815 and 2000 had scabies; the prevalence during wartime reached over 30%.³

ETIOLOGY AND PATHOPHYSIOLOGY

- Human scabies is caused by the mite *Sarcoptes scabiei*, an obligate human parasite (**Figure 143-3**).^{1,4}
- Adult mites spend their entire life cycle, around 30 days, within the epidermis. After copulation the male mite dies and the female mite burrows through the superficial layers of the skin excreting feces (**Figure 143-4**) and laying eggs (**Figure 143-5**).
- Mites move through the superficial layers of skin by secreting proteases that degrade the stratum corneum.
- Infected individuals usually have less than 100 mites. In contrast, immunocompromised hosts can have up to 1 million mites, and are susceptible to crusted scabies also called Norwegian scabies (**Figures 143-1**, **143-2**, and **143-6** to **143-10**).¹
- Transmission usually occurs via direct skin contact. Scabies in adults is frequently sexually transmitted.⁵ Scabies mites can also be transmitted from animals to humans.¹

FIGURE 143-1 Crusted scabies (Norwegian scabies) in a 2-year-old boy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 143-2 The boy in **Figure 143-1** with a close-up of his hand showing crusting and a fissure. (Courtesy of Richard P. Usatine, MD.)

- Mites can also survive for 3 days outside of the human epidermis allowing for infrequent transmission through bedding and clothing.
- The incubation period is on average 3 to 4 weeks for an initial infestation. Sensitized individuals can have symptoms within hours of reexposure.

RISK FACTORS

- Scabies is more common in young children, healthcare workers, homeless and impoverished persons, and individuals who are immunocompromised or suffering from dementia.¹
- Institutionalized individuals and those living in crowded conditions also have a higher incidence of the infestation.¹

DIAGNOSIS

CLINICAL FEATURES

- Pruritus is a hallmark of the disease.¹
- Skin findings include papules (**Figure 143-10**), burrows (**Figure 143-11** and **143-12**) nodules (**Figures 143-13**), and vesiculopustules (**Figure 143-14**).
- Burrows are the classic morphologic finding in scabies and the best location to find the mite (**Figures 143-11** and **143-12**).
- Infants and young children can also exhibit irritability and poor feeding.
- Pruritic papules/nodules around the axillae (**Figure 143-13**), umbilicus, or on the penis and scrotum (**Figure 143-15** and **143-16**) are highly suggestive of scabies.

TYPICAL DISTRIBUTION

- Classic distribution in scabies includes the interdigital spaces (**Figure 143-17**), wrists, ankles (**Figure 143-18**), waist (**Figures 143-19** and **143-20**), groin, axillae (**Figure 143-13**), palms, and soles (**Figures 143-1**, **143-2**, **143-6**, and **143-7**).
- Genital involvement can also occur (**Figures 143-15** and **143-16**).
- In children, the head can also be involved (**Figure 143-21**).

LABORATORY STUDIES AND IMAGING

- Light microscopy of skin scrapings provides a definitive diagnosis when mites, eggs, or feces are identified (**Figures 143-3** to **143-5**). This can be challenging and time-consuming, even when mites, eggs, or feces are present. Packing tape stripping of skin has also been used instead of a scalpel to find mites for examination under the microscope.⁶ The inability to find these items should not be used to rule out scabies in a clinically suspicious case. In what is believed to be a recurrent case, it is helpful to find definitive evidence that your diagnosis is correct.
- Dermoscopy is a useful and rapid technique for identifying a scabies mite at the end of a burrow (see Appendix 3: Dermoscopy).⁷ The mite has been described as an arrowhead or a jet plane in its appearance (**Figure 143-22**). The advantage of the dermoscope is

FIGURE 143-20 Scabies around the waist showing postinflammatory hyperpigmentation along with multiple papules and some crusting. (Courtesy of Richard P. Usatine, MD.)

FIGURE 143-22 Two scabies mites visible with dermoscopy. Note how the darkest most visible aspect of the mite looks like an arrowhead or jet plane. In this case the oval bodies of the mites are also visible. The upper right inset shows the same burrows without dermoscopy. (Courtesy of Richard P. Usatine, MD.)

that multiple burrows can be examined quickly without causing any pain to the patient. Children are more likely to stay still for this than scraping with a scalpel or skin stripping with tape.

- If a dermoscope is available, start with this noninvasive examination. If the findings are typical, then a microscopic examination is not needed. If the findings are not convincing, or a dermoscope is not available, perform a scraping. It is best to scrape the skin at the end of a burrow. Use a #15 scalpel that has been dipped into mineral oil or microscope immersion oil. Scrape holding the blade perpendicular to the skin until the burrow (or papule) is opened (some slight bleeding is usual). Transfer the material to a slide and add a cover slip.
- Tips for microscopic examination—Start by examining the slide with the lowest power available as mites may be seen under 4 power and the slide can be scanned most quickly with the lowest power. If no mites are seen switch to 10 power and scan the slide again looking for mites, eggs, and feces. Forty power may be used to confirm findings under 10 power.
- In one study comparing dermoscopic mite identification with microscopic examination of skin scrapings, found the former technique to be of comparable sensitivity (91% and 90%, respectively) with specificity of 86% (vs. 100% by definition), even in inexperienced hands.⁸ Another study reported sensitivity of dermoscopy at 83% (95% confidence interval, 0.70 to 0.94).⁹ In this study, the negative predictive value was identical for dermoscopy and the adhesive tape test (0.85), making the latter a good screening test in resource-poor areas.
- Videodermoscopy can also be used to diagnose scabies.¹⁰ Videodermoscopy allows for skin magnification with incidental lighting at high magnifications for viewing mites and eggs. The technique is noninvasive and does not cause pain.
- *S. scabiei* recombinant antigens have diagnostic potential and are under investigation for identifying antibodies in individuals with active scabies.¹¹

BIOPSY

Rarely necessary unless there are reasons to suspect another diagnosis.

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis—Itching is a prominent symptom in atopic dermatitis and scabies. The distribution of involved skin can help to differentiate the 2 diagnoses. Look for burrows in scabies and a history of involved family members. In children, atopic dermatitis is often confined to the flexural and extensor surfaces of the body. In adults, the hands are a primary site of involvement (see Chapter 145, Atopic Dermatitis).
- Contact dermatitis—Characterized by vesicles and papules on bright red skin, which are rare in scabies. Chronic contact dermatitis often leads to scaling and lichenification and may not be as pruritic as scabies (see Chapter 146, Contact Dermatitis).
- Seborrheic dermatitis—A papulosquamous eruption with scales and crusts that is limited to the sebum rich areas of the body; namely, the scalp, the face postauricular areas, and the

intertriginous areas. Pruritus is usually mild or absent (see Chapter 151, Seborrheic Dermatitis).

- Impetigo—Honey-crusted plaques are a hallmark of impetigo. Scabies can become secondarily infected, so consider that both diagnoses can occur concomitantly with papules and pustules present (**Figure 143-23**) (see Chapter 116, Impetigo).
- Arthropod bites—Bites may exhibit puncta that allow for differentiation from scabies.
- Acropustulosis of infancy (**Figure 143-24**)—A vesicopustular recurrent eruption limited to the hands, wrists, feet, and ankles. It is rare after 2 years of age (see Chapter 110, Pustular Diseases of Childhood).

MANAGEMENT

NONPHARMACOLOGIC

- Environmental decontamination is a standard component of all therapies. **SOR B** Clothing, bed linens, and towels should be machine washed in hot water. Clothing or other items (e.g., stuffed animals) that cannot be washed may be dry cleaned or stored in sealed bags for at least 72 hours.¹²

MEDICATIONS

Treatment includes administration of an antiscabicide and an antipruritic.^{1,13}

- Permethrin 5% cream (Elimite, Acticin) is the most effective treatment based upon a systematic review in the Cochrane Database.¹³ **SOR A** The cream is applied from the neck down (include the head when it is involved) and rinsed off 8 to 14 hours later. Usually, this is done overnight. Repeating the treatment in 1 to 2 weeks may be more effective. **SOR C** In patients with crusted scabies, use of a keratolytic cream may facilitate the breakdown of skin crusts and improve penetration of the cream.¹⁴ Unfortunately, scabies resistance to permethrin is increasing.
- Ivermectin is an oral treatment for resistant or crusted scabies. Studies have demonstrated its safety and efficacy. Most studies used a single dose of ivermectin at 200 mcg/kg.¹³ **SOR A** Taking the drug with food may enhance drug penetration into the epidermis.¹⁴ Some experts advocate repeating a dose 1 week later. It is worth noting that the FDA has not labeled this drug for use in children weighing less than 15 kg. Ivermectin is currently available only in 3- and 6-mg tablets, so dosing often needs to be rounded up to accommodate the use of whichever tablets are available. As there is no oral suspension available, tablets may need to be cut and given with food for use in children.
- Diphenhydramine, hydroxyzine, and mid-potency steroid creams can be used for symptomatic relief of itching. **SOR C** It is important to note that pruritus may persist for 1 to 2 weeks after successful treatment because the dead scabies mites and eggs still have antigenic qualities that may cause persistent inflammation.
- All household or family members living in the infested home and sexual contacts should be treated. **SOR C** Failure to treat all involved individuals often results in recurrences within the family. Use of insecticide sprays and fumigants is not recommended.

FIGURE 143-23 A. Superinfected scabies from head to toe in this young boy. B. Note the large pustules on the foot of this boy demonstrating the bacterial superinfection. (Courtesy of Richard P. Usatine, MD.)

FIGURE 143-24 Infantile acropustulosis in a 9-month-old child that was mistakenly treated for scabies. No one else in the household had lesions and the scabies treatment did not lead to resolution of the pustules and vesicles. (Courtesy of Richard P. Usatine, MD.)

- Other less-effective medications include topical benzyl benzoate, crotamiton, lindane (no longer used in the United States because of concerns regarding neurotoxicity), and synergized natural pyrethrins.⁹ **SOR A** Topical agents used more commonly in other countries include 5% to 10% sulfur in paraffin (widely in Africa and South America), 10% to 25% benzyl benzoate (often used in Europe and Australia), and malathion.¹⁴ In infants younger than 2 months of age, crotamiton or a sulfur preparation is recommended by one author instead of permethrin because of theoretical concerns of systemic absorption of permethrin.¹⁴
- Antibiotics are needed if there is evidence of a bacterial superinfection (**Figure 143-23**). **SOR C**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Tea tree oil contains oxygenetic terpenoids, found to have rapid scabicial activity.¹⁵

PREVENTION

- Avoid direct skin-to-skin contact with an infested person or with items such as clothing or bedding used by an infested person.
- Treat members of the same household and other potentially exposed persons at the same time as the infested person to prevent possible reexposure and reinfestation.

PROGNOSIS

- The prognosis with proper diagnosis and treatment is excellent unless the patient is immunocompromised; reinfestation, however, often occurs if environmental risk factors continue.¹
- Postinflammatory hyper- or hypopigmentation can occur.¹

FOLLOW-UP

- Routine follow-up is indicated when symptoms do not resolve.
- Consider an immunologic work-up for individuals with crusted scabies.

PATIENT EDUCATION

- Patients should avoid direct contact including sleeping with others until they have completed the first application of the medicine.
- Patients may return to school and work 24 hours after first treatment.
- Patients should be warned that itching may persist for 1 to 2 weeks after successful treatment but that if symptoms are still present by the third week, the patient should return for further evaluation.

144 CUTANEOUS LARVA MIGRANS

Jennifer A. Keehbauch, MD

PATIENT STORY

A mother brought her 18-month-old son to the physician's office for an itchy rash on his feet and buttocks (**Figures 144-1** and **144-2**).¹ The first physician examined the child and made the incorrect diagnosis of tinea corporis. The topical clotrimazole cream failed. The child was unable to sleep because of the intense itching and was losing weight secondary to his poor appetite. He was taken to an urgent care clinic where the physician learned that the family had returned from a trip to the Caribbean prior to the visit to the first physician. The child had played on beaches that were frequented by local dogs. The physician recognized the serpiginous pattern of cutaneous larva migrans (CLM) and successfully treated the child with oral ivermectin. The child was 15 kg so the dose was 3 mg (0.2 mg/kg) and the tablet was ground up and placed in applesauce.

SYNONYMS

Creeping eruption, Plumber's itch.

EPIDEMIOLOGY

- Endemic in developing countries, particularly Brazil, India, South Africa, Somalia, Malaysia, Indonesia, and Thailand.^{2,3}
- Peak incidence in the rainy seasons.³
- During peak rainy seasons, the prevalence in children is as high as 15% in resource poor areas, but much less common in affluent communities in these same countries with only 1 to 2 per 10,000 individuals per year.⁴
- In the United States, it is found predominantly in Florida, southeastern Atlantic states, and the Gulf Coast.²
- Children are more frequently affected than adults.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused most commonly by dog and cat hookworms (i.e., *Ancylostoma braziliense*, *Ancylostoma caninum*, *Uncinaria stenocephala*).⁴
- Eggs are passed in cat or dog feces.²
- Larvae are hatched in moist, warm, sand/soil.²
- Infective stage larvae penetrate the skin.²

DIAGNOSIS

The diagnosis is based on history and clinical findings.

FIGURE 144-1 The serpiginous rash of cutaneous larva migrans on the foot of an 18-month-old boy after a family trip to the beaches of the Caribbean. (Courtesy of Richard P. Usatine, MD. Usatine RP. A rash on the feet and buttocks. *West J Med.* 1999;170(6):344-335.)

FIGURE 144-2 Cutaneous larva migrans on the buttocks and thigh of the same boy showing significant excoriations. (Courtesy of Richard P. Usatine, MD. Usatine RP. A rash on the feet and buttocks. *West J Med.* 1999;170(6):344-335.)

CLINICAL FEATURES

- Elevated, serpiginous, or linear reddish-brown tracks 1 to 5 cm long (**Figures 144-1 to 144-3**).^{2,5}
- Intense pruritus, which often disrupts sleep.³
- Symptoms last for weeks to months, and, rarely, years. Most cases are self-limiting.⁵

TYPICAL DISTRIBUTION

- Feet and lower extremities (73%), buttocks (13% to 18%), and abdomen (16%).^{6,7}
- Areas that come in contact with contaminated skin.
 - Most commonly the feet, buttocks, and thigh.³

LABORATORY AND IMAGING

- Not indicated, but rarely blood tests shows Eosinophilia or elevated immunoglobulin E levels.⁵

DIFFERENTIAL DIAGNOSIS

May be confused with the following conditions:

- Cutaneous fungal infections—Lesions are typically scaling plaques and annular macules with central clearing. If the serpiginous track of CLM is circular, this can lead to the incorrect diagnosis of “ringworm.” The irony is that ringworm is a dermatophyte fungus whereas CLM really is a worm (see Chapter 138, Tinea Corporis).
- Contact dermatitis—Differentiate by distribution of lesions, presence of vesicles, and absence of classical serpiginous tracks (see Chapter 146, Contact Dermatitis).
- Erythema migrans of Lyme disease—Lesions are usually annular macules or patches and are not raised and serpiginous (see Chapter 218, Lyme Disease).
- Phytophotodermatitis—The acute phase of phytophotodermatitis is erythematous with vesicles; this later develops into postinflammatory hyperpigmented lesions. This may be acquired while preparing drinks with lime on the beach and not from the sandy beach infested with larvae (see Chapter 199, Photosensitivity).

MANAGEMENT

- Oral thiabendazole was the first proven therapy with FDA approval. It was removed from the market in 2010.
- Ivermectin (Stromectol) lacks FDA indication, but has been well studied and is the current drug of choice.³
 - A single dose of ivermectin 0.2 mg/kg is recommended.³ **SOR B**
 - Cure rates of 77% to 100% with a single dose.³
 - Ivermectin has been used worldwide on millions with an excellent safety profile.³
 - Ivermectin is contraindicated in pregnancy, breastfeeding mothers, and in children weighing less than 15 kg.³
- Albendazole has been successfully prescribed for more than 25 years, and is the Centers for Disease Control and Prevention (CDC) drug of choice.⁵

FIGURE 144-3 Close-up of a serpiginous burrow from cutaneous larva migrans on the leg. The actual larva is 2 to 3 cm beyond the visible tracks. (Courtesy of John Gonzalez, MD.)

- Albendazole also lacks FDA indication and the recommended dose is 400 mg daily for 3 to 7 days.^{3,5}
- Cure rates with albendazole exceed 92%, but it is less with single dosage.³
- Studies on compounded ivermectin and albendazole for topical use are limited, but promising for use in children.³
- Cryotherapy is ineffective and harmful and should be avoided.³ **SOR B**

ADJUNCT THERAPY

- Antihistamines may relieve itching.
- Antibiotics may be used if secondary infection occurs.

PATIENT EDUCATION

- Wear shoes on beaches where animals are allowed.
- Keep covers on sand boxes.
- Pet owners should keep pets off the beaches, deworm pets, and dispose of feces properly.

FOLLOW-UP

- Follow-up if lesions persist.

SECTION 7 DERMATITIS/ALLERGIC

145 ATOPIC DERMATITIS

Richard P. Usatine, MD
Lindsey B. Finklea, MD

PATIENT STORY

A 1-year-old Asian American girl is brought to her family physician for a new rash on her face and legs (**Figures 145-1** and **145-2**). The child is scratching both areas but is otherwise healthy. There is a family history of asthma, allergic rhinitis, and atopic dermatitis (AD) on the father's side. The child responded well to low-dose topical corticosteroids and emollients.

INTRODUCTION

AD is a chronic and relapsing inflammatory skin disorder characterized by itching and inflamed skin that is triggered by the interplay of genetic, immunologic, and environmental factors.

SYNONYMS

Eczema, atopic eczema.

EPIDEMIOLOGY

- AD is the most frequent inflammatory skin disorder in the United States and the most common skin condition in children.¹
- Worldwide prevalence in children is 15% to 20% and is increasing in industrialized nations.²
- Sixty percent of cases begin during the first year of life and 90% by 5 years of age.¹ One third will persist into adulthood.²
- Sixty percent of adults with AD have children with AD (**Figure 145-3**).¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Strong familial tendency, especially if atopy is inherited from the maternal side.
- Associated with elevated T-helper (Th) 2 cytokine response, elevated serum immunoglobulin (Ig) E, hyperstimulatory Langerhans cells, defective cell-mediated immunity, and loss of function mutation in filaggrin, an epidermal barrier protein.
- Exotoxins of *Staphylococcus aureus* act as superantigens and stimulate activation of T-cells and macrophages, worsening AD without actually showing signs of superinfection.

FIGURE 145-1 Atopic dermatitis on the cheeks of an infant. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2004.)

FIGURE 145-2 Atopic dermatitis on the leg of the infant in **Figure 145-1**. The coin-like pattern is that of nummular eczema. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2004.)

- Patients may have a primary T-cell defect. This may be why they can get more severe skin infections caused by herpes simplex virus (eczema herpeticum as seen in **Figure 145-4**) or bacteria (widespread impetigo). They are also at risk of a bad reaction to the smallpox vaccine with dissemination of the attenuated virus beyond the vaccination site. Eczema vaccinatum is a potentially deadly complication of smallpox vaccination (**Figure 145-5**).

DIAGNOSIS

- History—Pruritus is the hallmark symptom of AD. It is referred to as “the itch that rashes” as patients will often feel the need to scratch before a primary lesion appears. If it does not itch, it is not AD. Persons with AD often have a personal or family history of other allergic conditions, namely asthma and allergic rhinitis.
- The atopic triad is AD, allergic rhinitis, and asthma. Atopic persons have an exaggerated inflammatory response to factors that irritate the skin.
- Physical examination—Primary lesions include vesicles, scale, papules, and plaques.
- Secondary (or sequential) lesions include linear excoriations from scratching or rubbing which may result in lichenification (thickened skin with accentuation of skin lines), fissuring, and prurigo nodularis. Crust may indicate that a secondary infection has occurred. Postinflammatory hyperpigmentation and follicular hyperaccentuation (more prominent hyperkeratotic follicles) (**Figure 145-6**) may also be identified.

TYPICAL DISTRIBUTION

- AD often starts on the face in infancy and childhood (**Figures 145-1** and **145-7**) and then appears in the flexural folds, especially the antecubital and popliteal fossa (**Figures 145-8** to **145-10**).
- Involvement of the neck, wrists, and ankles also may occur (**Figures 145-11** and **145-12**).
- AD in adults can occur on the hands, around the mouth, or eyelids as well as all the other areas (**Figures 145-13** and **145-14**).
- In one series, the prevalence of hand involvement in patients with active AD was 58.9%. There was a significant trend toward an increasing prevalence of hand involvement with increasing age.³

OTHER FEATURES OR CONDITIONS ASSOCIATED WITH ATOPIC DERMATITIS

- Keratosis pilaris (**Figure 145-15**).
- Ichthyosis (**Figure 145-16**).
- Pityriasis alba (**Figures 145-17** and **145-18**).
- Palmar or plantar hyperlinearity.
- Dennie-Morgan lines (infraorbital fold) (**Figure 145-14**).
- Hand or foot dermatitis (see Chapter 147, Hand Eczema).
- Cheilitis (see Chapter 32, Angular Cheilitis).
- Susceptibility to cutaneous infections (**Figures 145-4** and **145-5**).
- Xerosis (dry skin) (**Figure 145-19**).
- Eye findings—Recurrent conjunctivitis, keratoconus (**Figure 145-20**), cataracts, orbital darkening.

FIGURE 145-3 The child and his mother both have atopic dermatitis but not in the most typical distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 145-16 Acquired ichthyosis on the leg of a 9-year-old boy with atopic dermatitis. Note the fish-scale appearance along with the dry skin. (Courtesy of Richard P. Usatine, MD.)

FIGURE 145-18 An 18-month-old girl with atopic dermatitis visible in her popliteal fossa and pityriasis alba on her arm. (Courtesy of Richard P. Usatine, MD.)

- A horizontal nasal crease may be seen over the bridge of the nose in a patient with allergic rhinitis prone to performing the allergic salute. In some patients this crease may become hyperpigmented (**Figure 145-21**).

LABORATORY STUDIES

Labs are rarely needed if the history and physical examination support the diagnosis. Occasionally, a KOH preparation may be needed to rule out tinea or a skin scraping to rule out scabies. Of course, both of these conditions can occur on top of AD. RAST (radioallergen sorbent test) testing for food allergies and serum IgE levels are not of proven benefit.

DIFFERENTIAL DIAGNOSIS

- Dyshidrotic eczema—Dry inflamed scaling skin on the hands and feet with tapioca-like vesicles, especially seen between the fingers (see Chapter 147, Hand Eczema).
- Seborrheic dermatitis—Greasy, scaly lesions on scalp, face, and chest (see Chapter 151, Seborrheic Dermatitis).
- Psoriasis—Thickened plaques on extensor surfaces, scalp, and buttocks; pitted nails (see Chapter 152, Psoriasis).
- Lichen simplex chronicus (sometimes called neurodermatitis)—Usually, a single patch in an area accessible to scratching such as the ankle, wrist, and neck (see Chapter 149, Self-Inflicted Dermatoses).
- Contact dermatitis—Positive exposure history, rash in area of exposure; absence of family history. Patch testing may be helpful in distinguishing from AD (see Chapter 146, Contact Dermatitis).
- Scabies—Papules, burrows, finger web involvement, positive skin scraping (see Chapter 143, Scabies).
- Dermatophyte infection—On the hands or feet can look just like hand or foot dermatitis; a positive KOH preparation for hyphae can help make the diagnosis (see Chapter 140, Tinea Pedis).

MANAGEMENT

- There is some evidence suggesting that controlling house dust mites reduces severity of symptoms in patients with the atopic triad. Bedding covers were found to be the most effective method to control dust mites and AD symptoms in this subgroup of AD patients. Unfortunately, dust mite interventions are not proven to be effective for patients with AD that do not have the full atopic triad.¹ **SOR B**
- Dietary restriction is controversial but may be useful for infants with proven egg allergies. **SOR B** There is insufficient evidence that dietary manipulation in children or adults reduces symptom severity and may cause iatrogenic malnourishment.
- Patient education, avoidance of possible triggers (enzyme-rich detergents, wool clothing), and dry skin care should be optimized.
- Dilute bleach baths (0.5 cup of 6% bleach in tub of bath water) lower the *S. aureus* burden on the skin, decreasing severity of AD.⁴ **SOR B**

FIGURE 145-19 Severe atopic dermatitis in a 2-year-old black boy with very dry (xerotic) skin. He is spontaneously scratching and crying out in discomfort. (Courtesy of Richard P. Usatine, MD.)

FIGURE 145-20 Keratoconus in a young woman with severe atopic dermatitis. She admits to rubbing her eyes frequently. In keratoconus the cornea bulges out in the middle like a cone and can adversely affect the health of the eye. (Courtesy of Richard P. Usatine, MD.)

- There is some evidence suggesting probiotic treatment of pregnant mother and prolonged nursing of child may delay onset of AD.¹

SOR **B**

TOPICAL THERAPIES

- Topical steroids and emollients have been proven to work for AD and are the mainstay of treatment.¹ SOR **A**
- Vehicle selection and steroid strength area based on age, body location, and lesion morphology. The ointments are best for dry and cracked skin and are more potent. Creams are easier to apply and are better tolerated by some patients.
- Use stronger steroids for thicker skin, severe outbreaks, or lesions that have not responded to weaker steroids. Avoid strong steroids on face, genitals, and armpits and in infants and small children.
- To avoid adverse effects, the highest potency steroids (e.g., clobetasol) should not be used for longer than 2 weeks continuously. However, they can be used intermittently for recurring AD in a pulse-therapy mode (e.g., apply every weekend, with no application on weekdays).
- Topical calcineurin inhibitors (immunomodulators, such as pimecrolimus and tacrolimus) reduce the rash severity and symptoms in children and adults.¹ SOR **A** These work by suppressing antigen-specific T-cell activation and inhibiting inflammatory cytokine release. These are steroid-sparing medications that are helpful for eyelid eczema and in other areas when steroids may thin the skin (**Figure 145-22**). These agents are now only approved for persons older than 2 years of age and the FDA states that they should not be used as first-line agents because of a possible risk of causing cancer. The American Academy of Dermatology (AAD) has released a statement that the “data does not prove that the proper topical use of pimecrolimus and tacrolimus is dangerous.”
- Short-term adjunctive use of topical doxepin may aid in the reduction of pruritus.¹ SOR **A**
- Topical and systemic antibiotics are used for AD that has become secondarily infected with bacteria. The most common infecting organism is *S. aureus*. Weeping fluid and crusting during an exacerbation should prompt consideration of antibiotic use¹ (**Figures 145-7, 145-8, and 145-23**). SOR **A**

ORAL/SYSTEMIC THERAPIES

- For extensive flares, consider oral prednisone or an IM shot of triamcinolone (40 mg in 1 mL of 40 mg/mL suspension for adults).¹ SOR **C**
- The value of antihistamines in AD is controversial. If antihistamines are to be used, the sedating agents are most effective and can be given at night.¹ SOR **B**
- Cyclosporine for severe refractory AD can be used in long-term maintenance therapy to treat and avoid relapse.¹ SOR **A** Cyclosporine is approved for 1 year of lifetime therapy for skin diseases in the United States and 2 years in Europe (**Figure 145-24**).
- UV phototherapy may also be used in severe refractory AD with some success.¹ SOR **A**
- Azathioprine, methotrexate, and mycophenolate mofetil are of possible benefit, but there is less evidence for their effectiveness.¹ SOR **C**

FIGURE 145-21 Hyperpigmented horizontal nasal crease in a patient with the atopic triad who repeatedly performs the allergic salute when her nose is feeling itchy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 145-22 Atopic dermatitis involving the eyelids in this 19-year-old woman with relatively severe atopic dermatitis since infancy. A topical calcineurin inhibitor helped to get the eyelid eczema under control. (Courtesy of Richard P. Usatine, MD.)

TABLE 145-1 Written Action Plan to Be Given to Patients (or Their Parents)

No skin lesions or dry skin	Prevention: Emollients, dry skin care, fragrance-free detergent, no drier sheets, once weekly bleach bath
Mild flare	Prevention plus low-mid potency topical steroid and/or calcineurin inhibitors (e.g., hydrocortisone 2.5% or tacrolimus 0.1% to face, axillae, genitals; desonide 0.1% or triamcinolone 0.1% to body)
Moderate flare	Prevention plus mid-high potency topical steroids and/or calcineurin inhibitor (e.g., triamcinolone under wet pajamas bid to clobetasol for short course)
Severe flare	Systemic therapy

Source: Adapted from Rance F, Boguniewicz M, and Lau S,² and from Chisolm SS, Taylor SL, Balkrishnan R, et al.⁵

PATIENT EDUCATION

Patients need to know that scratching their AD makes it worse. Behavior modification is especially challenging in young children and may involve cutting fingernails short and occluding hands/body at night with cotton gloves or clothing. Because of its chronicity and cyclic nature, AD patients may have poor adherence. In one recent study, overall adherence was 32%. A written action plan may be employed to improve adherence (**Table 145-1**).

FOLLOW-UP

Regular follow-up should be given to patients with chronic and difficult-to-control AD. Establishing a good regimen is crucial to good control and then visits may be adjusted to longer intervals between visits.

146 CONTACT DERMATITIS

Richard P. Usatine, MD

PATIENT STORY

A 38-year-old woman twisted her right ankle and applied a Chinese medicine patch to relieve the pain. The following day the patient developed a severe contact dermatitis (CD) with many small vesicles (<5 mm) and bullae (>5 mm) (**Figure 146-1**). The erythema had a well-demarcated border and was traced by the doctor's pen. Cold compresses and a high potency topical steroid were prescribed. When the patient showed little improvement a 2-week course of oral prednisone was given starting with 60 mg daily and tapering down to 5 mg daily. The patient responded rapidly and the CD fully resolved.^{1,2}

INTRODUCTION

CD is a common inflammatory skin condition characterized by erythematous and pruritic skin lesions resulting from the contact of skin with a foreign substance. Irritant contact dermatitis (ICD) is caused by the non-immune-modulated irritation of the skin by a substance, resulting in a skin changes. Allergic contact dermatitis (ACD) is a delayed-type hypersensitivity reaction in which a foreign substance comes into contact with the skin, and upon reexposure, skin changes occur.³

EPIDEMIOLOGY

- Some of the most common types of CD are secondary to exposures to poison ivy, nickel, and fragrances.⁴
- Patch testing data indicate that the five most prevalent contact allergens out of more than 3700 known contact allergens are nickel (14.3% of patients tested), fragrance mix (14%), neomycin (11.6%), balsam of Peru (10.4%), and thimerosal (10.4%).⁵
- Occupational skin diseases (chiefly CD) rank second only to traumatic injuries as the most common type of occupational disease. Chemical irritants such as solvents and cutting fluids account for most ICD cases. Sixty percent were ACD and 32% were ICD. Hands were primarily affected in 64% of ACD and 80% of ICD⁴ (**Figure 146-2**).

ETIOLOGY AND PATHOPHYSIOLOGY

- CD is a common inflammatory skin condition characterized by erythematous and pruritic skin lesions resulting from the contact of skin with a foreign substance.
- ICD is caused by the non-immune-modulated irritation of the skin by a substance, resulting in a skin rash.

FIGURE 146-1 Severe acute allergic contact dermatitis on the ankle of a woman after application of a Chinese topical medicine for a sprained ankle. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier, Inc; 2004.)

FIGURE 146-2 Occupational irritant contact dermatitis in a woman whose hands are exposed to chemicals while making cowboy hats in Texas. (Courtesy of Richard P. Usatine, MD.)

- ACD is a delayed-type hypersensitivity reaction in which a foreign substance comes into contact with the skin, and is linked to skin protein forming an antigen complex that leads to sensitization. Upon reexposure of the epidermis to the antigen, the sensitized T cells initiate an inflammatory cascade, leading to the skin changes seen in ACD.

DIAGNOSIS

HISTORY

Ask about contact with known allergens (i.e., nickel, fragrances, neomycin, and poison ivy/oak).

- Nickel exposure is often related to the wearing of rings, jewelry, and metal belt buckles (**Figures 146-3** through **146-6**).
- Fragrances in the forms of deodorants and perfumes (**Figure 146-7**).
- Neomycin applied as a triple antibiotic ointment by patients (**Figures 146-8** and **146-9**).
- Poison ivy/oak in outdoor settings. Especially ask when the distribution of the reaction is linear (**Figures 146-10** and **146-11**).
- Ask about occupational exposures, especially solvents. For example, chemicals used in hat making can cause ICD on the hands (**Figure 146-2**).
- Tapes applied to skin after cuts or surgery are frequent causes of CD (**Figure 146-12**).
- If the CD is on the feet, ask about new shoes (**Figures 146-13** and **146-14**).

A detailed history of products used on the skin may reveal a suspected allergen. In **Figure 146-15**, this truck driver was using baby wipes to clean his skin during long drives. Patch testing ultimately revealed that he was allergic to one of the ingredients in those wipes.

CLINICAL FEATURES

All types of CD have erythema. Although it is not always possible to distinguish between ICD and ACD, here are some features that might help:

- ICD:
 - Location—usually the hands.
 - Symptoms—burning, pruritus, pain.
 - Dry and fissured skin (**Figure 146-2**).
 - Indistinct borders.
- ACD:
 - Location—usually exposed area of skin, often the hands.
 - Pruritus is the dominant symptom.
 - Vesicles and bulla (**Figures 146-1** and **146-8**).
 - Distinct angles, lines, and borders (**Figures 146-8** through **146-12**).

Both ICD and ACD may be complicated by bacterial superinfection showing signs of exudate, weeping, and crusts.

Toxicodendron (Rhus) dermatitis (poison ivy, poison oak, and poison sumac) is caused by urushiol, which is found in the saps of this plant family. Clinically, a line of vesicles can occur from brushing against one of the plants. Also, the linear pattern occurs from scratching oneself and dragging the oleoresin across the skin with the fingernails (**Figures 146-10** and **146-11**).

FIGURE 146-12 Allergic contact dermatitis to the tape used after an abdominal hysterectomy. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier, Inc; 2004.)

FIGURE 146-14 A 25-year-old man with allergic contact dermatitis to a chemical in his boots. His boots were higher but he cut them down to try to alleviate the discomfort coming from the boots higher on his leg. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier, Inc; 2004.)

Systemic CD is a rare form of CD seen after the systemic administration of a substance, usually a drug, to which topical sensitization has previously occurred.⁶

LABORATORY STUDIES

The diagnosis is most often made by history and physical examination. Consider culture if there are signs of superinfection and there is a concern for methicillin-resistant *Staphylococcus aureus* (MRSA). The following tests may be considered when the diagnosis is not clear.

- KOH preparation and/or fungal culture if tinea is suspected.
- Microscopy for scabies mites and eggs.
- Latex allergy testing—This type of reaction is neither ICD (nonimmunologic) nor ACD. The latex allergy type of reaction is a type I, or immunoglobulin (Ig)E-mediated response to the latex allergen.
- Patch testing—Common antigens are placed on the skin of a patient. The T.R.U.E. Test comes in three tape strips that are easy to apply to the back (Figure 146-16). There is no preparation needed to test for the 29 common allergens embedded into these strips (Table 146-1 for a list of the 29 allergens). The strips are removed in 2 days and read at that time and again in 2 more days (Figure 146-17). The T.R.U.E. Test website provides detailed information on how to perform the testing and how to counsel patients about the meaning of their results. Any clinician with an interest in patch testing can easily perform this service in the office.
 - A metaanalysis of the T.R.U.E. Test shows that nickel (14.7% of tested patients), thimerosal (5.0%), cobalt (4.8%), fragrance mix (3.4%), and balsam of Peru (3.0%) are the most prevalent allergens detected using this system.⁵
 - Critics of the T.R.U.E. Test state that it misses other important antigens. There are a number of dermatologists who create their own more extensive panels in their office. If the suspected allergen is not in the T.R.U.E. Test, refer to a specialist who will customize the patch testing. Also, personal products, such as cosmetics and lotions, can be diluted for special patch testing.
 - A metaanalysis of children patch tested for ACD showed the top five allergens to be nickel, ammonium persulfate, gold sodium thiosulfate, thimerosal, and toluene-2,5-diamine (*p*-toluenediamine).⁷ Only two of these five allergens are in the T.R.U.E. Test, so it may be best to not use this standardized patch testing for children.
 - Once the patch test results are known, it is important to determine if the result is “relevant” to the patient’s dermatitis. One method for classifying clinical relevance of a positive patch test reaction is: (a) current relevance—the patient has been exposed to allergen during the current episode of dermatitis and improves when the exposure ceases; (b) past relevance—past episode of dermatitis from exposure to allergen; (c) relevance not known—not sure if exposure is current or old; (d) cross-reaction—the positive test is a result of cross-reaction with another allergen; and (e) exposed—a history of exposure but not resulting in dermatitis from that exposure, or no history of exposure but a definite positive allergic patch test.⁶
- Punch biopsy—When another underlying disorder is suspected that is best diagnosed with histology (e.g., psoriasis).

FIGURE 146-15 A 49-year-old truck driver developed pruritic erythematous eruption on his arms and trunk that persisted for 1 year despite various treatments. Patch testing ultimately revealed that he was allergic to isothiazolinone. He went home and discovered this was one of the ingredients in the baby wipes he used to clean his skin during long drives. His allergic contact dermatitis resolved once he stopped using the wipes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 146-16 The T.R.U.E. Test is an easy-to-use standardized patch test that is applied to the back using 3 tape strips to test for 36 common allergens. Extra hypoallergenic tape is applied to keep the strips from peeling off for 2 days. (Courtesy of Richard P. Usatine, MD.)

FIGURE 146-17 This positive patch test result for nickel shows small vesicles on an erythematous base. The T.R.U.E. Test reading strip is held against the skin to identify the positive antigen. (Courtesy of Richard P. Usatine, MD.)

TABLE 146-1 Allergens in T.R.U.E. Test (Patch Test for Contact Dermatitis)

Panel 1.2	Panel 2.2	Panel 3.2
1. Nickel Sulfate	13. <i>p</i> -tert-Butylphenol Formaldehyde Resin	25. Diazolidinyl urea
2. Wool Alcohols	14. Epoxy Resin	26. Quinoline mix
3. Neomycin Sulfate	15. Carba Mix	27. Tixocortol-21-pivalate
4. Potassium Dichromate	16. Black Rubber Mix	28. Gold sodium thiosulfate
5. Caine Mix	17. Cl ⁺ Me ⁻ Isothiazolinone (MCI/MI)	29. Imidazolidinyl urea
6. Fragrance Mix	18. Quaternium-15	30. Budesonide
7. Colophony	19. Methylidibromo glutaronitrile	31. Hydrocortizone-17-butyrate
8. Paraben Mix	20. <i>p</i> -Phenylenediamine	32. Mercaptobenzothiazole
9. Negative Control	21. Formaldehyde	33. Bacitracin
10. Balsam of Peru	22. Mercapto Mix	34. Parthenolide
11. Ethylenediamine Dihydrochloride	23. Thimerosal	35. Disperse blue 106
12. Cobalt Dichloride	24. Thiuram Mix	36. 2-Bromo-2-nitropropane- 1,3-diol (Bronopol)

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis is usually more widespread than CD. There is often a history of other atopic conditions, such as allergic rhinitis and asthma. There may be family history of allergies. However, persons with atopic dermatitis are more prone to CD (**Figure 146-6**; Chapter 145, Atopic Dermatitis).
- Dyshidrotic eczema—Seen on the hands and feet with tapioca vesicles, erythema, and scale. Although this is not primarily caused by contact to allergens, various irritating substances can make it worse (see Chapter 147, Hand Eczema).
- Immediate IgE contact reaction (e.g., latex glove allergy)—Immediate erythema, itching, and possibly systemic reaction after contact with a known (or suspected) allergen.
- Fungal infections—A dermatophyte infection that can closely resemble CD when it occurs on the hands and feet. Tinea pedis is usually seen between the toes, on the soles or on the sides of the feet. CD of the feet is often on the dorsum of the foot and related to rubber or other chemicals in the shoes (**Figures 146-13** and **146-14**; Chapter 140, Tinea Pedis).
- Scabies on the hands can be mistaken for CD. Look for burrows and for the typical distribution of the scabies infestation to distinguish this from CD (see Chapter 143, Scabies).
- Allergies to the dyes used in tattoos can occur. Although this is not strictly a CD because the dye is injected below the skin, the allergic process is similar (**Figure 146-18**).

MANAGEMENT

- Identify and avoid the offending agent(s).⁴ **SOR A**
 - Be aware that some patients are actually allergic to topical steroids. This unfortunate situation can be diagnosed with patch testing.

FIGURE 146-18 Man with allergy to red dye in tattoo. Everywhere that the red dye was used, the patient developed pain and swelling. (Courtesy of Richard P. Usatine, MD.)

- In cases of nickel ACD, we recommend the patient cover the metal tab of their jeans with an iron-on patch or a few coats of clear nail polish.
- Cool compresses can soothe the symptoms of acute cases of CD.⁴ SOR C
- Calamine and colloidal oatmeal baths may help to dry and soothe acute, oozing lesions.^{3,4} SOR C
- Localized acute ACD lesions respond best with mid-potency to high-potency topical steroids such as 0.1% triamcinolone to 0.05% clobetasol, respectively.⁴ SOR A
- On areas of thinner skin (e.g., flexural surfaces, eyelids, face, anogenital region) lower-potency steroids such as desonide ointment can minimize the risk of skin atrophy.^{3,4} SOR B
- There is insufficient data to support the use of topical steroids for ICD, but because it is difficult to distinguish clinically between ACD and ICD, these agents are frequently tried. SOR C
- If ACD involves extensive skin areas (>20%), systemic steroid therapy is often required and offers relief within 12 to 24 hours. The recommended dose is 0.5 to 1 mg/kg daily for 5 to 7 days, and if the patient is comfortable at that time, the dose may be reduced by 50% for the next 5 to 7 days. The rate of reduction of steroid dosage depends on factors such as severity, duration of ACD, and how effectively the allergen can be avoided.⁴ SOR B
- Oral steroids should be tapered over 2 weeks because rapid discontinuance of steroids can result in rebound dermatitis. Severe poison ivy/oak is often treated with oral prednisone for 2 to 3 weeks. Avoid using a Medrol dose-pack, which has insufficient dosing and duration.⁴ SOR B
- The efficacy of topical immunomodulators (tacrolimus and pimecrolimus) in ACD or ICD has not been well established.⁴ However, one randomized controlled trial (RCT) did demonstrate that tacrolimus ointment is more effective than vehicle in treating chronically exposed, nickel-induced ACD.⁸ SOR B
- Although antihistamines are generally not effective for pruritus associated with ACD, they are commonly used. Sedation from more soporific antihistamines may offer some degree of palliation (diphenhydramine, hydroxyzine).⁴ SOR C
- Bacterial superinfection should be treated with an appropriate antibiotic that will cover *Streptococcus pyogenes* and *S. aureus*. Treat for MRSA if suspected.
- Once the diagnosis of any CD is established, emollients and moisturizers may help soothe irritated skin.⁴ SOR C

For ICD and occupational CD of the hands:

- Wear protective gloves when working with known allergens or potentially irritating substances such as solvents, soaps, and detergents.^{6,9} SOR A
- Use cotton liners under the gloves for both comfort and the absorption of sweat. Wearing cotton glove liners can prevent the development of an impaired skin barrier function caused by prolonged wearing of occlusive gloves.⁹ SOR B
 - There is insufficient evidence to promote the use of barrier creams to protect against contact with irritants.^{6,9} SOR A
 - After work, conditioning creams can improve skin condition in workers with damaged skin.⁹ SOR A

FIGURE 146-19 Severe occupational contact dermatitis to petroleum products in a man who works as a car mechanic. (Courtesy of Richard P. Usatine, MD.)

- Keep hands clean, dry, and well-moisturized whenever possible.
- Petrolatum applied twice a day is a great way to moisturize dry and cracked skin without exposing the patient to new irritants.

If the CD is severe enough (**Figure 146-19**), the patient may need to change work to completely avoid the offending irritant or antigen.

FOLLOW-UP

May need frequent follow-up if the offending substance is not found, the rash does not resolve and if patch testing will be needed.

PATIENT EDUCATION

Avoid the offending agent and take the medications as prescribed to relieve symptoms.

147 HAND ECZEMA

Richard P. Usatine, MD

PATIENT STORY

An Asian American physician presents with dry scaling on her hands. Frequent hand washing makes it worse and it sometimes cracks. She has allergic rhinitis and she had more widespread atopic dermatitis in her youth. This is a case of chronic atopic hand dermatitis (**Figure 147-1**). The treatment suggested was use of Cetaphil (or equivalent nonsoap cleanser) instead of soap and water. She was directed to soak her hands 3 to 5 minutes in warm water every night, apply triamcinolone 0.1% ointment, and cover with cotton gloves overnight. Her hands cleared 90% with this treatment and she was pleased with the results.

INTRODUCTION

Hand eczema refers to a wide spectrum of inflammatory skin diseases of the hands, including atopic dermatitis, contact dermatitis, pompholyx, and dyshidrotic eczema.

SYNONYMS

Hand dermatitis, pompholyx, dyshidrotic eczema, vesicular palmoplantar eczema. Although some people use pompholyx and dyshidrotic eczema synonymously, others reserve pompholyx for hand eczema with vesicles and bullae on the palms and dyshidrotic eczema for conditions with smaller vesicles between the fingers and toes.

EPIDEMIOLOGY

- The prevalence of hand dermatitis is estimated at approximately 2% to 8.9% in the general population.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- There are many clinical variants of hand dermatitis and a number of different classification schemas. Here is one accepted classification scheme:
 1. Contact (i.e., allergic and irritant) (**Figure 147-2**).
 2. Hyperkeratotic (i.e., psoriasiform) (**Figure 147-3**).
 3. Frictional (**Figure 147-4**).
 4. Nummular (**Figure 147-5**).
 5. Atopic (**Figure 147-6**).
 6. Pompholyx (i.e., dyshidrosis) (**Figures 147-7 and 147-8**).
 7. Chronic vesicular hand dermatitis.¹ (**Figure 147-9**)

FIGURE 147-6 Atopic hand dermatitis on palms in Asian American woman with long history of atopic dermatitis. (Courtesy of Richard P. Usatine, MD. Previously published in *Practical Allergy*.)

FIGURE 147-4 Frictional hand eczema that is worse on the hand that is used for the cane. The other side was affected by a stroke so only one hand is usable for ambulating with a cane. (Courtesy of Richard P. Usatine, MD.)

FIGURE 147-7 Dyshidrotic eczema with acute outbreak of tapioca vesicles on the sides of the fingers. (Courtesy of Richard P. Usatine, MD.)

FIGURE 147-5 Nummular hand dermatitis with tiny papules, papulovesicles, and "coin-shaped" eczematous plaques on the distal fingers of a 14-year-old girl. (Courtesy of Richard P. Usatine, MD.)

FIGURE 147-8 Severe pompholyx worsening with topical steroids. Patch testing showed she was allergic to topical steroids. Her hands finally cleared with oral cyclosporine and avoidance of all topical and oral steroids. (Courtesy of Richard P. Usatine, MD.)

- Another way of looking at hand dermatitis is to break it down into three categories:²
 1. Endogenous—Atopic, psoriasis, pompholyx, dyshidrotic (we do not include psoriasis as a type of hand eczema in this chapter).
 2. Exogenous—Allergic and irritant contact dermatitis.
 3. Infectious—Tinea, *Candida*, and/or superimposed *S. aureus* (**Figure 147-10**).
- Most contact dermatitis of the hands is secondary to irritants such as soap, water, solvents, and other chemicals.
- Allergic contact dermatitis (ACD) is a type IV, delayed-type, cell-mediated, hypersensitivity reaction.
- The nine most frequent allergens related to hand contact dermatitis were identified by patch testing from 1994 to 2004.³ These are quaternium-15 (16.5%), formaldehyde (13.0%), nickel sulfate (12.2%), fragrance mix (11.3%), thiuram mix (10.2%), balsam of Peru (9.6%), carba mix (7.8%), neomycin sulfate (7.7%), and bacitracin (7.4%).³
- Rubber allergens were commonly associated with occupation. One third of patients with ACD had identifiable relevant irritants.³
- Most common allergens are preservatives, metals, fragrances, topical antibiotics, or rubber additives.³

DIAGNOSIS

CLINICAL FEATURES¹

Contact (i.e., allergic and irritant) (**Figure 147-2**).

- Symptoms include burning, stinging, itching, and tenderness at the site of exposure to the irritant or allergen.¹
- Acute signs include papules, vesicles, bullae, and edema.
- Weeping and crusting can occur with or without superinfection.
- Chronic signs include plaques with fissuring, hyperpigmentation, and/or lichenification.
- Irritant contact dermatitis may predispose to ACD.

Hyperkeratotic (i.e., psoriasiform) (**Figure 147-3**).

- Symmetric hyperkeratotic plaques.
- May be localized to the proximal or middle part of the palms.
- Painful fissures are common.

Frictional (**Figure 147-4**).

- Mechanical factors, often from work, such as trauma, friction, pressure, and vibration, induce skin changes with erythema and scale.
- “Wear-and-tear dermatitis.”¹
- Can be caused by contact with paper and fabrics.

Nummular (**Figure 147-5**).

- Nummular hand dermatitis (also called discoid hand dermatitis).
- Tiny papules, papulovesicles, or “coin-shaped” eczematous plaques.
- Dorsal hands and distal fingers are often involved.

FIGURE 147-9 Chronic vesicular hand dermatitis going on for decades in this 51-year-old Hispanic woman. It is particularly bad in the hypothenar area. (Courtesy of Richard P. Usatine, MD.)

FIGURE 147-10 Contact hand dermatitis in a Chinese cook superinfected with *Candida*. See white scale between the fingers. The *Candida* in the interdigital space is also called erosio interdigitalis blastomycetica and is seen in patients with diabetes. (Courtesy of Richard P. Usatine, MD.)

Atopic

- Patients with childhood atopic dermatitis are predisposed to develop hand dermatitis as adults (**Figure 147-6**).
- There is no characteristic pattern and it can occur on any part of the hand.
- Extension to or involvement of the wrist is common (**Figure 147-11**).

Pompholyx (i.e., dyshidrosis, dyshidrotic eczema).

- Has recurrent crops of papules, vesicles, and bullae on the lateral aspects of the fingers, as well as the palms and soles, on a background of nonerythematous skin (**Figures 147-7 and 147-8**).
- These are described as tapioca vesicles as they look like the small spheres in tapioca. The vesicles open and the skin then peels (mild desquamation).
- There may be pruritus or pain.
- Although some use the names pompholyx and dyshidrotic eczema interchangeably, others only use the name pompholyx to describe an explosive onset of large bullae, usually on the palms (**Figure 147-8**) and dyshidrotic eczema to mainly describe chronic small tapioca vesicles on the sides of the fingers (**Figure 147-7**).
- Both conditions may last 2 to 3 weeks and resolve, leaving normal skin, only to recur again at varying intervals.
- Both conditions are idiopathic and closely related, if not identical.
- Symptoms may be associated with exogenous factors (e.g., nickel or hot weather) or endogenous factors (e.g., atopy or stress).

Chronic vesicular hand dermatitis (**Figure 147-9**).

- Chronic vesicles that are mostly palmar and pruritic.
- Differentiated from pompholyx by a more chronic course and the presence of vesicles with an erythematous base.
- The soles of the feet may also be involved.
- Poorly responsive to treatments.
- In one series, 55% of patients with this type of hand dermatitis were found to have positive patch test results.⁴

TYPICAL DISTRIBUTION

Of course, hand dermatitis is on the hands, but both hands and feet can be involved in dyshidrotic eczema and chronic vesicular hand dermatitis.

LABORATORY STUDIES

Scraping and using microscopy with KOH (with or without a fungal stain) to look for dermatophytes is helpful (see Chapter 129, Cutaneous Fungal Infections).

Patch testing can be crucial to the diagnosis and treatment of hand eczema. Patch testing is described in detail in the previous chapter (Chapter 146, Contact Dermatitis). The patient in **Figure 147-8** had severe pompholyx worsening with topical steroids. Patch testing showed she was allergic to topical steroids (**Figure 147-12**). Her hands finally cleared with oral cyclosporine and avoidance of all topical and oral steroids.

FIGURE 147-11 Hand dermatitis with prominent wrist involvement in a 20-year-old Hispanic woman with moderately severe widespread atopic dermatitis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 147-12 Patch testing positive to two types of topical steroids in a patient with severe pompholyx and topical steroid allergic contact dermatitis. Reading of T.R.U.E. test. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Tinea manus is often found as part of the two-foot, one-hand syndrome in which both feet have scaling tinea pedis and one hand has scale as well (**Figure 147-13**) (see Chapter 129, Cutaneous Fungal Infections, and Chapter 140, Tinea Pedis).
- *Candida* can be seen in between the fingers with erythema and scale over the fingers and hand (**Figure 147-10**) (see Chapter 136, Candidiasis).
- Psoriasis often involves the hand. It can present with plaques on the dorsum of hand and over the knuckles of the fingers or on the palm of the hand. Palmoplantar psoriasis will involve the hands and feet (see Chapter 152, Psoriasis).
- Knuckle pads are thickening of the skin over the knuckles. These can be accompanied by hyperpigmentation.

MANAGEMENT

- Lifestyle modifying factors, as listed in **Table 147-1**, are essential.
- Avoid irritants and “wet work” at home and at work as much as possible. **SOR C**
- Wear protective gloves when working with known allergens or potentially irritating substances such as solvents, soaps, and detergents.^{5,6} **SOR A**
- Use cotton liners under the gloves for both comfort and the absorption of sweat. Wearing cotton glove liners can prevent the development of an impaired skin barrier function caused by prolonged wearing of occlusive gloves.^{5,6} **SOR B**

There is insufficient evidence to promote the use of barrier creams to protect against contact with irritants.^{5,6} **SOR A**

Applying conditioning creams after work can improve skin condition in workers with damaged skin on the hands.⁶ **SOR A**

- Avoid latex gloves because of a high risk of latex allergy among patients with hand dermatitis. **SOR C**
- Frequent and liberal use of emollients can help restore normal skin-barrier function. Simple, inexpensive, petrolatum-based emollients were found to be equally as effective as an emollient containing skin-related lipids in a 2-month study of 30 patients with mild to moderate hand dermatitis.⁷ **SOR B**
- For patients with very dry skin that is not irritated by water, it may help to soak hands 3 to 5 minutes in warm water at night, apply triamcinolone 0.1% ointment, and cover with cotton gloves overnight. The cotton gloves may be used repeatedly even though they will soak up some of the ointment. **SOR C**
- Do not wash hands with soap. Use Cetaphil, a nonsoap cleanser. **SOR C**

See **Table 147-2** for a summary of the recommended therapeutic agents for different types of hand dermatitis.

TOPICAL AGENTS

- Topical steroids are first-line agents for inflammatory hand dermatitis. Ointments are considered more effective and contain fewer

FIGURE 147-13 Tinea manus in a patient with two-foot, one-hand syndrome. The scraping showed hyphae under the microscope with a KOH preparation. (Courtesy of Richard P. Usatine, MD.)

TABLE 147-1 Sample Patient Handout on Lifestyle Management of Hand Dermatitis

Hand washing and moisturizing:

- Use lukewarm or cool water, and mild cleansers without perfume, coloring, or antibacterial agents, and with minimal preservatives. In general, bar soaps tend to have fewer preservatives than liquid soaps (Cetaphil or Aquanil liquid cleansers or generic equivalents are exceptions to this statement).
- Pat hands dry, especially between fingers.
- Immediately following partial drying of hands (e.g., within 3 minutes), apply a generous amount of a heavy cream or ointment (not lotion); petroleum jelly, a one-ingredient lubricant, works well.
- It is helpful to have containers of creams or ointments next to every sink in your home (next to the bed, next to the TV, in the car, and at multiple places at work).
- Moisturizing should be repeated as often as possible throughout the day, ideally 15 times per day.
- Avoid using washcloths, rubbing, scrubbing, or overuse of soap or water.

Occlusive therapy at night for intensive therapy:

- Apply a generous amount of your doctor's recommended emollient or prescribed medicine on your hands.
- Then put on cotton gloves and wear overnight.

When performing "wet work":

- Wear cotton gloves under vinyl or other nonlatex gloves.
- Try not to use hot water and decrease exposure to water to less than 15 minutes at a time, if possible.
- Use running water rather than immersing hands, if possible.
- Remove rings before wet or dry work.

Wear protective gloves in cold weather and for dusty work. For frictional exposures, wear tight-fitting leather gloves (e.g., riding or golfing gloves).

Avoid direct contact with the following, if possible:

- Shampoo;
- Peeling fruits and vegetables, especially citrus fruits;
- Polishes of all kinds;
- Solvents (e.g., white spirit, thinners, and turpentine);
- Hair lotions, creams, and dyes;
- Detergents and strong cleansing agents;
- Fragranced chemicals;
- "Unknown" chemicals.

Heavy-duty vinyl gloves are better than rubber, nitrile, or other synthetic gloves because vinyl is less likely to cause allergic reactions.

Source: Reprinted with permission from Fig. 9 in Warshaw E, Lee G, Storrs FJ. Hand dermatitis: a review of clinical features, therapeutic options, and long-term outcomes. *Am J Contact Dermat.* 2003;14:126.

preservatives and additives than creams. Some patients will prefer a cream vehicle, so that patient preference should be considered in prescribing topical steroids. It is better to have a patient use a cream than not use an ointment.

- Start with 0.1% triamcinolone ointment bid as it is inexpensive and effective. **SOR C** Cut back on use when possible to avoid skin atrophy, striae, and telangiectasias.
- Topical calcineurin inhibitors, tacrolimus and pimecrolimus, are effective in the treatment of atopic and other allergic types of hand dermatitis.^{8,9} **SOR B** Skin burning or an unpleasant sensation of warmth is reported by approximately 50% of patients using topical tacrolimus and 10% with pimecrolimus.¹⁰

PHOTOTHERAPY AND IONIZING RADIATION

- Psoralen and UVA irradiation (PUVA) has been used to treat patients with all forms of hand dermatitis.¹⁰ **SOR C**

- Grenz rays (ionizing radiation with ultra-soft X-rays or Bucky rays) usually requires 200 to 400 rad (2 to 4 Grays or Gy) every 1 to 3 weeks for up to a total of 6 treatments, followed by a 6-month hiatus.¹⁰ **SOR C**

SYSTEMIC STEROIDS AND IMMUNOMODULATORS

- Oral prednisone may be used to treat the most severe and recalcitrant case of hand dermatitis. Pulse dosing of 40 to 60 mg daily for 3 to 4 days may be valuable.¹⁰ For atopic dermatitis of the hands, an injection of 40 mg triamcinolone acetonide is another option when topical meds are not fully working. **SOR C**
- Cyclosporine is a potent immunomodulating agent used to treat severe and recalcitrant cases of atopic dermatitis and hand dermatitis. In a systematic review, cyclosporin consistently decreased the severity of atopic dermatitis. The decrease in disease severity was greater at 2 weeks with dosages greater than or equal to 4 mg/kg.

TABLE 147-2 Recommended Therapies for Hand Dermatitis Variants

Therapeutic Agent	Hand Dermatitis Variant						
	Irritant Contact	Allergic Contact	Hyperkeratotic	Nummular	Pompholyx (Dyshidrosis)	Frictional	Chronic Vesicular
Corticosteroids:							
Topical	✓	✓		✓	✓	✓	✓
Oral		✓			✓*		✓
Cyclosporine		✓			✓		✓
Methotrexate		✓	✓		✓		✓
Mycophenolate mofetil		✓		✓	✓		✓
Tacrolimus or pimecrolimus (topical)	✓	✓		✓	✓		✓
Phototherapy (UVB, psoralen UVA, and Grenz)	✓	✓	✓	✓	✓	✓	✓
Retinoids (topical and/or oral)			✓			✓	✓
Calcipotriene (topical)			✓			✓	✓

*Acute flares.

Source: Reprinted with permission from Warshaw E, Lee G, Storrs FJ. Hand dermatitis: a review of clinical features, therapeutic options, and long-term outcomes. *Am J Contact Dermat.* 2003;14:128.

After 6 to 8 weeks the relative effectiveness was 55%.¹¹ For patients with severe functional problems this can be a great relief (Figure 147-8). Unfortunately, relapse rates are high after discontinuation of the cyclosporine.¹⁰ **SOR B**

- Mycophenolate mofetil and methotrexate have been reported to be beneficial in case reports.¹⁰ **SOR C**
- Alitretinoin (9-*cis*-retinoic acid) is an effective treatment for severe chronic hand eczema.¹² **SOR B** Like all systemic retinoids it is teratogenic and requires careful monitoring. This medication is not yet available in the United States, but is being used in Canada and the United Kingdom.

PATIENT EDUCATION

- See **Table 147-1**.

FOLLOW-UP

Patients with chronic hand dermatitis are often desperately looking for help and often appreciate frequent follow-up until the dermatitis is controlled. Patch testing requires three visits within a 1-week period.

148 NUMMULAR ECZEMA

Yu Wah, MD
Richard P. Usatine, MD

PATIENT STORY

A 2-year-old Hispanic male presents to the clinic with erythematous, round, moist, crusted lesions on the left thigh (**Figure 148-1**) and right arm. His mother noted several small bumps initially, which developed into coin-shaped lesions over the next few weeks. The child is scratching them but is otherwise healthy. A KOH preparation of the scraping from the lesions did not show fungal structures. The child responds well to treatment with topical midpotency corticosteroids, emollients, and dressing in long-sleeve clothes to prevent scratching the lesions. His nummular eczema resolved in 6 weeks.

INTRODUCTION

Nummular eczema (NE) is a type of eczema characterized by circular or oval-shaped scaling plaques with well-defined borders. The term *nummular* refers to the shape of a coin (Latin for coin is *nummus*). The lesions are typically multiple and most commonly found on the dorsa of the hands, arms, and legs. It often overlaps with other clinical types of eczema: atopic dermatitis, stasis dermatitis, and asteatotic eczema.^{1,2}

SYNONYMS

Nummular dermatitis, discoid eczema, microbial eczema, and orbicular eczema.

EPIDEMIOLOGY

- Prevalence is reported to range widely from 0.1% to 9.1%.¹
- It is slightly more common in males than in females.¹
- Males are also affected at a later age (peak older than age 50 years) than females (peak younger than age 30 years).¹
- It is less common in children.

ETIOLOGY AND PATHOPHYSIOLOGY

Many factors have been reported in association with NE but their role in the etiology and pathogenesis is not well established:

- NE has been viewed as microbial in origin, either secondary to bacterial colonization or hematogenous spread of bacterial toxins,^{1,3} but an infectious source is not identified in most cases of NE.
- NE is reported to be associated with xerosis of the skin that subsequently weakens the skin barrier function and sensitizes it to environmental allergens.⁴

FIGURE 148-1 A 2-year-old child with nummular eczema on the left thigh. The lesion shows abrasions and excoriations from scratching. He has another similar lesion on the right arm. (Courtesy of Yu Wah, MD.)

- NE is frequently reported in association with contact sensitization to various agents, including nickel, chromate, balsam of Peru, and fragrances. Allergic or chronic contact dermatitis has been frequently reported to manifest as NE on the dorsa of the hands.^{1,5}
- Onset of NE has been reported in association with various medications, including interferon and ribavirin therapy for hepatitis C^{6,7} and isotretinoin.⁸ Most of these reports are based on single or limited number of cases.
- Mercury in the dental amalgam was reported to induce NE in two cases with relapsing NE.⁹

DIAGNOSIS

HISTORY

- Onset is reported to be within days to week. Simultaneous or subsequent development of multiple lesions is often reported.
- Intense pruritus or burning is common.
- Lesions may last months to years without treatment and may be recurrent.
- History of medications, atopy, and exposure to allergens may be helpful to tailor the management of NE.

PHYSICAL EXAMINATION

- Primary morphology includes small papules and vesicles that coalesce to form circular to oval shape patches and plaques (**Figures 148-2** and **148-3**).
- Secondary morphology includes abrasion and excoriations from scratching (**Figure 148-1**), weeping and crusting after the vesicles leak (**Figures 148-2** to **148-4**), and scaling and lichenification in more chronic lesions (**Figures 148-5** and **148-6**). Excessive weeping and crusting may indicate secondary bacterial infection.

TYPICAL DISTRIBUTION

- Dorsal hand is most commonly affected (**Figures 148-2** and **148-7**). The extensor aspects of the forearm (**Figures 148-3** and **148-6**) and the lower leg (**Figure 148-5**), the thighs (**Figure 148-1**), and the flanks are frequently involved, but NE may be seen in any part of the body (**Figures 148-4**, **148-8**, and **148-9**).

LABORATORY TESTING

- Diagnosis in most cases is made from clinical features.
- KOH preparation is helpful to investigate for tinea corporis.
- Patch testing may be considered if contact allergy is suspected.

BIOPSY

- Biopsy is rarely needed, but should be performed if there is suspicion of other serious clinical entities (e.g., mycosis fungoides, psoriasis) or if the diagnosis is uncertain.

DIFFERENTIAL DIAGNOSIS

- Tinea corporis may present as pruritic annular lesions with scales and vesicles. Vesicles are typically at the periphery of the lesion compared to NE, where they are also seen in the center. A positive

FIGURE 148-2 Multiple nummular lesions on the dorsum of the hand, a common site of nummular eczema. The lesions show multiple papules and vesicles that coalesce to form coin-shaped plaques; oozing and crusting can be seen from ruptured vesicles. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-3 Nummular eczema on the forearm of a 22-year-old man. The lesions show multiple papules and vesicles that coalesce to form coin-shaped plaques; oozing and crusting can be seen from ruptured vesicles. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-4 Nummular eczema on the face of a young man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-5 Multiple nummular lesions on the lower leg of a 15-year-old girl. Lesions of nummular eczema can be dry and scaly. The lesions prevented the patient from shaving her legs. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-8 Nummular eczema on the dorsum of the foot. Contact dermatitis and tinea pedis were also in the differential diagnosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-6 Nummular eczema on the extensor surface of the forearms and elbows. Thickened, scaly lesions resemble psoriatic plaques. A biopsy was performed to confirm the diagnosis of nummular eczema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-7 Nummular eczema on the dorsum of the hand and wrist. (Courtesy of Richard P. Usatine, MD.)

FIGURE 148-9 Nummular eczema on the abdomen of a 27-year-old man. (Courtesy of Richard P. Usatine, MD.)

KOH preparation for hyphae can help with the diagnosis (see Chapter 138, Tinea Corporis).

- Psoriasis typically presents with thickened plaques on the extensor surfaces of arms and legs, scalp and sacral areas. Nail changes may be present (see Chapter 152, Psoriasis).
- Lichen simplex chronicus usually presents as a single plaque in an area easily accessible to scratching such as the ankle, wrist, and neck (see Chapter 149, Self-Inflicted Dermatoses).
- Mycosis fungoides is a type of cutaneous T-cell lymphoma, which may present with scaly patches or plaques that are often pruritic and usually erythematous. A biopsy can help make the diagnosis (see Chapter 176, Mycosis Fungoides).
- Nummular lesions of atopic dermatitis may have features similar to NE. Presence of other lesions typically on flexural surfaces, and a history of atopy, asthma, or seasonal allergies may help make the diagnosis (see Chapter 145, Atopic Dermatitis).
- Contact dermatitis (CD) may present with nummular lesions. History of exposure to contact allergens at the affected areas can raise the suspicion for CD. Patch testing may be used to confirm the clinical suspicion (see Chapter 146, Contact Dermatitis).
- Asteatotic dermatitis may have overlapping features with NE but has a less-well-defined margin.

MANAGEMENT

- Emollients are beneficial to help restore and maintain normal skin barrier function. **SOR C**
- Hydration by bathing before bedtime followed by ointment application to wet skin is reported as an effective method of skin care in patients with eczema.¹⁰ **SOR B**
- A medium- to high-potency topical corticosteroid ointment is the first line of treatment. A cream preparation may be used if patient compliance is a concern with ointments. **SOR C**
- Topical calcineurin inhibitors such as topical tacrolimus and pimecrolimus have the benefit of not causing skin atrophy and have been shown to be effective in many types of eczema.¹ **SOR B** They have a higher cost compared to topical corticosteroids and have a black box warning because of a reported risk of malignancies.
- Short courses of systemic corticosteroids may be necessary in severe or acute cases. **SOR C**
- Methotrexate is reported to be safe, effective, and well-tolerated in treatment of moderate to severe childhood NE.¹¹ This was reported in a case series of 25 pediatric patients with refractory NE treated with 5 or 10 mg of methotrexate per week. Sixty-four percent had total clearance after an average of 10.5 months. No serious adverse events were observed in this study.¹¹ **SOR B**
- Phototherapy may be used in generalized, severe, or refractory cases.^{1,2} Narrow-band UVB is commonly used and psoralen UVA has been used in more severe cases.² **SOR C**
- Topical and oral antihistamines are often needed to treat pruritus. Topical doxepin is reported to be effective in treatment of pruritus associated with eczematous conditions and has a favorable safety profile.¹² **SOR B**

- Topical and systemic antibiotics may be needed to treat secondary or associated bacterial infection. **SOR C**
- Complementary therapy with probiotics is not effective in treatment of eczema and carries a small risk of adverse events.¹³ **SOR A**

FOLLOW-UP

Regular follow-up is needed for the patient with chronic, refractory, or relapsing nummular dermatitis until remission or resolution is achieved.

PATIENT EDUCATION

Hydration and protection of skin from irritants is important. Apply moisturizer or topical medications immediately after bathing while the skin is still moist. Avoid strong soaps and use mild fragrance-free soap, or soap alternatives. Avoid tight clothing and fabrics that irritate the skin.

149 SELF-INFLICTED DERMATOSES

Richard P. Usatine, MD
Anne E. Johnson, MD

PATIENT STORY

A 55-year-old woman presents with severe itching on her arms and legs. The itching disrupts her sleep and she sometimes scratches her arms and legs until exhaustion (**Figures 149-1** and **149-2**).¹ She had used moisturizers, emollients, and topical corticosteroids, but they only alleviated the itching temporarily. The itching began 10 months earlier after finalizing the divorce from her husband of 20 years. The patient's right leg had been amputated above the knee after a car accident, and she now wore a prosthetic leg. The patient readily admitted to a great deal of psychological distress. She described feeling depressed since her divorce, and the loss of her leg further aggravated her situation. She has had difficulty securing a job and had high anxiety about being able to pay for rent and bills. The diagnosis made was neurotic excoriations (neurodermatitis) and the patient understood that she was doing this to her own skin. The patient improved with nail cutting, acknowledging the self-inflicted nature of her excoriations and topical clobetasol. One year later, the patient was working in the hospital laboratory with a tremendous improvement in her skin condition (**Figure 149-3**).

INTRODUCTION

The self-inflicted dermatoses (sometimes referred to as psychogenic dermatoses) include neurotic excoriations, lichen simplex chronicus, and prurigo nodularis. These conditions are caused by pruritus for which no medical cause is apparent, which initiates an itch–scratch cycle. The self-inflicted dermatoses can present a challenge to the clinician, as multiple underlying medical etiologies must be ruled out to arrive at their diagnosis and the pathophysiology of these diseases is not well understood. In addition, they may be difficult to treat successfully. There is no clear standard of care for treatment, although a vast array of treatments targeting different etiologies has been tried clinically, and many have some amount of research to support them. As with other psychosomatic conditions, non-pharmacologic interventions, including the physician–patient relationship itself, can be important to treatment.

SYNONYMS

- Neurotic excoriations—Neurodermatitis.
- Lichen simplex chronicus—Neurodermatitis circumscripta.
- Prurigo nodularis—Picker's nodules; lichen simplex chronicus, prurigo nodularis type; atypical nodular form of neurodermatitis circumscripta.

FIGURE 149-1 Neurotic excoriations (neurodermatitis) seen on 3 of 4 extremities. The fourth extremity is a prosthetic leg. (From Usatine RP, Saldana-Arregui MA. Excoriations and ulcers and legs. *J Fam Pract.* 2004;53(9):713-716. Reproduced with permission from Frontline Medical Communications.)

FIGURE 149-2 Neurotic excoriations with close-up of arm. (From Usatine RP, Saldana-Arregui MA. Excoriations and ulcers and legs. *J Fam Pract.* 2004;53(9):713-716. Reproduced with permission from Frontline Medical Communications.)

EPIDEMIOLOGY

- Studies show that neurotic excoriations primarily affect females, with a mean onset between the ages of 30 and 45 years¹ (**Figures 149-1 to 149-5**).
- Neurotic excoriations are present in 2% of patients seen in dermatologic clinics.¹
- Lichen simplex chronicus (LSC) is observed more commonly in females than in males (**Figures 149-6 to 149-9**). Lichen nuchae is a form of lichen simplex that occurs on the midposterior neck (**Figures 149-8 and 149-9**).
- LSC occurs mostly in mid-to-late adulthood, with highest prevalence in persons ages 30 to 50 years.²
- For prurigo nodularis (PN) there is no documented difference in frequency between males and females. PN most often occurs in middle-aged and older persons³ (**Figures 149-10 to 149-15**).

ETIOLOGY AND PATHOPHYSIOLOGY

- All 3 conditions are found on the skin in regions accessible to scratching.
- Pruritus provokes scratching that produces clinical lesions.
- The underlying pathophysiology is unknown for all 3 conditions. Central nervous system (CNS)⁴ and peripheral nervous system⁵⁻⁷ dysfunction have been implicated in the pathogenesis of the pruritus underlying the self-inflicted dermatoses.
- Some skin types are more prone to lichenification, such as skin that tends toward eczematous conditions (i.e., atopic dermatitis).²
- One study showed an association between LSC and a certain genotype (short/short) at the serotonin transporter gene-linked polymorphic region.⁸
- Neurotic excoriations (neurodermatitis) is a result of a psychodermatologic disorder in which patients inflict excoriations and ulcers on their skin and admit to their involvement.
- The pathogenesis of PN is still unknown. PN shares some histologic features (epidermal proliferation) with psoriasis and ichthyosis but is largely self-inflicted.³ There is some evidence to suggest immune dysregulation is involved, as PN is more common in patients with HIV/AIDS and other forms of immunosuppression than in the general population.⁹

DIAGNOSIS

CLINICAL FEATURES

Itching is the common historical theme for all three self-inflicted dermatoses.

Common psychiatric problems associated with all self-inflicted dermatoses include significant social stress, depression, anxiety, and obsessive-compulsive disorder.

FIGURE 149-3 Same patient 1 year later after successful therapy. Hypopigmented scarring remains. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-5 Neurotic excoriations on the upper arm with hypopigmented scarring. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-7 Lichen simplex chronicus on the ankle. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-6 Lichen simplex chronicus on the hand of a middle-aged woman with thick lichenification, erythema, and hyperpigmentation. She was continually scratching at her hand. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-8 Lichen simplex chronicus on the neck of a Hispanic woman who also has acanthosis nigricans. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-9 Lichen simplex chronicus on the neck of a Hispanic woman with thick plaque formation that resembles prurigo nodularis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-11 Prurigo nodularis on the arms and legs after 9 months of unsuccessful treatment in the patient in Figure 149-10. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-10 Prurigo nodularis on the arms and legs of a 42-year-old Hispanic woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-12 Severe prurigo nodularis on the arm. The nodules are somewhat linear from years of scratching. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-13 Prurigo nodularis on the upper back of a man. (Courtesy of Richard P. Usatine, MD.)

Patients are often observed scratching and rubbing their skin. This results in:

- Lichenification of the skin (skin thickening with exaggerated skin lines) (**Figures 149-6** and **149-9**).
- Pigmentary changes (especially hyperpigmentation) (**Figures 149-4**, **149-5**, **149-9**, **149-11**, and **149-15**).
- Excoriations, erosions, and ulcerations.

Common physical examination findings for all three disorders include:

- Neurotic excoriations—May vary from dug-out erosions, to ulcers covered with crusts and surrounded by erythema to areas receding into hypopigmented depressed scars (**Figure 149-5**).
- LSC—One or more slightly erythematous, scaly, well-demarcated, lichenified, firm, rough plaques² (**Figures 149-6** to **149-9**).
- Prurigo nodularis—Raised nodules from 2 to 20 mm, colors vary from shades of red to brown (**Figures 149-10** to **149-15**).

Excoriations are almost always present on initial presentation. With treatment the excoriations may subside and the nodules may remain.

TYPICAL DISTRIBUTION

- Neurotic excoriations occur on areas easily reached by the patient, such as the arms, legs, and upper back (**Figures 149-1** to **149-5**).
- LSC occurs on:
 - Hands, wrists, extensor forearms, and elbows (**Figure 149-6**).
 - Knees, lower legs, and ankles (**Figure 149-7**).
 - Nape of neck (**Figures 149-8** and **149-9**).
 - Vulva and scrotum.
- In PN, nodules occur on the extensor surfaces of the arms, the legs, and sometimes the trunk (**Figures 149-10** to **149-15**).

LABORATORY STUDIES

Punch biopsy may be helpful when the diagnosis is uncertain.

DIFFERENTIAL DIAGNOSIS

- Acne keloidalis nuchae—Acneiform eruption at the hairline from ingrown hairs, worse with shaving and short haircuts (see Chapter 114, Pseudofolliculitis and Acne Keloidalis Nuchae).
- Atopic dermatitis—An allergic skin disorder in patients with a personal or family history of atopic conditions. Patients with atopic dermatitis are more likely to get LSC (see Chapter 145, Atopic Dermatitis).
- Contact dermatitis—A common inflammatory skin condition characterized by erythematous and pruritic skin lesions resulting from the contact of skin with a foreign substance (see Chapter 146, Contact Dermatitis).
- Delusions of parasitosis—Delusions that tiny bugs or parasites are living on or below the patient's skin leading them to try to dig them out with their nails and fingers. This condition looks just like

FIGURE 149-14 A cluster of nodules on the back of the same patient with prurigo nodularis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 149-15 Severe prurigo nodularis on the legs with prominent hyperpigmentation of the nodules and some secondary infection. (Courtesy of Richard P. Usatine, MD.)

neurotic excoriations; however, the patient believes there are parasites causing the pruritus and it is very difficult to convince them otherwise.

- Nummular eczema—Eczematous lesions in the shape of coins seen most often on the legs.
- Scabies—Look for burrows between the fingers and the typical distribution of scabies on the hands, feet, wrists, waist, and axillae to differentiate scabies from a self-inflicted dermatosis. If you do a scraping and find evidence of the scabies mite that is the best way to confirm a true scabies infestation. Often family members have itching and lesions as well when the real diagnosis is scabies (see Chapter 143, Scabies).

MANAGEMENT

For all 3 self-inflicted dermatoses there is little evidence to guide therapy. The following 3 treatments can be used in all 3 conditions and are based on expert opinion and a few small studies: **SOR C**

- Topical corticosteroids—Use mid-potency to high-potency steroids except in areas of thin skin.
- Oral antihistamines—Sedating H₁ blockers and consider doxepin (start with 10 to 25 mg PO qhs and titrate to response) for refractory cases.
- Oral antibiotics, if secondary infection is present.
- One small study of 3 patients with inflammatory skin diseases and severe nocturnal pruritus who underwent treatment with mirtazapine (Remeron) suggests that this may be an effective alternative for the treatment of nocturnal pruritus.¹⁰ **SOR C**

Get a good psychosocial history and offer the patient treatment for any problems uncovered. It may help for patients to understand the connection between their self-inflicted lesions and their stressors. Some patients will have anxiety disorders or depression, whereas others will be suffering with great psychosocial stressors like loss of work, homelessness, or grief. Offer pharmacotherapy (including selective serotonin reuptake inhibitors [SSRIs]) and counseling if indicated. Refer as needed for these therapies.

Other specific treatments to consider are as follows:

- LSC
 - Doxepin 5% cream has been studied in patients with LSC, nummular eczema, and contact dermatitis. Applied 4 times per day for a period of 7 days led to an 84% response rate in reduction of pruritus (not lesions).¹¹ **SOR B**
 - Tacrolimus 0.1% ointment applied twice daily for approximately 2 months, then once daily for an additional 3 months was effective in achieving remission from LSC in 1 case report.¹²
 - In one study of 22 patients with LSC, transcutaneous electrical nerve stimulation (TENS) reduced pruritus by greater than more than 50% in 80% of the patients.⁵
- Prurigo nodularis—A difficult condition to treat with mild-to-moderate success at best. Here are some treatments to consider:
 - Intralesional steroids—Triamcinolone 5 to 10 mg/cc. **SOR C**

- Cryotherapy—Applied to each nodule to flatten the nodules and decrease pruritus. **SOR C**
- Calcipotriol—After 8 weeks of calcipotriol treatment, the reduction in the number and size of nodules was 49% and 56%, respectively, compared with 18% and 25% for the betamethasone valerate.¹³ **SOR B**
- UV light (narrow-band UVB) is sometimes useful when the condition is widespread. **SOR C**
- Monochromatic excimer light (308 nm) showed partial or complete remission from PN in 9 (81%) of 11 patients.¹⁴ **SOR C**
- Oral dapsone has been tried with some reported success in this difficult condition. **SOR C**

Gabapentin has some reported success in reducing pruritus in patients with PN and LSC.⁶ One case series of oral cyclosporine showed some benefit for PN.¹⁵

In AIDS patients with PN, maintaining a CD4+ count over 50 may improve pruritus.⁹

PATIENT EDUCATION

Help patients to understand that they are unintentionally hurting their own skin. Patients need to minimize touching, scratching, and rubbing affected areas. Suggest that patients gently apply their medication or a moisturizer instead of scratching the pruritic areas. Give patients hope and show them **Figures 149-1 to 149-3** to demonstrate that even the most severe cases can heal if they stop manipulating their skin.

FOLLOW-UP

Follow-up is essential because these problems are chronic and difficult to treat. Patients need to know that you will not abandon them and will continue to work with them to get relief. This is especially important when the patient is suffering from anxiety, depression, or other psychological problems.

150 URTICARIA AND ANGIOEDEMA

Richard P. Usatine, MD

PATIENT STORY

A 26-year-old man was given trimethoprim-sulfamethoxazole for sinusitis and broke out in hives 1 week later. The hives were all over his trunk and arms (**Figures 150-1** and **150-2**). He had no airway compromise and had only urticaria without angioedema. His sinus symptoms were mostly resolved, so he was told to stop the antibiotic and take an oral antihistamine. The H₁-blocker gave him relief of symptoms and the wheals disappeared over the next 2 days.

INTRODUCTION

Urticaria and angioedema are a heterogeneous group of diseases that cause swelling of the skin and other soft tissues. They both result from a large variety of underlying causes, are elicited by a great diversity of factors, and present clinically in a highly variable way.¹ Standard hives with transient wheals is the most common manifestation of urticaria.

SYNONYMS

Hives.

EPIDEMIOLOGY

- It is estimated that 15% to 25% of the population may have urticaria sometime during their lifetime.²
- Urticaria affects 6% to 7% of preschool children and 17% of children with atopic dermatitis.²
- Among all age groups, approximately 50% have both urticaria and angioedema, 40% have isolated urticaria, and 10% have angioedema alone.²
- Acute urticaria is defined as less than 6 weeks' duration. A specific cause is more likely to be identified in acute urticaria.²
- The cause of chronic urticaria (>6 weeks' duration) is determined in less than 20% of cases.²
- Chronic urticaria is twice as common in women as in men.³
- Chronic urticaria predominantly affects adults.³
- Up to 40% of patients with chronic urticaria of more than 6 months' duration still have urticaria 10 years later.³

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathophysiology of angioedema and urticaria can be immunoglobulin (Ig) E mediated, complement mediated, related to physical stimuli, autoantibody mediated, or idiopathic.

FIGURE 150-1 A 26-year-old man with acute urticaria due to trimethoprim-sulfamethoxazole. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-2 Note the confluence of wheals with a well-demarcated border on the arm of the man with acute urticaria due to trimethoprim-sulfamethoxazole. (Courtesy of Richard P. Usatine, MD.)

- These mechanisms lead to mast cell degranulation resulting in the release of histamine. The histamine and other inflammatory mediators produce the wheals, edema, and pruritus.
- Urticaria is a dynamic process in which new wheals evolve as old ones resolve. These wheals result from localized capillary vasodilation, followed by transudation of protein-rich fluid into the surrounding skin. The wheals resolve when the fluid is slowly reabsorbed.
- Angioedema is an edematous area that involves transudation of fluid into the dermis and subcutaneous tissue (**Figures 150-3 and 150-4**).

The following etiologic types exist:

- Immunologic—IgE mediated, complement mediated. Occurs more often in patients with an atopic background. Antigens are most commonly foods or medications. The most common foods are milk, nuts, wheat, and shellfish.
- Physical urticaria—Dermatographism, cold, cholinergic, solar, pressure, vibratory urticaria (**Figures 150-5 and 150-6**).
- Urticaria caused by mast cell-releasing agents—Mastocytosis, urticaria pigmentosa (**Figures 150-7 and 150-8**).
- Urticaria associated with vascular/connective tissue autoimmune disease.
- Hereditary angioedema is a potentially life-threatening disorder that is inherited in an autosomal dominant manner. In this disease, angioedema occurs without urticaria (**Figure 150-9**).

DIAGNOSIS

CLINICAL FEATURES

- Symptoms include itching, burning, and stinging.
- Wheals vary in size from small, 2-mm papules of cholinergic urticaria (**Figure 150-6**) to giant hives where a single wheal may cover a large portion of the trunk.
- The wheal may be all red or white, or the border may be red with the remainder of the surface white.
- Wheals may be annular (**Figures 150-10 and 150-11**).
- If dermatographism is present, one can write on the skin and be able to see the resulting words or shapes (**Figure 150-5**).
- If you suspect urticaria pigmentosa, stroke a lesion with the wooden end of a cotton-tipped applicator. This induces erythema of the plaque and the wheal is confined to the stroke site. This is called Darier sign (**Figure 150-12**).

TYPICAL DISTRIBUTION

- Angioedema is seen more often on the face and is especially found around the mouth and eyes (**Figures 150-3 and 150-4**). Sometimes angioedema can occur on the genitals or the trunk (**Figure 150-13**).
- Urticaria can be found anywhere on the body and is often on the trunk and extremities (**Figures 150-1 and 150-2**).

FIGURE 150-8 Urticaria pigmentosa in a 4-month-old black boy. His lesions started on day 2 of life and have proliferated. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-7 Urticaria pigmentosa on the chest of this 9-month-old girl. She has a positive Darier sign in which stroking the lesion results in edema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-9 Hereditary angioedema. **A.** Severe edema of the face during an episode, leading to grotesque disfigurement. **B.** Angioedema will subside within hours. The patient had a positive family history and had multiple similar episodes including colicky abdominal pain. (With permission from Fitzpatrick's *Color Atlas and Synopsis of Clinical Dermatology*, 5th ed. New York, NY: McGraw-Hill; 2005.)

LABORATORY STUDIES

Consider tests that might help reveal the cause of the urticaria and/or angioedema.

- Order complement studies to investigate for hereditary or acquired C1 esterase inhibitor deficiency when angioedema occurs repeatedly without urticaria (**Figure 150-9**).
- Consider allergen skin testing and/or in vitro tests for when the history reveals that urticaria/angioedema occurs after direct contact with a suspected allergen.
- Punch biopsy of the involved area may be used to diagnose urticarial vasculitis or mastocytosis.

DIFFERENTIAL DIAGNOSIS

- Insect bites—A good history and physical examination should help to distinguish between insect bites and urticaria.
- Erythema multiforme like urticaria can occur in response to an allergic/immunologic reaction to medications, infections, and neoplasms. The classic lesion of erythema multiforme is the target lesion in which there is disruption of the epithelium in the center. This disruption may be a vesicle, bulla, or erosion. Do not confuse annular lesions or concentric rings with erythema multiforme if the epidermis is intact (**Figure 150-11** is *not* erythema multiforme) (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Urticarial vasculitis typically has lesions that last longer than 24 hours. The lesions are found more commonly on the lower extremities, and when they heal, they often leave hyperpigmented areas. Causes range from a hypersensitivity vasculitis, such as Henoch-Schönlein purpura, to underlying connective tissue disease (**Figure 150-14**).²
- Mast cell releasability syndromes are syndromes in which there are too many mast cells in the skin or other organs of the body. These include cutaneous mastocytosis and urticaria pigmentosa (**Figures 150-5, 150-6, and 150-11**).
- Pruritic urticarial papules and plaques of pregnancy can be differentiated from urticaria in pregnancy because the eruption remains fixed and increases in intensity until delivery (**Figure 150-15**) (see Chapter 75, Pruritic Urticarial Papules and Plaques of Pregnancy).
- Pemphigoid gestationis can have lesions that are urticarial. However, it also has bullae that distinguish it from urticaria and of course the patient is pregnant or postpartum (see Chapter 76, Pemphigoid Gestationis).

MANAGEMENT

NONPHARMACOLOGIC THERAPY

- Avoid any causative agent, medication, stimulus, or antigen if found. **SOR B**
- Angiotensin-converting enzyme inhibitors (ACEIs) are especially prone to causing angioedema so should be stopped as soon as possible when suspected to be causative of angioedema or urticaria

FIGURE 150-10 Chronic urticaria with annular urticarial plaques. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-11 Giant urticaria (urticaria multiforme). Although this appears to have targets the real target lesions of erythema multiforme have a central lesion and have a scaling or bullous component affecting the epidermis. The history suggests that this may have been a serum sickness type reaction. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2003; and Daniel Stulberg, MD.)

FIGURE 150-12 Positive Darier sign in which stroking the lesion of urticaria pigmentosum results in edema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-14 Henoch-Schönlein purpura on the leg of a 20-year-old woman. This is a type of urticarial vasculitis. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2003; and Richard P. Usatine, MD.)

FIGURE 150-13 Angioedema and urticaria of the back. The thicker deeper wheals are angioedema. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2003; and Daniel Stulberg, MD.)

FIGURE 150-15 Pruritic urticarial papules and plaques of pregnancy on the arm of a pregnant woman. The wheals are indistinguishable from other types of urticaria. (With permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. *Practical Allergy*. Philadelphia, PA: Elsevier; 2003; and Richard P. Usatine, MD.)

(**Figure 150-3**).¹ **SOR A** Even an angiotensin receptor blocker (ARB) can cause angioedema and should be suspected in a patient on this class of medication (**Figure 150-16**).

- In chronic urticaria, patients may benefit from avoidance of potential urticarial precipitants such as aspirin, NSAIDs (**Figure 150-17**), opiates, and alcohol.¹ **SOR B**
- Infections may be a cause, an aggravating factor, or an unassociated bystander.¹ Look for sources of chronic infections such as parasitic infections, dental infections, GI infections, respiratory infections, and tinea pedis. Treat these, as it is possible, but unproven, that they can contribute to the chronic urticaria. **SOR C**
- Stop all unnecessary nonprescription medications, supplements, and vitamins in chronic urticaria. **SOR C**
- Avoidance of physical stimuli for the treatment of physical urticaria is desirable, but not always possible (observational studies only).¹ **SOR B**
- Stress reduction techniques may help in chronic urticaria but this is unproven. **SOR C**

ANTIHISTAMINES

- Low-sedating, second-generation antihistamines should be prescribed as a first-line treatment for chronic urticaria.⁴⁻⁶ **SOR A**
- Increasing the dose of cetirizine from 10 mg to 20 mg daily produced a significant improvement in the severity of wheal and itching in urticaria refractory to the standard doses of antihistamines.⁷ **SOR B**
- The British guidelines even suggest using antihistamines at up to quadruple the manufacturers' recommended dosages before changing to an alternative therapy. They also recommend waiting up to 4 weeks to allow full effectiveness of the antihistamines before considering referral to a specialist.¹ **SOR C**
- All patients should be offered the choice of at least two low-sedating H₁ antagonists because responses and tolerance vary between individuals.⁸ **SOR A**
- Addition of a sedating antihistamine at night may help patients sleep better, although they probably add little to existing H₁ receptor blockade.⁸
- The addition of an H₂ antagonist may give better control of urticaria than H₁ antagonists alone, **SOR B** although a benefit is not always seen.⁸ In one study, adding H₂ blockers to H₁ antagonists resulted in improvement of certain cutaneous outcomes for patients presenting with acute allergic syndromes to an emergency department.⁹ **SOR B**
- When initial antihistamines are not working, consider doxepin, an antidepressant and potent H₁ antagonist.¹⁰ **SOR B** Its use is limited by the side effects of sedation and dry mouth. Start with 10 mg doxepin in the evening and titrate up as needed and tolerated.
- Low-sedating antihistamines seem to be effective in the treatment of acquired cold urticaria by significantly reducing the presence of wheals and pruritus after cold exposure.¹¹ **SOR A**

CORTICOSTEROIDS

- Oral corticosteroids should be restricted to short courses for severe acute urticaria or angioedema affecting the mouth (e.g., prednisone 60 mg/day for 3 to 4 days in adults).^{8,12} **SOR B**

FIGURE 150-16 Angioedema secondary to an angiotensin receptor blocker given for hypertension. The angioedema resolved and did not return once the patient stopped the offending medication. (Courtesy of Richard P. Usatine, MD.)

FIGURE 150-17 Urticaria that occurred within an hour after a boy was given ibuprofen to treat a high fever. (Courtesy of Richard P. Usatine, MD.)

- Short tapering courses of oral steroids over 3 to 4 weeks may be necessary for urticarial vasculitis and severe delayed pressure urticaria.
- Long-term oral corticosteroids should not be used in chronic urticaria. It is better to use oral cyclosporine if needed as it has a far better risk-to-benefit ratio compared with steroids.^{1,8}
- A randomized controlled trial showed that clobetasol 0.05% in a foam formulation was safe and effective in the short-term treatment of patients with delayed pressure urticaria.¹³ **SOR B**

IMMUNOMODULATORY AGENTS

- Immunosuppressive therapies for autoimmune urticaria should be restricted to patients with disabling disease who have not responded to optimal conventional treatments.⁶
- A retrospective study of methotrexate in 8 patients with recalcitrant chronic urticaria indicated that methotrexate was both safe and effective, with a mean dose of 15 mg methotrexate/week. Seven of 8 patients achieved a complete response and 5 of 8 remained disease-free after methotrexate was stopped.¹⁴ **SOR B**
- Cyclosporine, plasmapheresis, anti-IgE (Omalizumab), and intravenous immunoglobulin have been used in severe recalcitrant cases.¹ **SOR C**
- Plasmapheresis is very costly and should be reserved for autoantibody-positive chronic spontaneous urticaria patients.¹

OTHERS

- Epinephrine is valuable in severe acute urticaria or angioedema, especially if there is a suspicion of airway compromise or anaphylaxis.
- The evidence for leukotriene modifiers in the treatment of urticaria is poor. **SOR C**
- Ecallantide is a new plasma kallikrein inhibitor for the subcutaneous treatment of acute attacks of hereditary angioedema.¹⁵ **SOR B**
- Antiinflammatory drugs, such as colchicine, dapsone and sulfasalazine, have been reported as helpful in uncontrolled trials or case series.¹

PATIENT EDUCATION

In most cases, we are not able to find the cause of urticaria. This is especially true for chronic urticaria. Fortunately, most chronic urticaria will subside over time and there are medicines to treat the condition until it runs its course. If one medication doesn't work keep your follow-up visits to try other medications. Carefully observe for causative agents.

FOLLOW-UP

Follow-up is especially needed when the urticaria/angioedema persist or recur.

SECTION 8 PAPULOSQUAMOUS CONDITIONS

151 SEBORRHEIC DERMATITIS

Meredith M. Hancock, MD
Yoon-Soo Cindy Bae-Harboe, MD
Richard P. Usatine, MD

PATIENT STORY

A 59-year-old man presents with a 3-month history of an itchy rash on his face (**Figures 151-1** and **151-2**). He states that he has had this rash intermittently for many years, but that it had recently worsened. He denies any major risk factors for HIV and does not have Parkinson disease. He has been under more stress lately and has noticed that this rash flares when under increased stress. Note the scale visible on the forehead and under the eyebrows and beard. There is also some mild erythema on the cheeks and around the nasolabial folds. The diagnosis of seborrheic dermatitis is made and treatment is begun with appropriate topical agents to treat the inflammation and the *Malassezia*. On the following visit, the patient has complete clearance of his seborrheic dermatitis.

INTRODUCTION

Seborrheic dermatitis is a common, chronic, relapsing dermatitis affecting sebum-rich areas of the body. Infants and adults, men and women may be affected. Presentation may vary from mild erythema to greasy scales, and, rarely, as erythroderma. Treatment is targeted to reduce inflammation and irritation, as well as to eliminate *Malassezia* fungus, whose exact role is not completely understood.

SYNONYMS

Seborrhea, seborrheic eczema, dandruff, and cradle cap.

EPIDEMIOLOGY

- Seborrheic dermatitis is most commonly seen in male patients ages 20 to 50 years. The prevalence is approximately 3% to 5% in healthy young adults who are HIV-negative.¹ More people may be affected, but many do not seek medical attention for mild cases.
- The prevalence is higher in immunocompromised persons (e.g. HIV-positive/AIDS); however, the vast majority of affected persons have a normal immune system.
- More common in persons with Parkinson disease.
- Infants can have seborrhea of the scalp (cradle cap), face, and diaper area.

FIGURE 151-1 Seborrheic dermatitis following the typical distribution on the face of a 59-year-old man. Note the prominent scale and erythema on his forehead, glabella, and beard region. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Seborrheic dermatitis is a chronic, superficial, localized inflammatory dermatitis that is found in sebum-producing areas of the body.
- The actual cause of seborrheic dermatitis is not well-understood. It appears to be related to the interplay between host susceptibility, environmental factors, and local immune response to antigens.²⁻⁴
- Patients with seborrheic dermatitis may be colonized with certain species of lipophilic yeast of the genus *Malassezia* (also called *Pityrosporum*). However, *Malassezia* is considered normal skin flora and unaffected persons also may be colonized.
- Recent evidence suggests that *Malassezia* may produce different irritants or metabolites on affected skin.⁴

RISK FACTORS

- Male gender
- Immunocompromise (HIV/AIDS, Parkinson disease)
- Stress
- Environmental factors (cold, dry weather)
- Certain medications, including captopril, cimetidine, interleukin-2, isotretinoin, nicotine, and psoralens, may cause seborrheic dermatitis to flare.⁵⁻⁹

DIAGNOSIS

The clinical diagnosis is made by history and physical examination.

Figures 151-1 and **151-2** reveal erythema and scale across the eyebrows, cheeks, and under beard. Biopsy is not generally indicated unless ruling out other possibilities (see Differential Diagnosis below).

CLINICAL FEATURES

- Chronic skin condition characterized by remissions and exacerbations.
- Poorly demarcated, erythematous plaques of greasy, yellow scale (**Figure 151-3**), in the characteristic seborrheic distribution (see description below).
- Common precipitating factors are stress, immunosuppression, and cold weather.
- Face, scalp, and ears may be very pruritic.
- May be the presenting sign of HIV seropositivity
- In dark-skinned individuals, the involved skin and scale may become hyperpigmented (**Figure 151-4**).

TYPICAL DISTRIBUTION

Scalp (i.e., dandruff), eyebrows (**Figures 151-5** and **151-6**), nasolabial creases, forehead, cheeks, around the nose, behind the ears (**Figure 151-7**), external auditory meatus, and under facial hair (**Figure 151-8**). Seborrhea can also occur over the sternum and in the axillae, submammary folds, umbilicus, groin, and gluteal creases.

FIGURE 151-2 Close-up of seborrheic dermatitis showing the flaking scale and erythema around the beard region. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-3 Severe seborrheic dermatitis on the face of a hospitalized man. The stress of his illness has worsened his otherwise mild seborrhea. (Courtesy of Richard P. Usatine, MD.)

Infants may develop scales on the scalp, known as cradle cap (**Figure 151-9**). The eyebrows may also be affected (**Figure 151-5**). Some infants have a wider distribution involving the neck creases, armpits, or groin.

LABORATORY STUDIES

Test for HIV and/or syphilis if patient has risk factors (**Figures 151-10** and **151-11**).

Also consider testing for systemic lupus erythematosus (SLE) in setting of associated systemic symptoms or if treatment-resistant.

Consider KOH test to rule out tinea.

Consider zinc level or alkaline phosphatase to rule out nutritional/zinc deficiency.

DIFFERENTIAL DIAGNOSIS

- Psoriasis—The scale of psoriasis tends to be thicker, on well-demarcated plaques distributed over extensor surfaces along with the scalp. Look for signs of nail involvement that may support the diagnosis of psoriasis (see Chapter 152, Psoriasis).
- SLE with butterfly rash—Rash across nasal bridge in patient with associated systemic symptoms and abnormal blood tests (see Chapter 180, Lupus: Systemic and Cutaneous).
- Rosacea—The erythema on the face is often associated with papules, pustules, telangiectasia, and an absence of scales. May also present with chalazia or hordeola (see Chapter 113, Rosacea).
- Tinea capitis—Scale and erythema commonly with associated hair loss. KOH and/or culture can help make the distinction (see Chapter 137, Tinea Capitis).
- Secondary syphilis—Skin presentation may mimic seborrheic dermatitis. Examine patient for mucosal or palmar involvement. Lab testing for syphilis may be necessary.
- Perioral dermatitis—Usually restricted around the mouth with minimal scale.
- Tinea versicolor (trunk)—The scale of tinea versicolor is fine and white and scales with scraping.
- Allergic or irritant contact dermatitis—may present with a well demarcated lesion with fine white scale, secondarily impetiginized lesions may have associated yellow colored crust, not scale.
- Candidiasis—May be found in intertriginous areas, but present bright red with satellite lesions.
- Nutritional deficiency (i.e., zinc)—May present with facial lesions and acral rash.

MANAGEMENT

As seborrheic dermatitis is a recurrent, chronic condition, repeated and/or maintenance therapy is often required.

- Mainstay of treatment is topical antifungals.
- For seborrheic dermatitis of the scalp, patients should wash their hair with antifungal shampoos (containing selenium sulfide, ketoconazole, or ciclopirox) several times per week, each time leaving the lather on the affected areas for several minutes until remission

FIGURE 151-4 Seborrhea in a black woman with hyperpigmentation related to the inflammation. Note the prominent involvement in the nasolabial folds. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-5 Mild seborrheic dermatitis with subtle flaking around the eyebrows of a 2-month-old girl who also has cradle cap. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-6 Seborrheic dermatitis with erythema and scale under the eyebrows and in the glabella region on a young man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-8 Seborrhea of the beard and mustache distribution with prominent erythema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-7 Seborrheic dermatitis behind the ear in a young woman. This is a good place to look for evidence of seborrhea. (Courtesy of Richard P. Usatine, MD.)

FIGURE 151-9 Cradle cap in an infant that also has atopic dermatitis. (Courtesy of Richard P. Usatine, MD.)

is attained. Patients may continue to use antifungal shampoo as maintenance therapy.³

- Shampoos containing ketoconazole, selenium sulfide or zinc pyrithione (ZPT) are active against the *Malassezia* and are effective in the treatment of moderate to severe dandruff.^{10,11} **SOR A**
- Ketoconazole 2% shampoo was found to be superior to ZPT 1% shampoo when used twice weekly. Ketoconazole led to a 73% improvement in the total dandruff severity score compared with 67% for ZPT 1% at 4 weeks.¹¹ **SOR B**
- Ciclopirox shampoo 1% is effective and safe in the treatment of seborrheic dermatitis of the scalp.^{12,13} **SOR A** It is by prescription only and is very expensive.
- Ketoconazole 2% cream, gel, or emulsion is safe and effective for facial seborrheic dermatitis.^{14–16} **SOR B**
- Ciclopirox 1% cream is also safe and effective for facial seborrheic dermatitis and is equivalent to ketoconazole 2% cream.^{14,17} **SOR B**
- Oral terbinafine 250 mg daily for 4 weeks is effective for moderate to severe seborrhea.^{18,19} **SOR A** However, because of the potential for harmful side effects of oral antifungals and the limited study of their efficacy, they are not first-line treatments.³ Oral terbinafine may be considered in erythroderma caused by seborrhea.

Topical corticosteroids are useful in treating associated erythema and pruritis.³ Long-term use may lead to skin atrophy³ and should be used with caution.

- Lotion or solution is preferable on hair-covered area for patient comfort and usability.
- Hydrocortisone 1% cream or lotion can be used bid on the face, scalp, and other affected areas.^{16,20} **SOR B**
- Desonide 0.05% lotion is safe and effective for short-term treatment of seborrheic dermatitis of the face.¹⁸ **SOR B** It is a nonfluorinated low to midpotency steroid that is higher in potency than hydrocortisone 1%.
- For moderate to severe seborrheic dermatitis on the scalp.
 - Fluocinonide 0.05% solution once daily is affordable and beneficial. **SOR C**
 - Clobetasol 0.05% shampoo, solution, spray, or foam works well but is more costly. **SOR C**

OTHER TREATMENTS

- Pimecrolimus cream 1% is an effective and well-tolerated treatment for facial seborrheic dermatitis.^{20,22,23} **SOR B** In one study, there was more burning noted with the pimecrolimus than with the betamethasone 17-valerate 0.1% cream.²²
- Metronidazole gel—Two small studies have found different results in the treatment of seborrheic dermatitis on the face. One suggests it works better than the vehicle alone and the other found no statistically significant difference from placebo.^{24,25} **SOR B**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Tea tree oil 5% shampoo showed a 41% improvement in the quadrant-area-severity score compared with 11% in the placebo.

FIGURE 151-10 Seborrheic dermatitis on the face of a man with acquired immune deficiency syndrome. Note the involvement of the forehead, cheeks, and chin causing hypopigmentation and scaling. (Courtesy of Yoon-Soo Cindy Bae-Harboe, MD.)

FIGURE 151-11 Seborrheic dermatitis on the face of a man with acquired immune deficiency syndrome. Note erythema and scale on the forehead, nose and cheeks. (Courtesy of Richard P. Usatine, MD.)

Statistically significant improvements were also observed in the total area of involvement score, the total severity score, and the itchiness and greasiness components of the patients' self-assessments.²⁶ **SOR B**

- One small randomized controlled trial using homeopathic medication consisting of potassium bromide, sodium bromide, nickel sulfate, and sodium chloride for 10 weeks showed significant improvement over placebo.²⁷ **SOR C**

FOLLOW-UP

Patients with longstanding and severe seborrhea will appreciate a follow-up visit in most cases. Milder cases can be followed as needed.

PATIENT EDUCATION

For improved treatment results, encourage patients to wash the hair and scalp daily with an antifungal shampoo. Some patients fear that washing their hair too often will cause a "dry" scalp and need to understand that the scaling and flaking will improve rather than worsen with more frequent hair washing.

152 PSORIASIS

Richard P. Usatine, MD

PATIENT STORY

A 33-year-old woman presents with uncontrolled psoriasis for 20 years. In addition to the plaque psoriasis (**Figure 152-1**), she has inverse psoriasis (**Figure 152-2**). Topical ultrahigh-potency steroids and topical calcipotriol have not controlled her psoriasis. The options for phototherapy and systemic therapy were discussed. The patient chose to try narrowband UVB treatment in addition to her topical therapy.

INTRODUCTION

Psoriasis is a chronic inflammatory papulosquamous and immune-mediated skin disorder. It is also associated with joint and cardiovascular comorbidities. Psoriasis can present in many different patterns from the scalp to the feet and cause psychiatric distress and physical disabilities. It is crucial to be able to identify psoriasis in all its myriad presentations so that patients receive the best possible treatments to improve their quality of life and avoid comorbidities.

EPIDEMIOLOGY

Psoriasis affects approximately 2% of the world population.¹ The prevalence of psoriasis was 2.5% in white patients and was 1.3% in African American patients in one population study in the United States.²

- Sex—No gender preference.
- Age—Psoriasis can begin at any age. In one population study of the age of onset of psoriasis two peaks were revealed, one occurring at the age of 16 years (female) or 22 years (males) and a second peak at the age of 60 years (female) or 57 years (males).³

ETIOLOGY AND PATHOPHYSIOLOGY

- Immune-mediated skin disease, where the T cell plays a pivotal role in the pathogenesis of the disease.
- Langerhans cell (antigen-presenting cells in the skin) migrate from the skin to regional lymph nodes, where they activate T cells that migrate to the skin and release cytokines.
- Cytokines are responsible for epidermal and vascular hyperproliferation and proinflammatory effects.

FIGURE 152-1 Typical plaque psoriasis on the elbow and arm. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-2 Inverse psoriasis in the inframammary folds of the patient in **Figure 152-1**. This is not a *Candida* infection. (Courtesy of Richard P. Usatine, MD.)

TABLE 152-1 Factors that Trigger or Exacerbate Psoriasis

- Stress
- Physical trauma to the skin (Koebner phenomenon)
- Cold dry weather
- Sun exposure and hot weather
- Infections (e.g. strep throat, HIV)
- Medications (e.g. ACE-inhibitors, antimalarials, Beta-blockers, lithium, NSAIDs)

RISK FACTORS

- Family history.
- Obesity.
- Smoking and environmental smoke.
- Heavy alcohol use.

Table 152-1 lists the factors that trigger or exacerbate psoriasis.⁴

The risk of psoriasis is higher in:⁵

- Family history of psoriasis (odds ratio [OR] = 33.96; 95% confidence interval [CI] 14.14 to 81.57)
- Change in work conditions (OR = 8.34; 95% CI = 1.86 to 37.43)
- Divorce (OR = 5.69; 95% CI = 2.26 to 14.34)
- Urban dwellers (OR = 3.61; 95% CI = 0.99 to 13.18)
- Alcohol consumption (OR = 2.55; 95% CI = 1.26 to 5.17)
- Environmental tobacco smoke at home (OR = 2.29; 95% CI = 1.12 to 4.67)

DIAGNOSIS

Psoriasis has many forms and locations. These nine categories were used to describe psoriasis in a consensus statement of the American Academy of Dermatology (AAD):⁶

1. Plaque (80% to 90% of patients with psoriasis) (**Figures 152-1 and 152-3**).
2. Scalp psoriasis (**Figure 152-4**).
3. Guttate psoriasis (**Figure 152-5**).
4. Inverse psoriasis (**Figures 152-2 and 152-6**).
5. Palmar-plantar psoriasis (**Figure 152-7**). Also known as palmoplantar psoriasis.
6. Erythrodermic psoriasis (**Figure 152-8**).
7. Pustular psoriasis—localized and generalized (**Figure 152-9**).
8. Nail psoriasis (**Figure 152-10**) (see Chapter 195, Psoriatic Nails).
9. Psoriatic arthritis (**Figure 152-11**).

Typical distribution in general: elbows, knees, extremities, trunk, scalp, face, ears, hands, feet, genitalia and intertriginous areas, and

TABLE 152-2 The Most Common Locations of Lesions in Patients With Psoriasis

Location	% of Psoriasis Patients
Scalp	80
Elbows	78
Legs	74
Knees	57
Arms	54
Trunk	53
Lower part of the body	47
Base of the back	38
Palms and soles	12

nails. **Table 152-2** provides percentages for the most common locations of lesions in patients with psoriasis.

Plaque psoriasis:

- White scale on an erythematous raised base with well-demarcated borders (**Figures 152-1** and **152-3**).
- Silvery scale with hyperpigmentation may be seen in patients with darker skin (**Figures 152-12** and **152-13**).
- Plaques can appear in different colors including hypopigmented (**Figure 152-14**) and silvery gray (**Figure 152-15**). A tricolored presentation occurs when the inflammation leads to leukoderma (**Figure 152-16**).
- The thickness and extent of the scale is variable (**Figure 152-15**).
- Positive Auspitz sign in which the peeling of the scale produces pinpoint bleeding on the plaque below.
- Typical distribution includes the elbows and knees and other extensor surfaces. The plaques can be found from head to toe including the penis (**Figure 15-17**).
- Plaques tend to be symmetrically distributed.
- Plaques can be annular with central clearing (**Figure 152-18**).
- When plaques occur at a site of injury, it is known as the Koebner phenomenon (**Figure 152-19**).

Scalp psoriasis:

- Plaque on the scalp that may be seen at the hairline and around the ears (**Figure 152-4**).
- The thickness and extent of the plaques are variable as seen in plaque psoriasis.

Guttate psoriasis:

- Small round plaques that resemble water drops (guttate means like a water drop) (**Figure 152-20**).
- Classically described as occurring after strep pharyngitis or another bacterial infection. This is one type of psoriasis that occurs in childhood.

FIGURE 152-12 Plaque psoriasis with silvery scale on a black man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-13 Psoriasis on the knee of a Hispanic man showing postinflammatory hyperpigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-14 Plaque psoriasis with hypopigmentation in this 12-year-old obese boy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-16 Plaque psoriasis that has caused hypopigmentation in a band across the back. His original skin color is brown so that the brown, white, and pink colors produce the appearance of Neapolitan ice cream. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-15 Thick plaque psoriasis covering the lower legs of this obese man. Note the silver gray color to his plaques. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-17 Plaque psoriasis on the penis, covering the glans and part of the shaft. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-18 Plaque psoriasis with an annular configuration. (Courtesy of Richard P. Usatine, MD.)

- Typical distribution: the trunk and extremities but may include the face and neck (**Figure 152-21**).

Inverse psoriasis:

- Found in the intertriginous areas of the axilla, groin, inframammary folds, and intergluteal fold (**Figures 152-2, 152-6, and 152-22**). It can also be seen below the pannus or within adipose folds in obese individuals.
- The term *inverse* refers to the fact that the distribution is not on extensor surfaces but in areas of body folds.
- Morphologically the lesions have little to no visible scale.
- Color is generally pink to red but can be hyperpigmented in dark-skinned individuals.

Palmar-plantar (palmoplantar) psoriasis:

- Psoriasis that occurs on the plantar aspects of the hands and feet (palms and soles) (**Figure 152-23**). The psoriasis can also be seen on other parts of the hands and feet.
- Patients with this type of psoriasis often experience severe foot and hand pain that can impair walking and other daily activities of living. Hand involvement can result in pain with many types of work.
- Morphologically this can be plaque-like, vesicular, or pustular (**Figure 152-24**). Brown spots may be present as macules or flat papules. These are called mahogany spots and although they are not always present, they are characteristic of palmar-plantar psoriasis. Exfoliation of the skin can occur on the palms and soles.

Erythrodermic psoriasis:

- Erythrodermic psoriasis is widespread and erythematous covering most of the skin (**Figure 152-25**).
- Morphologically, it can have plaques and erythema or the erythroderma can appear with the desquamation of pustular psoriasis.
- Widespread distribution can impair the important functions of the skin and this can be a dermatologic urgency requiring hospitalization and IV fluids. Chills, fever, tachycardia, and orthostatic hypotension are all signs that the patient may need hospitalization.

Pustular psoriasis:

- Pustular psoriasis comes in localized and generalized types. One example of the local type is pustular psoriasis on the feet (**Figure 152-24**).
- In the generalized type, the skin initially becomes fiery red and tender and the patient experiences constitutional signs and symptoms such as headache, fever, chills, arthralgia, malaise, anorexia, and nausea (**Figure 152-26**). The desquamation that occurs in the generalized form can impair the important functions of the skin predisposing to dehydration and sepsis. This is a dermatologic emergency requiring hospitalization and IV fluids, preferably in a monitored bed with good nursing care.
- Typical distribution: Flexural and anogenital (**Figure 152-27**). Less often, facial lesions occur. Pustules may occur on the tongue and subungually, resulting in dysphagia and nail shedding, respectively.
- Time course: Within hours, clusters of nonfollicular, superficial 2- to 3-mm pustules may appear in a generalized pattern. These pustules coalesce within 1 day to form lakes of pus that dry and desquamate in sheets, leaving behind a smooth erythematous

FIGURE 152-26 Generalized pustular psoriasis in a 47-year-old man with fever, exfoliation, and dehydration. This is the twentieth time for this patient in his life. His siblings also get severe generalized pustular psoriasis. (Courtesy of Meng Lu, MD.)

FIGURE 152-25 Erythrodermic psoriasis in a 45-year-old man. Note the extensive exfoliation of the skin along with the deep erythema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-27 Localized pustular psoriasis in the groin. (Courtesy of Jeffrey Meffert, MD.)

surface on which new crops of pustules may appear. These episodes of pustulation may occur for days to weeks causing the patient severe discomfort and exhaustion. Upon remission of the pustular component, most systemic symptoms disappear; however, the patient may be in an erythrodermic state or may have residual lesions.¹

Nail psoriasis:

- Nail involvement in psoriasis can lead to pitting, onycholysis, subungual keratosis, splinter hemorrhages, oil spots, and nail loss (**Figure 152-10** and Chapter 195, Psoriatic Nails).

Psoriatic arthritis:

- Asymmetric oligoarthritis typically involving the hands, feet, and knees. The arthritis can also be symmetric resembling rheumatoid arthritis. Distal interphalangeal joint (DIP) involvement is a classic finding, but DIP predominance is present in the minority of cases. The fingers may be swollen like sausages which is called dactylitis (**Figure 152-28**). See Table 95-1 in Chapter 95, Overview of Arthritis for a description of the five types of psoriatic arthritis.
- Hand involvement can be disabling (**Figure 152-11**). X-rays should be ordered when a person with psoriasis has joint pains suggesting psoriatic arthritis. Typical findings are juxtaarticular erosions and the pencil-cup deformity (**Figure 152-29**).
- There may be inflammation at the insertion of tendons onto bone (enthesopathy). This may occur at the Achilles tendon.
- Patients with psoriatic arthritis need to be treated with systemic agents (methotrexate or biologics) to prevent advancement of the disease.

DISEASE SEVERITY

- Moderate-to-severe disease is defined by psoriasis of the palms, soles, head and neck, or genitalia, and in patients with more than 5% body surface area (BSA) involvement. A person's palm is approximately 1% BSA and can be used to estimate BSA.
- Another grading system for severity uses the following numbers:
 - Mild: Up to 3% BSA
 - Moderate: 3% to 10% BSA
 - Severe: >10% BSA
- Patients with psoriatic arthritis may have limited skin disease but require more aggressive systemic therapies.
- Note that palmoplantar psoriasis is considered moderate-to-severe even if the BSA involved is not above 3% or 5% (**Figure 152-30**).

LABORATORY STUDIES

Laboratory studies are rarely needed. A punch biopsy or scoop shave is used for evaluating atypical cases. For pustular psoriasis, a 4-mm punch around an intact pustule is preferred (**Figure 132-31**).

IMAGING

Plain films should be ordered when a person with psoriasis has joint pains suggesting psoriatic arthritis (**Figure 152-29**). Early psoriatic arthritis often has no findings on plain films, but if history and physical exam suggest the diagnosis, one should not wait for irreversible visible joint damage to initiate therapy.

FIGURE 152-28 Dactylitis with sausage-shaped fingers in this middle-aged woman with plaque psoriasis and psoriatic arthritis. Note the nail involvement along with distal interphalangeal joint involvement. (Courtesy of Richard P. Usatine, MD.)

FIGURE 152-29 Radiograph showing the pencil-in-cup deformity at the distal interphalangeal joint of the second and third digits. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Cutaneous T-cell lymphoma (CTCL) can have plaques that resemble psoriasis. In most cases of psoriasis, the distribution and nail changes will help to differentiate between these diseases. Plaque-type CTCL tends to be more central and truncal, whereas psoriasis often involves the extremities along with the trunk. If needed, a punch biopsy can help to differentiate between these two conditions (see Chapter 176, Cutaneous T- cell Lymphoma).
- Lichen planus is another papulosquamous disease. Its distribution is more on flexor surfaces and around the wrists and ankles than the elbows and knees (see Chapter 154, Lichen Planus).
- Lichen simplex chronicus is a hyperkeratotic plaque with lichenification. It usually presents with fewer plaques than psoriasis and is typically found on the posterior neck, ankle, wrist, or lower leg. There is usually more lichenification than thick scale and it is always pruritic (see Chapter 149, Self-Inflicted Dermatoses).
- Nummular eczema presents with coin-like plaques. These are most commonly found on the legs and are usually not as thick as the plaques of psoriasis. Nummular eczema may also have vesicles and bullae. Psoriasis has a different distribution and often includes nail changes (see Chapter 145, Atopic Dermatitis).
- Pityriasis rosea is a self-limited process that has papulosquamous plaques. These plaques are less keratotic and have a collarette scale. Pityriasis rosea frequently has a herald patch (see Chapter 153, Pityriasis Rosea).
- Seborrheic dermatitis of the scalp can closely resemble psoriasis of the scalp, especially when it is severe. Psoriasis generally has thicker plaques on the scalp and the plaques often cross the hair-line. Seborrhea and psoriasis can both involve the ear. Both conditions respond to topical steroids (see Chapter 151, Seborrheic Dermatitis).
- Syphilis is the great imitator and secondary syphilis can have a papulosquamous eruption similar to psoriasis. Secondary syphilis often involves the palms and soles and the rapid plasma reagin (RPR) will be positive (see Chapter 216, Syphilis).
- Tinea corporis or cruris can resemble inverse psoriasis in the intertriginous areas as both conditions tend to have erythema and thinner plaques without central clearing in these regions. Tinea corporis in non-intertriginous areas typically presents with annular plaques with central clearing. Psoriasis can do this as seen in **Figure 152-18**. Tinea corporis usually does not have as many plaques as psoriasis but a KOH preparation can be used to look for fungal elements to distinguish between these two conditions (see Chapter 138, Tinea Corporis).
- Cutaneous candidiasis appears similar to inverse psoriasis when found in intertriginous areas (see Chapter 136, Candidiasis).
- Reactive arthritis (see Chapter 155, Reactive Arthritis) is a noninfectious acute oligoarthritis that occurs in response to an infection, most commonly in the GI or urogenital tract. Patients present 1 to 4 weeks after the triggering infection, with joint pain in asymmetric large joints, eye disease such as conjunctivitis, and skin changes including erythema nodosum, keratoderma blennorrhagicum, and circinate balanitis. Diagnosis is based on the clinical presentation

FIGURE 152-30 Palmoplantar psoriasis in a 31-year-old man with erythema, pustules, and lakes of pus. Note the typical brown macules that are called mahogany spots. High-potency topical steroids did not help at all. It is painful for him to walk and systemic therapy has just been started. This is a localized form of pustular psoriasis. (Courtesy of Jeff Meffert, MD.)

plus evidence of associated infection. The skin lesions closely resemble psoriasis so the diagnosis depends upon the constellation of the clinical involvement and the history.

MANAGEMENT

Treat precipitating and underlying factors when these are known. Encourage smoking cessation to all who smoke (Chapter 236, Tobacco Addiction). Avoid or minimize alcohol use (Chapter 237, Alcoholism). Stress management techniques can be suggested in patients whom admit that stress is an important factor in worsening their condition. Use preventive techniques as much as possible by avoiding known precipitants.

Patient perception of their disease and expectations for therapy are as important as the evidence and recommendations that follow. Some patients are willing to live with some skin changes rather than go on systemic treatment, whereas others want everything done with a goal of 100% clearance. Consequently, therapeutic choices are made in conjunction with patient's values and their life situation (economics and time issues surrounding treatment options).

Choice of topical vehicles:

- An ointment has a petrolatum base and will penetrate thick scale best.
- An emollient cream has some of the advantages of an ointment but is cosmetically more appealing to patients who find a basic ointment to be too greasy.
- Some patients prefer cream to avoid the oily feel of ointment even though it is less effective in general than an ointment. However, in many cases the most effective vehicle is the one the patient will use.
- Lotions and foams are good for hair-bearing areas when some moisturizing is desired.
- Steroid solutions work well for psoriasis of the scalp.
- New foam preparations have rapid absorption and are cosmetically appealing. These tend to be more expensive at this time.

Topical treatments:

- **Table 152-3** summarizes the strength of recommendations for the treatment of psoriasis using topical therapies.
- Research supports potent topical steroids as first-line therapy.⁸ **SOR A** Clobetasol is an ultrahigh-potency steroid that is generic and comes in many vehicles for use on the body and scalp. A metaanalysis of the studies with clobetasol demonstrated 68% to 89% of patients had clear improvement or complete healing.⁹ **SOR A**
- There are two vitamin D analogs available for topical use: calcipotriene (Dovonex and generic) and calcitriol (Vectical). These vitamin D preparations are recommended as first-line therapy with or without topical corticosteroids for the treatment of childhood psoriasis.¹⁰ **SOR A** They are also useful for adults but most patients report that clobetasol is more effective.
- Comparable efficacy has been shown for topical calcipotriene (vitamin D analog) and tazarotene (retinoid) with a slight increase in adverse effects for tazarotene.⁸ **SOR A**
- Using topical steroids and calcipotriene or tazarotene is an effective regimen. It has increased efficacy and fewer side effects.^{8,9} **SOR A** However, in monotherapy studies of topical agents in psoriasis,

FIGURE 152-31 Pustular psoriasis in a 41-year-old woman. A 4-mm punch biopsy including at least one pustule helped to confirm the clinical diagnosis. The patient was stable for outpatient treatment and was started on cyclosporine and acitretin together with the plan to stop the cyclosporine once the pustules have cleared. **A.** Arm involvement. **B.** Close-up of pustules on the leg. (Courtesy of Robert T. Gilson, MD.)

TABLE 152-3 Strength of Recommendations for the Treatment of Psoriasis Using Topical Therapies¹

Agent	Strength of Recommendation	Level of Evidence
Class I corticosteroids (highest potency)	A	I
Class II corticosteroids	B	II
Classes III/IV corticosteroids (medium potency)	A	I
Classes V/VI/VII corticosteroids (lowest potency)	A	I
Vitamin D analogs	A	I
Tazarotene	A	I
Tacrolimus and pimecrolimus	B	II
Anthralin	C	III
Coal tar	B	II
Combination corticosteroid and salicylic acid	B	II
Combination corticosteroid and vitamin D analog	A	I
Combination corticosteroid and tazarotene	A	I
Combination tacrolimus and salicylic acid	B	II

Adapted from Menter A, Korman NJ, Elmets CA, et al; American Academy of Dermatology. Guidelines of care for the management of psoriasis and psoriatic arthritis. Section 3. Guidelines of care for the management and treatment of psoriasis with topical therapies. *J Am Acad Dermatol.* 2009;60(4):643-659.

steroids caused fewer adverse reactions compared to vitamin D analogs and tazarotene.¹¹ **SOR A**

- One expensive topical preparation combines betamethasone and calcipotriene (Taclonex ointment) to be applied once daily. Another option is to prescribe generic clobetasol ointment and generic calcipotriene cream to be used simultaneously or in an alternating fashion.
- Clobetasol in the morning and tazarotene in the evening is a good combination to reduce irritation and increase efficacy.⁹ **SOR A**
- Two trials randomized potent steroid treatment responders to either an intermittent maintenance regime (three applications each weekend) or to no maintenance. The results of more than 6 months indicate that patients receiving maintenance therapy were more than three times as likely to stay in remission.¹² **SOR B**
- Older treatments still in use include topical coal tar and topical anthralin.⁹ Evidence does not support the use of coal tar alone or in combination at this time.⁹ **SOR A** Topical anthralin is messy, not practical for long-term use and not supported by evidence.^{1,5} **SOR A**
- Topical calcineurin inhibitors previously approved for eczema are being studied for use in psoriasis. Tacrolimus ointment seems most effective in treating psoriasis of the face and intertriginous areas where the skin is thin. Clinical trials suggest that tacrolimus (0.1%) ointment twice a day produces a good response in a majority of patients with facial and intertriginous (inverse) psoriasis (**Figure 152-6**).¹³⁻¹⁵ **SOR B**
- Emollients and keratolytics are safe and probably beneficial as adjunctive treatment. **SOR C**
- Intralesional steroids may help small plaques resolve (**Figure 152-32**). Use triamcinolone acetonide 5 to 10 mg/mL injected with a 27-gauge needle into the plaque. **SOR C**

FIGURE 152-32 Intralesional injection of small plaques over the knee that were resistant to treatment with high potency topical steroids. A 27-gauge needle was employed with 5 mg/mL triamcinolone. (Courtesy of Richard P. Usatine, MD.)

TABLE 152-4 Systemic Drugs Used in Treatment of Psoriasis³¹

Drug Name	Classification/ Mechanism of Action	Comments
Acitretin	Oral retinoid	First-line systemic drug for chronic palmoplantar or pustular psoriasis in patients of nonchildbearing potential. Limited benefit for plaque psoriasis.
Cyclosporine	Oral calcineurin inhibitor	Fast-acting systemic drug that is often used first-line for pustular psoriasis or erythrodermic psoriasis. For intermittent use in periods up to 12 wk as a short-term agent to control a flare of psoriasis.
Methotrexate sodium	Inhibitor of folate biosynthesis	May be used as a first-line systemic drug for plaque psoriasis and psoriatic arthritis. Compared with cyclosporine, has a more modest effect, but can be used continuously for years or decades.
Adalimumab	TNF inhibitor	May be used as first-line systemic treatment of plaque psoriasis and psoriatic arthritis. Has higher efficacy and lower rate of adverse effects compared with methotrexate.
Etanercept	TNF inhibitor	Commonly used as a first-line systemic drug for chronic plaque psoriasis and psoriatic arthritis.
Infliximab	TNF inhibitor	Intravenous infusion with high rates of effectiveness. Fast-acting drug that is often used as a second- or third-line biological for chronic plaque psoriasis.
Ustekinumab	Monoclonal antibody that binds the shared p40 protein subunit of IL-12 and IL-23	Favorable results when compared with etanercept in terms of efficacy and safety. May be used as first-line systemic treatment for chronic plaque psoriasis.

IL, interleukin; *TNF*, tumor necrosis factor.

Phototherapy:

- Is indicated in the presence of extensive and widespread disease (practically defined as more lesions than can be easily counted) and psoriasis not responding to topical therapy.
- Narrowband UVB is more effective than broadband UVB and approaches psoralen and UVA (PUVA) in efficacy for the treatment of psoriasis in patients with skin types I to III (lighter skin).¹⁶ **SOR A**
- At present, there are no predictors of the type(s) of psoriasis most responsive to narrowband UVB.¹⁶
- Of patients with psoriasis, 63% to 80% will clear with a course of narrowband UVB with equivalent relapse rates compared with PUVA.¹⁶
- Lack of requirement for psoralen and convenience suggests that narrowband UVB could be considered as the first-line phototherapy option with PUVA reserved for treatment failures.¹⁶
- Methotrexate pretreatment (15 mg per week × 3) allowed physicians to clear psoriasis in fewer phototherapy sessions than when phototherapy was administered alone in one study.¹⁷ **SOR B**
- According to one consensus conference, acitretin combined with UV therapy is safe and effective and limits treatment frequency, duration, and cumulative doses of both agents. They state this

combination is better tolerated, more convenient, less costly, and, perhaps, safer during long-term treatment than phototherapy alone.¹⁸ **SOR C**

- Avoid use of cyclosporine with UV therapy because of an increased risk of skin cancer.¹⁹

Systemic:

- When topical agents (and/or phototherapy fail), systemic agents (including biologic agents) are the next step. **Table 152-4** summarizes the systemic drugs used in treatment of psoriasis.
- Methotrexate and biologic agents are especially valuable in patients with psoriatic arthritis and may be started early in the course of treatment to prevent permanent joint damage.
- Do not use systemic corticosteroid therapy for psoriasis. Pustular flares of disease may be provoked and these flares can be fatal (**Figure 152-18**).
- Methotrexate and oral retinoids can cause birth defects so appropriate counseling, contraception, and testing should accompany therapy with these agents.
- Methotrexate (MTX) is given as a weekly dose of 7.5 to 25 mg/week depending upon response and side effects.²⁰ **SOR A** Tuberculosis screening with purified protein derivative (PPD) or QuantiFERON-TB Gold blood test should precede treatment (if positive results, then the tuberculosis [TB] needs treatment before starting this therapy). Pretreatment laboratories should include a complete blood count (CBC), differential, liver function tests (LFTs), a chemistry profile, and hepatitis B and C serologies. A CBC and LFTs should be followed regularly. Patients should take folic acid 1 mg/day to prevent some of the possible adverse effects of MTX. For MTX, reliable contraceptive methods should be used during and for at least 3 months after therapy in both men and women.⁵
- The starting dose of MTX is between 5 and 10 mg/week for the first week based on expert experience.²¹ The dose is escalated with monitoring to obtain a therapeutic target dose of 15 to 25 mg/week. Oral dosing is preferred but SQ dosing is an option in the event of poor GI tolerance (same dosing as oral). Type 2 diabetes and obesity appear to be significant risk factors in fibrosis.²¹ A combination of fibrotests and fibroscans together with measurement of the type III serum procollagen aminopeptide are noninvasive methods to monitor for liver toxicity.²¹ **SOR C** The question of whether or when to do a liver biopsy and/or stop MTX is controversial.

The National Psoriasis Foundation has published that liver “biopsies are now advocated after a cumulative dose of 3.5 g in low-risk patients and 1.5 g in high-risk patients.” The same recommendations are cited in the 2009 National Psoriasis Foundation Consensus Conference on MTX and psoriasis.²² **SOR C**

- Cyclosporine (oral) is a T-cell inhibitor and is very effective in rapidly treating psoriasis. The recommended starting dose is 2.5 to 6 mg/kg per day (actual body weight) divided twice a day.¹⁹ **SOR C** Serum creatinine and blood pressure should be monitored monthly. Also CBC, uric acid, potassium, lipids, LFTs, and magnesium should be monitored monthly. Cyclosporine can be used for long-term therapy in patients with severe psoriasis for up to 2 years lifetime maximum based on European guidelines and 1 year maximum based upon the U.S. guidelines.^{9,19} **SOR C** Cyclosporine is pregnancy category C, with several studies indicating an increased risk of premature birth but no major malformations.¹⁹
- Oral retinoids: Acitretin is a potent systemic retinoid used for psoriasis.²³ **SOR A** Acitretin appears to provide better efficacy in pustular psoriasis (including palmoplantar psoriasis) than in plaque-type psoriasis as a single agent treatment (**Figure 152-31**).²⁴ **SOR A** Low-dose acitretin therapy (25 mg/day) seems to be better tolerated and associated with fewer abnormalities found after laboratory testing and fewer adverse effects than the 50 mg/day dosage.²³ Acitretin is known to cause fetal malformations just like isotretinoin so it is best to avoid use in women capable of pregnancy, especially as it may remain in the body for up to 3 years after stopping therapy.

Biologic agents:

There are 4 biologic agents available and FDA approved for treating psoriasis. See **Table 152-5** and **152-6** for information about mechanism of action and the effectiveness of these agents.

- Before starting therapy, obtain a PPD or QuantiFERON-TB Gold blood test. These agents can reactivate dormant TB. Screening for TB should continue yearly during biologic therapy.²⁶
- The TNF inhibitors (adalimumab, etanercept, and infliximab) share a common mechanism of action that leads to safety concerns. Safety concerns include serious infections (e.g., sepsis, tuberculosis, and viral infections), autoimmune conditions (lupus and demyelinating disorders), and lymphoma.²⁷
- Etanercept (subcutaneous): For adults the dose is 50 mg SQ twice weekly for 3 months then 50 mg weekly thereafter.⁹ **SOR A** This

TABLE 152-5 FDA-Approved Biologic Agents for Treating Psoriasis

Biologic Agent	Product Name	Mechanism of Action	Route of Delivery	Frequency of Maintenance Dosing
Adalimumab	Humira	TNF inhibitor	SQ	Every 2 weeks
Etanercept	Enbrel	TNF inhibitor	SQ	Once to twice weekly
Infliximab	Remicade	TNF inhibitor	IV infusion	Every 6-8 weeks
Ustekinumab	Stelara	Monoclonal antibody that binds p40 protein subunit of IL-12 and IL-23	SQ	Every 3 months

IL, Interleukin; TNF, tumor necrosis factor.

TABLE 152-6 Biologic Agents as Treatment of Plaque Psoriasis—Estimated Probabilities of Response Based Upon Synthesis of Evidence

	PASI 50, mean (95% CrI)	PASI 75, mean (95% CrI)	PASI 90, mean (95% CrI)
Placebo	13% (12–14)	4% (3–4)	1% (0–1)
Etanercept 25 mg	65% (56–73)	39% (30–48)	15% (10–21)
Etanercept 50 mg	76% (71–81)	52% (45–59)	24% (19–30)
Adalimumab	81% (74–87)	58% (49–68)	30% (23–39)
Ustekinumab 45 mg	88% (84–91)	69% (62–75)	40% (33–48)
Ustekinumab 90 mg	90% (87–93)	74% (68–80)	46% (39–54)
Infliximab	93% (89–96)	80% (70–87)	54% (42–64)

CrI, Credible interval; PASI, Psoriasis Area and Severity Index is used to express the severity of psoriasis. It combines the severity (erythema, induration, and desquamation) and percentage of affected area (lower number is better and the highest number for worst disease is 72); PASI 50 = 50% reduction in PASI score—clinically meaningful improvement; PASI 75 = 75% reduction in PASI score—very good improvement; PASI 90 = 90% reduction in PASI score—excellent improvement.

Adapted from Reich K, Burden AD, Eaton JN, Hawkins NS. Efficacy of biologics in the treatment of moderate to severe psoriasis: a network meta-analysis of randomized controlled trials. *Br J Dermatol*. 2012;166:179-188.

agent is especially valuable in patients with psoriatic arthritis as well as psoriasis.⁹ **SOR A**

- Ustekinumab is a new biologic agent that is given SQ every 3 months. It targets interleukin (IL)-12 and IL-23 in the treatment of moderate-to-severe psoriasis. The safety profile of continued ustekinumab exposure through up to 3 years is favorable including the risk for either infections or malignancies.^{28,29}
- While the biologic agents are all very expensive, insurance often pays and there are patient assistance programs for uninsured patients with limited resources.

Methotrexate versus biologic agents:²⁰

- MTX is a very inexpensive medication with more than a 40-year track record, but with known potential for hepatotoxicity. It is very effective, but requires monitoring of the LFTs and the blood count on a regular basis.
- The biologic agents are engineered proteins with a potentially safer profile than MTX. However, they are very expensive and require parenteral administration. Biologics have the advantage of requiring less monitoring with blood tests. The biologic agents are not side-effect free and some of the potential side effects, while rare, are quite dangerous, and include the risks of sepsis, malignancy, and demyelinating disease.

THERAPY BY TYPE OF PSORIASIS

PLAQUE TYPE

Mild-to-moderate plaque psoriasis: Clobetasol twice daily for 2 to 4 weeks. Then decrease use of clobetasol and consider adding a steroid-sparing topical agent such as a vitamin D topical product.

Severe plaque form psoriasis: One systematic review found 665 studies dealing with the treatment of severe plaque psoriasis.¹⁷ Photochemotherapy showed the highest average proportion of patients with

clearance (70% [6947/9925]) and good response (83% [8238/9925]), followed by UVB (67.9% [620/913]) and cyclosporine (64% [1030/1609]) therapy.³⁰ **SOR A** Expert consensus in a meeting following data analysis supported the following sequence for the treatments: UVB, photochemotherapy, MTX, acitretin, and cyclosporine.³⁰ **SOR C**

The Consensus guidelines for the management of plaque psoriasis published in 2012 is based on U.S. National Psoriasis Foundation review and update of the Canadian Guidelines for the Management of Plaque Psoriasis. It includes newly approved agents such as ustekinumab and the excimer laser. The management of psoriasis in special populations is discussed.³¹ In particular, current evidence does support the use of tumor necrosis factor (TNF) antagonists for the treatment of psoriasis in patients with hepatitis C.³¹ **Table 152-4** summarizes the systemic treatments for plaque type psoriasis.

SCALP

One head-to-head trial (no pun intended) in scalp psoriasis demonstrated no therapeutic difference between a topical vitamin D derivative and a topical potent steroid.¹² Generic fluocinonide solution daily to the scalp is effective. Derma-smooth is another affordable scalp product that combines a high-potency steroid with a peanut oil. Calcipotriene daily to scalp also helps but is more expensive. Mineral oil may be used to moisturize and remove scale. Shampoos with tar and/or salicylic acid (T-Gel and T-Sal) can help to dissolve and wash away some of the scale. Of course, systemic therapies for more severe psoriasis will help clear scalp psoriasis.

GUTTATE PSORIASIS

Phototherapy works particularly well for guttate psoriasis.⁶ **SOR C** Narrow-band UVB therapy may produce clearing in less than one month. Topical therapies are a reasonable option when phototherapy is not available (**Figure 152-20**).⁶ **SOR C** Although both antibiotics and tonsillectomy have frequently been advocated for patients with guttate psoriasis, there is no good evidence that either intervention is beneficial.³²

INVERSE PSORIASIS

Mid- to high-potency topical steroids can be used for inverse psoriasis even though the disease occurs in skinfolds (**Figure 152-6**). A number of studies have shown that tacrolimus works well to treat inverse psoriasis when applied twice daily.^{13–15} **SOR B** Some patients did report a warm sensation or pruritus upon application so patients should be warned of this and told not to stop using the tacrolimus as this may improve over time.^{13–15}

PALMAR-PLANTAR PSORIASIS

For mild disease, start with topical treatments as in plaque psoriasis. For moderate to severe cases, systemic therapy such as oral acitretin, MTX, or one of the biologics may be needed.

ERYTHRODERMIC/GENERALIZED PSORIASIS

Treatment considerations include hospitalization for dehydration and close monitoring, cyclosporine, MTX, oral retinoids, phototherapy, or photochemotherapy.⁶ **SOR C** Cyclosporine is very effective in rapidly treating the most severe erythrodermic psoriasis (**Figure 152-25**). The recommended starting dose is 2.5 to 6 mg/kg per day (actual body weight) divided twice a day.¹⁹

PUSTULAR PSORIASIS

Options include oral retinoids such as isotretinoin or acitretin (depends on sex and age of the patient), MTX, cyclosporine, phototherapy, and hospitalization as needed.⁶ **SOR C** Cyclosporine is very effective in rapidly treating pustular psoriasis at 2.5 to 6 mg/kg per day (actual body weight) divided twice a day.¹⁹ One strategy is to start cyclosporine and acitretin together and to stop the cyclosporine once the pustules have cleared (**Figure 152-31**).

PROGNOSIS

Prognosis is dependent upon the type of psoriasis with the palmar-plantar type being the most difficult to treat. While erythrodermic and generalized pustular psoriasis are the most immediately dangerous types the response to treatment may vary from excellent to disappointing. Widespread plaque psoriasis is challenging to treat but the prognosis is not easily predictable and patient adherence is a very important factor in the prognosis. Excellent control is always the goal and cure should not be expected (even guttate psoriasis in children can come back as plaque psoriasis later in life).

FOLLOW-UP

- Follow-up may need to be frequent for various therapies including cytotoxic drugs, the biologics, and light therapy.
- While there are many safety concerns with the biologic agents a recent integrated safety analysis of short- and long-term safety profiles of etanercept in patients with psoriasis concluded that rates of noninfectious and infectious adverse events were comparable between placebo and etanercept groups.³³ Also, there was no increase in overall malignancies with etanercept therapy compared with the psoriasis population.³³

TABLE 152-7 Patient Education Topics for Discussion Over Time

- Psoriasis is not curable but can be controlled
- Adherence to treatment is important
- Importance of losing weight
- Smoking Cessation
- Drinking alcohol in moderation or not drinking if patient has alcohol abuse disorder
- Factors that trigger or exacerbate psoriasis
- Range of therapeutic options from topical agents to systemic medications
- Hereditary issues
- Possible systemic manifestations including arthritis
- Psychological issues
- Membership in the National Psoriasis Foundation

- Well-controlled psoriasis on topical agents does not require frequent follow-up.

PATIENT EDUCATION

This is a chronic disease that cannot be cured. There are many methods to control psoriasis. Patients need to develop a relationship with a family physician or dermatologist to control the psoriasis for maximum quality of life. **Table 152-7** lists important patient education topics for discussion over time.

153 PITYRIASIS ROSEA

David Henderson, MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old young woman is brought to the office by her mom because of a rash that appeared 3 weeks ago for no apparent reason (**Figures 153-1 to 153-3**). She was feeling well and the rash is only occasionally pruritic. With and without mom in the room, the young woman denied sexual activity. The diagnosis of pityriasis rosea was made by the clinical appearance even though there was no obvious herald patch. The collarette scale was visible and the distribution was consistent with pityriasis rosea. The young woman and her mom were reassured that this would resolve spontaneously. At a subsequent visit for a college physical the skin was found to be completely clear with no scarring.

INTRODUCTION

Pityriasis rosea is a common, self-limited, papulosquamous skin condition originally described in the 19th century. It is seen in children and adults. Despite the long history, its etiology remains elusive. A number of infectious etiologies have been proposed, but at present, supporting evidence is inconclusive. Pityriasis rosea has unique features including a herald patch in many cases and collarette scale that are useful in distinguishing it from other papulosquamous eruptions.

EPIDEMIOLOGY

- Pityriasis rosea is a papulosquamous eruption of unknown etiology.¹
- It occurs throughout the life cycle. It is most commonly seen between the ages of 10 and 35 years.³
- The peak incidence is between 20 and 29 years of age.¹
- The gender distribution is essentially equal.¹
- The rash is most prevalent in winter months.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of pityriasis rosea is unknown, although numerous causes have been proposed.
- It has long been suspected that it may have a viral etiology because a viral-like prodrome often occurs prior to the onset of the rash. Human herpesviruses 6 and 7 have been proposed as causes, but numerous studies have failed to demonstrate conclusive supportive evidence.^{1,2}
- *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *Legionella pneumophila* have been proposed as potential etiologic agents, but studies have not demonstrated any significant rise in antibody levels against any of these pathogens in patients with pityriasis rosea.¹

FIGURE 153-1 Pityriasis rosea in a 17-year-old young woman. Lesions are often concentrated in the lower abdominal area. (Courtesy of Richard P. Usatine, MD.)

FIGURE 153-2 Scaling lesions seen on the buttocks of the same young woman. Note how some of the lesions are annular. (Courtesy of Richard P. Usatine, MD.)

- Pityriasis rosea has also been associated with negative pregnancy outcomes, particularly premature birth. The risk seems to be greatest when the condition occurs in the first 15 weeks of gestation.²
- Pityriasis rosea may rarely occur as the result of a drug reaction. Documented drug reactions that have produced a pityriasis rosea-like eruption include barbiturates, captopril, clonidine, interferon, bismuth, gold, and the hepatitis B vaccine.^{1,2}

DIAGNOSIS

CLINICAL FEATURES

- In approximately 20% to 50% of cases, the rash of pityriasis rosea is preceded by a viral-like illness consisting of upper respiratory or GI symptoms.
- This is followed by the appearance of a *herald patch* in 17% of cases (**Figures 153-4 to 153-6**).⁴
- The herald patch is a solitary, oval, flesh-colored to salmon-colored lesion with scaling at the border. It often occurs on the trunk, and is generally 2 to 10 cm in diameter (**Figures 153-4 and 153-5**).
- One to 2 weeks after the appearance of the herald patch, other papulosquamous lesions appear on the trunk and sometimes on the extremities.
- These lesions vary from oval macules to slightly raised plaques, 0.5 to 2 cm in size. They are salmon colored (or hyperpigmented in individuals with dark skin), and typically have a collarette of scaling at the border (**Figure 153-3**). It is common for some of the lesions to appear annular with central clearing.
- In many cases, the herald patch has resolved by the time the rest of the exanthem erupts which can make the diagnosis more difficult.
- There are no systemic symptoms.
- Itching occurs in approximately 25% of patients.
- The exanthem resolves in 8 weeks in 80% of patients.¹ However, it can last up to 3 to 5 months.³

TYPICAL DISTRIBUTION

- The rash is bilaterally symmetrical, generally most dense on the trunk, but also involves the upper and lower extremities.
- The lesions follow the cleavage, or Langer lines, and may create the typical *fir* or *Christmas tree* pattern over the back (**Figure 153-7**). Do not expect to always see a Christmas tree pattern.
- Over the chest, the lesions create a V-shaped pattern, and run transversely over the abdomen (**Figures 153-8 and 153-9**).
- An inverse form has been described, characterized by more intense involvement of the extremities and relative sparing of the trunk (**Figures 153-10 and 153-11**).

LABORATORY STUDIES

Pityriasis rosea is a clinical diagnosis. There are no laboratory tests that aid in the diagnosis. Biopsy of lesions typically reveals only nonspecific inflammatory changes. Because secondary syphilis is also a papulosquamous eruption and can be difficult to distinguish

FIGURE 153-3 Close-up of lesion showing collarette scale. Note how the lesions can be annular with some central clearing. (Courtesy of Richard P. Usatine, MD.)

FIGURE 153-4 Pityriasis rosea in a 25-year-old Hispanic man. Arrow points to herald patch. (Courtesy of Scott Youngquist, MD. Previously published in Youngquist S, Usatine R. It's beginning to look a lot like Christmas. *West J Med.* 2001;175(4):227-228.)

FIGURE 153-5 Pityriasis rosea in a 13-year-old boy. Arrow points to herald patch. (Courtesy of Richard P. Usatine, MD.)

FIGURE 153-7 Pityriasis rosea in a 16-year-old boy. The scaling lesions follow skin lines and resemble a Christmas tree. (Courtesy of E.J. Mayeaux, Jr., MD.)

FIGURE 153-6 Pityriasis rosea in a 15-year-old boy with the herald patch on the neck near the hairline. (Courtesy of Richard P. Usatine, MD.)

FIGURE 153-8 Pityriasis rosea in a 12-year-old boy showing classic scaling lesions across the chest and abdomen. Small annular lesions are visible. (Courtesy of Jeffrey Meffert, MD.)

from pityriasis rosea on clinical grounds, taking a sexual history is important when a diagnosis of pityriasis rosea is being considered. In patients with a history of sexually transmitted diseases, or sexual practices that place them at risk, a blood test for syphilis should be considered (**Figures 153-9** and **153-10**) (see Chapter 216, Syphilis).

DIFFERENTIAL DIAGNOSIS

- Tinea corporis is usually more localized than pityriasis rosea. However, the annular patterns, scale, and central clearing of some lesions in pityriasis rosea can mislead the clinician to misdiagnose tinea corporis. Tinea corporis tends to have fewer annular lesions and may have concentric circles rather than a single ring. Microscopy with KOH usually demonstrates branching hyphae (see Chapter 138, Tinea Corporis).
- Tinea versicolor has a distribution similar to pityriasis rosea, but is not associated with a herald patch. The pattern of scaling noted is generally more diffuse and not annular. Microscopy with KOH demonstrates the *spaghetti-and-meatball* pattern typical of *Pityrosporum* (see Chapter 141, Tinea Versicolor).
- Secondary syphilis is also a papulosquamous eruption. Lesions are often found on the palms and soles, which is not the case in pityriasis rosea; however, because the two conditions cannot always be accurately distinguished on clinical grounds, a blood test for syphilis is indicated if there is a significant doubt in the diagnosis (see Chapter 216, Syphilis).
- Nummular eczema has coin-like areas of scale that can resemble pityriasis rosea. The scale is not collarette and nummular eczema has a predilection for the legs, an area that is less often involved with pityriasis rosea (see Chapter 145, Atopic Dermatitis).
- Guttate psoriasis generally presents as oval to round, scaly macules on the trunk, and so can be confused with pityriasis rosea. However, the scaling is generally thicker and more adherent than in pityriasis rosea (see Chapter 152, Psoriasis).

MANAGEMENT

- Pityriasis rosea often requires no treatment at all other than reassurance.
- Topical steroids and oral diphenhydramine may be used to relieve itching when there is pruritus involved. **SOR C**
- One study found oral erythromycin to be effective in treating patients with pityriasis rosea,⁵ although a subsequent study did not find erythromycin to be better than placebo.⁶ **SOR B**
- Azithromycin did not cure pityriasis rosea in a study of children with this condition.⁷
- A Cochrane systematic review found inadequate evidence for efficacy for most treatments for pityriasis rosea.⁸ Based on one small randomized controlled trial (RCT), the review authors noted that oral erythromycin may be effective in treating the rash and decreasing the itch.^{5,8} The authors stated that this result should be treated with caution as it comes from only one small RCT.^{5,8} **SOR B**

FIGURE 153-9 Pityriasis rosea on the chest and abdomen of a young woman. Blood test for syphilis was negative. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 153-10 Pityriasis rosea in a 40-year-old man with an inverse pattern. Note how there is a higher density of lesions on the legs. Rapid plasma reagin (RPR) was negative and the diagnosis was confirmed with a punch biopsy. (Courtesy of Richard P. Usatine, MD.)

PATIENT EDUCATION

- Patients are often concerned about the duration of the rash and whether they are contagious. They should be reassured that pityriasis rosea is self-limited and not truly contagious. Although there have been reported clusters of pityriasis rosea in settings where people are living in close quarters (e.g., dormitories), it is not considered to be contagious. It has a reported recurrence rate of only 2%.⁵

FOLLOW-UP

- Patients should be instructed to follow up if the rash persists for longer than 3 months as reevaluation and consideration of an alternate diagnosis may be prudent.

154 LICHEN PLANUS

Robert L. Kraft, MD
Richard P. Usatine, MD

PATIENT STORY

A 38-year-old Hispanic woman presents with a rash on her forearms, wrists, ankle, and back (Figures 154-1 to 154-4). She states the rash is mildly itchy and she does not like the way it looks. She would like some medication to make this better. Lichen planus (LP) was diagnosed and clobetasol was prescribed to keep the LP under better control.

INTRODUCTION

LP is a self-limited, recurrent, or chronic autoimmune disease affecting the skin, oral mucosa, and genitalia. LP is generally diagnosed clinically with lesions classically described using the six Ps (planar, purple, polygonal, pruritic, papules, and plaques).

EPIDEMIOLOGY

- LP is an inflammatory dermatosis of skin or mucous membranes that occurs in approximately 1% of all new patients seen at health-care clinics.¹
- Although most cases occur between ages 30 and 60 years, LP can occur at any age.^{1,2}
- There may be a slight female predominance.²⁻⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Usually idiopathic, thought to be a cell-mediated immune response to an unknown antigen.^{2,3,5}
- Possible human leukocyte antigen (HLA)-associated genetic predisposition.²
- Lichenoid-type reactions may be associated with medications (e.g., angiotensin-converting enzyme inhibitors [ACEIs], thiazide-type diuretics, tetracycline, chloroquine), metals (e.g., gold, mercury), or infections (e.g., secondary syphilis).^{2,5}
- Associated with liver disease, especially related to hepatitis C virus.^{2,5,6}
- LP may be found with other diseases of altered immunity (e.g., ulcerative colitis, alopecia areata, myasthenia gravis).¹
- Malignant transformation has been reported in ulcerative oral lesions in men.¹

RISK FACTORS

- Possible HLA-associated genetic predisposition.
- Hepatitis C virus infection, although causal relationship is not established.⁶
- Certain drugs (see “Etiology and Pathophysiology” above).

FIGURE 154-1 A 38-year-old Hispanic woman with lichen planus on her wrist. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-2 Close-up of wrist showing linearity of the lesions on the flexor surface. Lesions may be pink rather than purple. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-3 Ankle of the woman in Figure 154-1 with typical lichen planus eruption. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES^{2,5}

- Classically, the six Ps of LP are planar, purple, polygonal, pruritic, papules, and plaques (**Figures 154-1 to 154-5**).
- These well-demarcated flat-topped violaceous lesions are often covered by lacy, reticular white lines (called Wickham striae or Wickham lines) (**Figure 154-4B**).
- An initial lesion is usually located on the flexor surface of the limbs, such as the wrists, followed by a generalized eruption with maximal spreading within 2 to 16 weeks.¹
- Lesions may demonstrate the Koebner phenomenon (linear distribution) from scratching (**Figure 154-2**).
- Lesions are more often hyperpigmented rather than purple or pink in dark-skinned persons, and skin may remain hyperpigmented after lesions resolve (**Figures 154-6 and 154-7**).
- Skin variants
 - Hypertrophic—Typical papules develop into thicker reddish-brown to purple plaques (**Figures 154-5 and 154-7**) most commonly on the foot and shins. Seen more often in black men with hyperpigmented and hypertrophic lesions (**Figure 154-7**).
 - Follicular—Pinpoint hyperkeratotic projections often on scalp, may lead to cicatricial alopecia.
 - Vesicular—Vesicles or bullae occur alongside the more typical LP lesions (**Figure 154-8**).
 - Actinic—Typical lesions in sun-exposed areas, such as the face, back of hands and arms (**Figure 154-9**).
 - Atrophic—the lesions are atrophic rather than standard plaques (**Figure 154-10**).
 - Ulcerative—Ulcers develop within typical lesions or start as waxy semitranslucent plaques on palms and soles; may require skin grafting.
- Mucous membrane variants
 - May be reticular (net-like; **Figure 154-11**), atrophic, erosive (**Figures 154-12 and 154-13**), or bullous. It is almost always bilateral.
 - Oral lesions may be asymptomatic or have a burning sensation; pain occurs with ulceration.^{1,4,6}
 - Oral LP is often associated with extraoral LP.^{7,8}
- Genitalia variants
 - Reticular, annular (**Figure 154-14**), papular (**Figure 154-15**), or erosive lesions on penis, scrotum, labia, or vagina.
 - Vulvar/vaginal lesions may be associated with dyspareunia, a burning sensation, and/or pruritus.^{1,7}
 - Vulvar and urethral stenosis can also be present.^{1,7}
- Hair and nail variants; the latter present in 10% of patients.¹
 - Violaceous, scaly, pruritic papules on the scalp can progress to scarring alopecia. Lichen planopilaris (LP of the scalp) can cause widespread hair loss (see Chapter 189, Scarring Alopecia).⁹
 - Nail plate thinning results in longitudinal grooving and ridging; rarely destruction of nailfold and nail bed with splintering (**Figure 154-16**).
 - Hyperpigmentation, subungual hyperkeratosis, onycholysis, and longitudinal melanonychia can result from LP.¹

FIGURE 154-4 A. Lichen planus on the back of the woman in **Figure 154-1**. B. Close-up of lesions on the back showing Wickham striae crossing the flat papules of lichen planus. These lines are white and reticular like a net. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-5 Hypertrophic lichen planus on the foot of a man. Purple polygonal papules and plaques are visible. (Courtesy of M. Craven, MD.)

FIGURE 154-7 Hypertrophic lichen planus on the leg of a black man. Note the hyperpigmentation that is common when lichen planus occurs in a person with dark skin. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-6 Hyperpigmented lichen planus on the back proven by punch biopsy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-8 Bullous lichen planus on the buttocks. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-9 Actinic lichen planus on the face. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-10 Atrophic lichen planus (biopsy proven) on the forearm showing multiple colors within the atrophic lesions. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-11 Asymptomatic white keratotic striae of lichen planus on left buccal mucosa of a 56-year-old woman. The patient had similar involvement of the right buccal mucosa and gingivae. Lichen planus in the mouth is bilateral. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-12 Erosive lichen planus, lateral surface of the tongue. This 52-year-old woman experiences tongue discomfort while eating acidic or spicy foods. (Courtesy of Richard P. Usatine, MD.)

FIGURE 154-13 Lichen planus in the mouth with erosions. The lips, tongue, and palate are all involved. (Courtesy of Eric Kraus, MD.)

FIGURE 154-14 Lichen planus on the penis showing a lacy white pattern. (Courtesy of Dan Stulberg, MD.)

FIGURE 154-16 Hypertrophic lichen planus covering the dorsum of both feet with nail splintering. Note the purple color and Wickham lines. (Courtesy of Eric Kraus, MD.)

FIGURE 154-15 Lichen planus on the penis that is more similar to the pattern seen on other parts of the body. This is an example of planar, purple, polygonal papules on the penis. (Courtesy of John Gonzales, MD.)

TYPICAL DISTRIBUTION

Wrists (**Figure 154-17**), ankles, lower back, eyelids, shins, scalp, penis, mouth (i.e., buccal mucosa, lateral tongue, and gingiva).^{2,5}

LABORATORY STUDIES

- Wickham striae can be accentuated by a drop of oil on the skin plaque and magnification.⁵ Not all LP has visible Wickham striae. This study is rarely needed. If the diagnosis is uncertain, a punch biopsy should be performed.

BIOPSY

- A punch biopsy is a valuable method to make as initial diagnosis if the clinical picture is not certain. A biopsy is rarely needed to evaluate for malignant transformation.^{5,10}
- Mainly lymphocytic immunoinflammatory infiltrate with hyperkeratosis, increased granular layer and liquefaction of basal cell layer.^{2,5}
- Linear fibrin and fibrinogen deposits along basement membrane.^{2,5}
- Direct immunofluorescence on biopsy specimen reveals globular deposits of immunoglobulin (Ig) G, IgM, IgA, and complement at dermal–epidermal junction.⁵

FIGURE 154-17 Thick hypertrophic papules and plaques on the wrist of the man in **Figure 154-16**. (Courtesy of Eric Kraus, MD.)

DIFFERENTIAL DIAGNOSIS

Skin lesions that may be confused with LP:

- Eczematous dermatitis—“The itch that rashes:” dry skin, itching, often excoriations and lichenification of skin with predilection for flexor surfaces (see Chapter 145, Atopic Dermatitis).
- Psoriasis has more prominent silvery scale and is generally located on extensor surfaces.⁵ A punch biopsy can be used to distinguish between these two when the clinical picture is not clear (see Chapter 152, Psoriasis).
- Stasis dermatitis—Lower-extremity eczematous dermatitis with inflammatory papules and often ulceration, in the setting of chronic venous insufficiency with dependent edema (see Chapter 52, Venous Stasis).
- Pityriasis rosea—Herald patch and subsequent pink papules and plaques with long axes along skin lines (Christmas tree pattern) (see Chapter 153, Pityriasis Rosea).
- Chronic cutaneous lupus erythematosus—Bright red sharply demarcated papules with adherent scale. Tend to regress centrally and can be light induced. Generally located on face, scalp, or forearms, and hands. Biopsy may be necessary to differentiate (see Chapter 180, Lupus: Systemic and Cutaneous).⁵
- Bowen disease—Sharply demarcated pink, red, brown, or black scaling or hyperkeratotic macule, papule, or plaque, usually mistaken for eczema or psoriasis, associated with ultraviolet radiation, human papilloma virus (HPV), chemicals, and chronic heat exposure. Biopsy is needed to make the diagnosis (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Lichen simplex chronicus—Localized confluence of lichenification from excoriation; patients have a strong urge to scratch their skin (see Chapter 149, Self-Inflicted Dermatoses).

- Prurigo nodularis—Nodular form of lichen simplex chronicus, brown to red hard, domed nodules from scratching and picking of intense pruritus. LP is not usually so pruritic (see Chapter 149, Self-Inflicted Dermatoses).

Other mucous membrane lesions that may appear similar:⁵

- Leukoplakia—White adherent patch or plaque to oral mucosa. Less net-like pattern. Biopsy warranted because of the risk of malignancy (see Chapter 42, Leukoplakia).
- Thrush—Removable whitish plaques over an erythematous mucosal surface caused by *Candida* infection, confirmed by KOH preparation (see Chapter 136, Candidiasis).
- Bite trauma in the mouth—May result in white areas of the lip or buccal mucosa; Persons may have a white bite line where the upper and lower molars occlude and this can be confused with oral LP. If in doubt, a biopsy may be needed.

Genital lesions that may be differentiated from LP:⁵

- Psoriasis on the penis can look like LP on the penis. A shave biopsy can be used to differentiate between these two diagnoses (see Chapter 152, Psoriasis).
- Syphilis—Primary infection manifests as painless shallow ulcer (chancre) at site of inoculation, if untreated secondary syphilis presents with macular and then papular, pustular, or acneiform eruption on trunk, neck, palms, and soles, condyloma lata (soft, moist, flat-topped pink to tan papules) in the anogenital region (see Chapter 216, Syphilis).

MANAGEMENT

LP may persist for months to years. Hypertrophic LP and oral LP can last for decades.² Any type of LP can recur. Antihistamines can be used for symptomatic pruritus.⁵ **SOR C** Symptomatic and severe cases can be treated as follows:

- Localized/topical treatment.
 - Topical corticosteroids twice a day.^{11–13} **SOR B** Mid to high-potency steroids are usually needed. Clobetasol cream or ointment may be used on the skin and clobetasol ointment or gel may be used in the mouth.
 - Topical aloe vera gel has demonstrated efficacy against oral LP.^{14,15} **SOR B**
 - Intralesional triamcinolone (3 to 5 mg/mL) for hypertrophic or mucous membrane lesions, may repeat every 3 to 4 weeks.^{2,5,10,11} **SOR B**
 - Tacrolimus, pimecrolimus, retinoids, or cyclosporine in mouthwash or adhesive base for oral disease unresponsive to topical corticosteroids.^{3,4,10,12,16–19} **SOR B**
 - Topical corticosteroids, tacrolimus and aloe vera gel have demonstrated efficacy for vulvar LP.^{20,21} **SOR B**
- Systemic treatment can be considered for resistant, widespread, or severe cases.
 - Oral steroids may be used starting with a 3-week tapered course of oral prednisone (60 mg/day starting dose).^{2,10,11,22,23} **SOR B**
 - Systemic retinoids, e.g., acitretin 25 mg/day. Monitor serum creatinine, liver function tests (LFTs), fasting lipids.^{3,10,23} **SOR B** Contraindicated in women of childbearing potential.

- Cyclosporine (5 mg/kg per day). Monitor complete blood count, serum creatinine, LFTs, and blood pressure.² SOR B
- Azathioprine may be used as a steroid-sparing agent (50 mg po daily to start and titrate to 100 to 250 mg po daily). Monitor complete blood count and LFTs.^{5,10} SOR C
- Psoralen UVA (PUVA) phototherapy may be effective but can cause phototoxic reactions and has long-term risks, including the development of squamous cell carcinoma.²⁴ SOR C
- Carbon dioxide laser and low-level laser therapy have reports of treatment success against oral LP.^{25,26} SOR C

PROGNOSIS

- Generally self-limiting and spontaneous resolution may occur in 12 to 18 months.
- Recurrences are common.
- Mucosal LP is generally more persistent than cutaneous forms.
- Malignant transformation of LP is rare.

FOLLOW-UP

- Follow-up depends on severity and treatment course.
- Oral and vaginal disease may be most challenging to treat.
- Follow oral or vaginal lesions for possible malignant transformation. Because of low risk of transformation even with oral LP (best estimate: 0.2% per year), routine screening and biopsy is not recommended.¹⁰ Biopsy if suspecting malignancy; lesion becomes larger, ulcerated, nodular, or lose reticular pattern.

PATIENT EDUCATION

- Patients should understand that LP is often self-limiting and may resolve in 12 to 18 months.
- There is a significant chance of recurrence.

155 REACTIVE ARTHRITIS

Heidi Chumley, MD
 Angela Shedd, MD
 Suraj Reddy, MD
 Richard P. Usatine, MD

PATIENT STORY

A 29-year-old man presented with concerns about an extensive rash that had developed over the previous month. The rash was reported to involve the scalp, abdomen, penis, hands, and feet (**Figures 155-1 to 155-5**). He also complained of severe joint pain, involving the back, knees, and feet. He denied ocular, GI, or genitourinary complaints, but was prescribed a course of antibiotics last month when his partner was diagnosed with *Chlamydia*.

The patient's young age, rapid onset of symptoms, dermatologic findings, and arthritis were suggestive of reactive arthritis. The patient's joint pain was treated with NSAIDs and skin lesions were treated with topical corticosteroids. No antibiotics were prescribed because no current infectious agent was identified. In conjunction with a dermatologist, acitretin 25 mg daily was started to treat his psoriasiform lesions.

INTRODUCTION

Reactive arthritis is a noninfectious acute oligoarthritis that occurs in response to an infection, most commonly in the GI or urogenital tract. Patients present 1 to 4 weeks after the triggering infection, with joint pain in asymmetric large joints; eye disease, such as conjunctivitis; and skin changes including erythema nodosum, keratoderma blennorrhagicum, and circinate balanitis. Diagnosis is based on the clinical presentation plus evidence of associated infection. Treatment includes antiinflammatory medications and treatment of triggering infection.

SYNONYMS

Reiter syndrome is no longer the preferred name as Dr. Reiter was a Nazi physician that performed unethical experimentation on human subjects.

EPIDEMIOLOGY

- Incidence is 0.6 to 27 per 100,000 people.¹
- Most common in young adults ages 30 to 40 years; rare in children.¹
- Reactive arthritis after a genitourinary (GU) infection is more common in young men; reactive arthritis after a GI infection is equally common in men and women.¹

FIGURE 155-1 Reactive arthritis in a young man showing annular scalp lesions (circinate plaques). (From Shedd AD, Reddy SG, Meffert JJ, Kraus EW. Acute onset of rash and oligoarthritis. *J Fam Pract.* 2007;56(10):811-814. Reproduced with permission from Frontline Medical Communications.)

FIGURE 155-2 Keratoderma blennorrhagicum with hyperkeratotic papules, plaques, and pustules that have coalesced to form circular borders. (From Shedd AD, Reddy SG, Meffert JJ, Kraus EW. Acute onset of rash and oligoarthritis. *J Fam Pract.* 2007;56(10):811-814. Reproduced with permission from Frontline Medical Communications.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Follows a GI (*Yersinia*, *Salmonella*, *Shigella*, *Campylobacter*, or rarely *Escherichia coli* or *Clostridium difficile*) or GU (*Chlamydia trachomatis*, *Ureaplasma urealyticum*) infection; less commonly follows a respiratory infection with *Chlamydia pneumoniae*.
- Mechanism by which the triggering agent leads to development of arthritis is not fully understood.

RISK FACTORS

- Infection with a triggering agent.
- Presence of human leukocyte antigen (HLA)-B27 is associated with an increased risk of chronic disease and a more severe arthritis.
- HLA-B27 has been found in a high percentage of patients with severe disease, but there is no increase in HLA-B27 prevalence in population studies.

DIAGNOSIS

Definite reactive arthritis: Both major criteria and one minor criterion.

Probable reactive arthritis: one major criterion and one minor criterion.

Major criteria:

- Arthritis with two of three features: asymmetric, mono- or oligoarthritis, lower limbs predominately affected.
- Preceding enteritis or urethritis.

Minor criteria:

- Evidence of triggering infection.
- Evidence of synovial infection.

CLINICAL FEATURES

- The classic triad consists of urethritis, conjunctivitis (**Figure 155-6**), and arthritis; however few patients present with the classic triad.
- Tendinitis, bursitis or enthesitis, or low back pain may be present.
- Skin findings (psoriasiform) typically involve the palms, soles (keratoderma blennorrhagicum) (**Figures 155-2 and 155-7**), and the glans penis (balanitis circinata). Nail dystrophy, thickening, and destruction may occur (**Figures 155-3 and 155-8**). Many other body surfaces may be affected including the scalp (see **Figure 155-1**), intertriginous areas (**Figure 155-4**), and the oral mucosa (**Figure 155-9**). Erosive lesions on the tongue and hard palate may be seen.
- Rarely, carditis and atrioventricular conduction disturbances are present.

LABORATORY TESTING

- No specific laboratory test is used to confirm reactive arthritis.
- Erythrocyte sedimentation rate (ESR) and C-reactive protein are usually elevated.
- Urethral/cervical swab or urine test for *C. trachomatis* when a GU infection precedes the onset of symptoms.

FIGURE 155-3 Erythema and scale seen on the toes of the patient in **Figure 155-1**. Note the nail involvement with subungual keratosis and onycholysis. The fourth toe is red and swollen; this is called dactylitis. (From Shedd AD, Reddy SG, Meffert JJ, Kraus EW. Acute onset of rash and oligoarthritis. *J Fam Pract.* 2007;56(10):811-814. Reproduced with permission from Frontline Medical Communications.)

FIGURE 155-4 The patient in **Figure 155-1** with psoriasiform lesion on the corona and glans. The patient also has erythema in the inguinal area that resembles inverse psoriasis. This particular case does not exemplify classic balanitis circinata, which is characterized by annular or arcuate thin scaly plaques, as opposed to the nonspecific scaly plaques found on this patient. (Courtesy of Suraj Reddy, MD.)

FIGURE 155-5 Psoriatic-appearing plaque on the leg in the same patient with reactive arthritis in **Figure 155-1**. (From Shedd AD, Reddy SG, Meffert JJ, Kraus EW. Acute onset of rash and oligoarthritis. *J Fam Pract.* 2007;56(10):811-814. Reproduced with permission from Frontline Medical Communications.)

FIGURE 155-7 Keratoderma blennorrhagicum on the soles of the foot of a man with reactive arthritis. (Courtesy of Ricardo Zuniga-Montes, MD.)

FIGURE 155-6 Reactive arthritis with conjunctivitis as a result of chlamydial pelvic inflammatory disease in a 42-year-old woman. She presented with fever, chills, and generalized pain in her joints, abdomen, and pelvis. (Courtesy of Joseph Mazziotta, MD, and from Mazziotta JM, Ahmed N. Conjunctivitis and cervicitis. *J Fam Pract.* 2004;53(2):121-123. Reproduced with permission from Frontline Medical Communications.)

FIGURE 155-8 Nail dystrophy, thickening, and nail destruction in a man with reactive arthritis. (Courtesy of Ricardo Zuniga-Montes, MD.)

- Stool culture may detect an enteric pathogen when GI infection precedes the onset of symptoms.
- *Salmonella*, *Yersinia*, and *Campylobacter* antibodies can be detected in the serum after microbes are no longer detectable in the stool.
- Skin biopsy if performed resembles that of psoriasis with acanthosis of the epidermis, a neutrophilic perivascular infiltrate, and spongiform pustules.

DIFFERENTIAL DIAGNOSIS

- Spondyloarthropathies and reactive arthropathies may present with acute joint pain but often lack the skin findings seen with reactive arthritis (see Chapter 98, Ankylosing Spondylitis).
- Psoriatic arthritis may be easily confused especially in immunocompromised patients. Lack of constitutional symptoms and a more chronic course help differentiate from reactive arthritis.
- Gonococcal arthritis is characterized by migratory polyarthralgia that settles in one or more joints. Often erythematous macules or hemorrhagic papules on acral sites help distinguish from reactive arthritis.
- Rheumatoid arthritis often presents with a progressive, symmetric polyarthritis of the small joints of the hands and wrists. Females are affected more often than males (see Chapter 97, Rheumatoid Arthritis).

MANAGEMENT

- Treat patients with acute *C. trachomatis* with 1 g azithromycin single dose or 100 mg doxycycline twice a day for 7 days.^{1,2} **SOR A** Treat partners when possible.¹
- The current recommendation no longer calls for long-term antibiotics as studies do not support this previous treatment.^{5,6} **SOR B**
- GI-triggering infections are typically self-limiting and do not require antibiotics.
- Treat inflammation with NSAIDs.² **SOR B**
- Consider glucocorticoid joint injections in patients with severe joint pain.
- For refractory arthritic disease, immunosuppressive agents, such as sulfasalazine at 2000 mg/day, have demonstrated some benefit.³ **SOR B**
- Treat mucosal and skin lesions with topical corticosteroids.
- Psoriasiform skin lesions may be treated with some of the same medications used to treat psoriasis (including acitretin). **SOR C**
- Systemic steroids are indicated for patients with systemic symptoms (fever) or in those who develop carditis.
- Current evidence demonstrates that chronic antimicrobial therapy is not recommended.^{5,6}

REFERRAL

- Refer patients with severe or nonresponsive joint pain to a rheumatologist.
- Refer patients who develop cardiac manifestations to a cardiologist.

FIGURE 155-9 Oral mucosal inflammation with reactive arthritis secondary to chlamydial pelvic inflammatory disease. The cervix was also inflamed on examination. (Courtesy of Joseph Mazziotta, and from Mazziotta JM, Ahmed N. Conjunctivitis and cervicitis. *J Fam Pract.* 2004;53(2):121-123. Reproduced with permission from Frontline Medical Communications.)

PROGNOSIS

- Arthritic symptoms typically resolve in 3 to 5 months.¹ Persistent symptoms that last longer than 6 months are associated with the development of chronic symptoms.
- Sixteen percent to 68% of patients developed chronic symptoms across several studies. Type of triggering infection and presence of HLA-B27 affect prognosis.

FOLLOW-UP

- Follow patients closely at the time of diagnosis to ensure response to therapy and timely referral for nonresponders.

PATIENT EDUCATION

There is no curative treatment. Symptoms may resolve permanently, relapse, or persist. Medications and physical/occupational therapy can help relieve pain and preserve function. Seek medical care for extraarticular symptoms, especially those involving the eye.

156 ERYTHRODERMA

David Henderson, MD

PATIENT STORY

A 34-year-old man presented with red skin from his neck to his feet for the last month (**Figure 156-1**). He was having a lot of itching and his skin was shedding so that wherever he would sit, there would be a pile of skin that would remain. He denied fever and chills. He admitted to smoking and drinking heavily. The patient's vital signs were stable with normal blood pressure and he preferred not to be hospitalized. He had some nail pitting but no personal or family history of psoriasis. The presumed diagnosis was erythrodermic psoriasis but a punch biopsy was done to confirm this. A complete blood count (CBC) and chemistry panel were ordered in anticipation of the patient needing systemic medications. A purified protein derivative (PPD) was also placed. The patient was started on total body 0.1% triamcinolone under wet wrap overnight and given a follow-up appointment for the next day. The patient was also counseled to quit smoking and drinking. The following day his labs showed mild elevation in his liver function tests (LFTs) only. The following day his PPD was negative and he was already feeling a bit better from the topical triamcinolone. Cyclosporine was started and the patient improved rapidly.

INTRODUCTION

Erythroderma is an uncommon condition that affects all age groups. It is characterized by a generalized erythematous rash with associated scaling. It is generally a manifestation of another underlying dermatosis or systemic disorder. It is associated with a range of morbidity, and can have life-threatening metabolic and cardiovascular complications. Therapy is usually focused on treating the underlying disease, as well as addressing the systemic complications.

SYNONYMS

Exfoliative dermatitis.

EPIDEMIOLOGY

Erythroderma or exfoliative dermatitis is an uncommon condition that is generally a manifestation of underlying systemic or cutaneous disorders.

- It affects all age groups, from infants to the elderly.
- In adults, the average age of onset is 41 to 61 years of age, with a male-to-female ratio of 2:1 to 4:1.¹
- It accounts for approximately 1% of all dermatologic hospital admissions.²
- It can be a very serious condition resulting in metabolic, infectious, cardiorespiratory, and thermoregulatory complications.³

FIGURE 156-1 Erythrodermic psoriasis in a 34-year-old man. (Courtesy of Richard P. Usatine, MD.)

TABLE 156-1 Conditions Most Commonly Associated with Erythroderma

Dermatoses	Infections	Systemic/Cancer	Pediatric	Drugs
Psoriasis (Figures 156-1, 156-2, 156-3, and 156-8)	HIV	Sarcoidosis	Omenn syndrome	Penicillins
Atopic dermatitis (Figure 156-4)	Norwegian scabies	Thyrotoxicosis	Kwashiorkor	Sulfonamides
Contact dermatitis (Figure 156-5)	Hepatitis	Graft versus host reaction	Cystic fibrosis	Tetracycline derivatives
Seborrhea (Figure 156-5)	Murine typhus (Figure 156-6)	Dermatomyositis	Amino acid disorders	Sulfonylureas
Pityriasis rubra pilaris	Human herpesvirus 6	Lung cancer	Immunodeficiency	Calcium channel blockers
Photosensitivity reaction	Toxic shock syndrome	Colon cancer		Captopril
Bullous pemphigoid	Staphylococcal scalded skin syndrome	Prostate cancer		Thiazides
Impetigo herpetiformis	Histoplasmosis Tuberculosis	Breast cancer B- and T-cell lymphoma (Figure 156-7) Leukemia		NSAIDs Barbiturates Vancomycin Lithium Antivirals Antimalarials

ETIOLOGY AND PATHOPHYSIOLOGY

In almost 50% of cases, erythroderma occurs in the setting of a pre-existing dermatosis; however, it may also occur secondary to underlying systemic disease, malignancy, and drug reactions. It is classified as idiopathic in 9% to 47% of cases.³

- The pathophysiology is not fully understood, but it is related to the pathophysiology of the underlying disease. However, the factors that promote the development of erythroderma are not well defined.
- The rapid maturation and migration of cells through the epidermal layer results in excessive scaling. The rapid turnover of the epidermis also results in fluid, electrolyte, and protein losses that may have severe metabolic consequences, including heart failure and acute respiratory distress syndrome.⁴
- The underlying pathogenesis may be an interaction of immunologic modulators, including Interleukins 1, 2, and 8, as well as tumor necrosis factor.²

Table 156-1 presents the conditions most commonly associated with erythroderma. Dermatologic conditions commonly associated with erythroderma include:¹⁻⁵

- Psoriasis, especially generalized pustular psoriasis with exfoliation (Figures 156-1 to 156-3).
- Atopic dermatitis (Figure 156-4).^{2,3}
- Contact dermatitis (Figure 156-5).
- Seborrhea (Figure 156-5).

FIGURE 156-2 Erythrodermic psoriasis with sheets of exfoliation causing dehydration and life-threatening illness. This is secondary to generalized pustular psoriasis. (Courtesy of Jack Resneck, Sr., MD.)

FIGURE 156-3 A. Generalized pustular psoriasis causing a life-threatening case of erythroderma in a 67-year-old woman. This all started 3 weeks before presentation and she had no previous history of psoriasis. Patient was hospitalized and treated with topical steroids and oral acitretin with good results. B. Close-up of posterior thigh showing pustules on an erythematous plaque in a new case of erythroderma from generalized pustular psoriasis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 156-4 Erythroderma atopic dermatitis in a 55-year-old woman. (Courtesy of Richard P. Usatine, MD.)

- Pityriasis rubra pilaris.
- Bullous pemphigoid.⁴
- Impetigo herpetiformis.⁴
- Photosensitivity reaction.⁴

Erythroderma may also occur secondary to a number of infectious diseases, including:

- HIV.
- Tuberculosis.
- Norwegian scabies.
- Hepatitis.
- Murine typhus (**Figure 156-6**).
- Human herpesvirus 6.⁴
- Toxic shock syndrome.⁴
- Staphylococcal scalded skin syndrome.⁴
- Histoplasmosis.³

Systemic diseases associated with erythroderma include the following:

- Sarcoidosis.
- Thyrotoxicosis.
- Graft versus host reaction.
- Dermatomyositis.^{3,4}

The exact incidence of erythroderma in association with underlying malignancy is not known but reticuloendothelial neoplasms are the most common, most notably T-cell lymphomas.^{1,2} It may precede or follow the diagnosis of cutaneous T-cell lymphoma, and chronic idiopathic erythroderma carries a high risk of development of cutaneous T-cell lymphoma over time (**Figure 156-7**).⁵ In addition colon, lung, prostate, and thyroid malignancies account for 1% of cases of erythroderma.² Specifically in children, it may be associated with:

- Kwashiorkor.
- Cystic fibrosis.
- Amino acid disorders.¹⁻⁵

Drug reactions are a common cause of erythroderma. The list of drugs associated with erythroderma is extensive and includes both systemic and topical medications, many of which are very commonly used, including a number of herbal, homeopathic, and ayurvedic medications.⁵ The list of medications includes the following:

- Penicillins.
- Sulfonamides.
- Tetracycline derivatives.
- Sulfonyleureas.
- Calcium channel blockers.
- Captopril.
- Thiazides.
- NSAIDs.
- Barbiturates.
- Lithium.^{2,3,5}

FIGURE 156-5 A. Erythroderma caused by seborrheic dermatitis and contact dermatitis. The biopsy showed changes consistent with seborrheic dermatitis but the history suggested that the erythroderma was worsened by contact with products used in auto maintenance. B. After the erythroderma cleared, the arms and hands would worsen every time the patient went back to working on cars. (Courtesy of Richard P. Usatine, MD.)

In children, an association with topical boric acid has been identified.⁵

The cause of erythroderma may not always be identified (**Figure 156-9**).

DIAGNOSIS

CLINICAL FEATURES

- The clinical presentation of erythroderma may be variable depending on the underlying cause. In association with drug reactions, the onset tends to be more abrupt and the resolution more rapid.
- Cutaneous manifestations begin with pruritic, erythematous patches that spread and coalesce into areas of erythema that cover the body. Scaling eventually develops. Large scales are seen more often in acute settings and in chronic erythroderma smaller scales predominate.
- Although the red color of erythroderma is very evident in light skin, erythroderma may be only light pink to brown in darker-skinned individuals (**Figure 156-9**).
- Scalp involvement is very common with alopecia occurring in 25% of patients.²
- Systemic manifestations associated with compromise of the protective cutaneous barrier and loss of vasoconstriction of vessels in the dermis that occurs in erythroderma include loss of fluid and electrolytes.
- Protein losses can be as high as 25% to 30% in psoriatic erythroderma, resulting in hypoalbuminemia and edema.³ Increased perfusion to denuded inflamed skin may result in thermoregulatory disturbances and high output cardiac failure. In addition, there is an increased risk of staphylococcal infection and sepsis.^{2,3} Any of these complications can be life threatening.

TYPICAL DISTRIBUTION

The distribution is variable, but there is usually sparing of mucous membranes, the palms, and the soles of the feet. Sparing of the nose and nasolabial region has also been reported.²

LABORATORY STUDIES

Skin biopsy is useful, but often nondiagnostic. Because 50% of individual biopsies fail to reveal a specific diagnosis, multiple biopsies are recommended when evaluating patients for erythroderma. In addition to conventional histopathologic evaluation, direct immunofluorescence may be helpful in immunobullous disease (e.g., pemphigus). T-cell receptor gene rearrangement studies may aid in the diagnosis of lymphoproliferative disorders.³ Laboratory tests are often nonspecific; however, common findings include:

- Leukocytosis.
- Lymphocytosis.
- Mild anemia.
- Eosinophilia.
- Elevated sedimentation rate.
- Polyclonal gammopathy.
- Elevated immunoglobulin (Ig) E levels.

FIGURE 156-6 Murine typhus causing erythema and exfoliation in a febrile systemically ill man in southern Texas. (Courtesy of Angela Peng, MD.)

FIGURE 156-7 Erythema secondary to new-onset mycosis fungoides. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

- Hypoalbuminemia.
- Elevated serum creatinine.
- Elevated uric acid levels.¹⁻⁵

HIV testing should be considered in those with risk factors.⁵ In children a sweat test, zinc, amino acid, and lipid levels should be considered.⁵

DIFFERENTIAL DIAGNOSIS

Erythroderma is the dermatologic manifestation of a number of underlying disease processes, including infectious diseases, lymphoproliferative disorders, malignancies, dermatoses, acquired and inborn metabolic disorders, and drug reactions. The key to proper diagnosis and treatment is contingent on identification of the underlying cause.¹⁻⁵ (For a list of underlying conditions, see “Etiology and Pathophysiology” above.)

MANAGEMENT

Hospitalization and urgent dermatologic referral should be considered for patients presenting with erythroderma acutely as the metabolic, infectious, thermoregulatory, and cardiovascular complications can be life threatening (**Figures 156-1 to 156-9**).^{2,5}

Therapeutic interventions include:

- Topical skin care measures such as emollients, oatmeal baths, and wet dressings.¹⁻⁵ **SOR C**
- Mid-potency topical steroid ointments such as 0.1% triamcinolone applied to all the affected areas.¹⁻⁵ **SOR C** Using the wet wrap technique (see Chapter 145, Atopic Dermatitis) can help promote quicker absorption and faster onset of action. **SOR C**
- High potency topical steroids and topical immunomodulators should be avoided owing to risk of increased cutaneous absorption.³ **SOR C**
- Systemic steroids are useful in drug reactions and eczema, but should be avoided in psoriasis.^{2,3,5} **SOR C**
- Consider methotrexate, cyclosporine, for cases secondary to psoriasis. Infliximab has also been used (**Figures 156-3 to 156-5**).^{2,4} **SOR C** Cyclosporine acts most rapidly in cases caused by psoriasis or atopic dermatitis. **SOR C**
- Immunosuppressive agents (methotrexate, azathioprine, infliximab).²⁻⁴ **SOR C**
- Discontinuation of all nonessential medications.^{2,3} **SOR C**
- Antibiotic therapy when infection is suspected.^{2,3} **SOR C**
- Close monitoring of fluid, electrolyte, and nutritional status and replacement of deficits.¹⁻⁵ **SOR C**

PATIENT EDUCATION

Patients should be advised that erythroderma can be life-threatening because of the infectious, thermoregulatory, metabolic, and cardiovascular complications. This is important when it might be necessary

FIGURE 156-8 Erythrodermic psoriasis in a black man showing visible scaling but less obvious erythema secondary to the darker skin color. (Courtesy of Richard P. Usatine, MD.)

to hospitalize a patient that does not appreciate the seriousness of the condition. They should also be advised that with certain underlying etiologies, the condition may recur. This is particularly true of idiopathic erythroderma (Figure 156-8).

FOLLOW-UP

The prognosis in erythroderma is very much dependent on the underlying cause. Most deaths occur in malignancy-associated erythroderma. Drug-induced erythroderma carries the best prognosis and the lowest risk of recurrence. Relapses occur in 15% of patients with psoriatic erythroderma. Fifty percent of patients with idiopathic erythroderma experience partial remission, and one third complete remission.³

SECTION 9 BENIGN NEOPLASMS

157 SKIN TAG

Mindy A. Smith, MD, MS

PATIENT STORY

A 55-year-old man requests removal of multiple skin tags around his neck. He is overweight and has diabetes and acanthosis nigricans. Although some of his skin tags occasionally get caught on his clothing, he just doesn't like the way they look. The patient chose to have many of them removed by the snip excision method.

INTRODUCTION

Skin tags (acrochordons) are flesh-colored, pedunculated lesions that tend to occur in areas of skin folds especially around the neck and in the axillae.

SYNONYMS

- Also referred to as fibroepithelial polyps.

EPIDEMIOLOGY

- In an unselected population study, skin tags were found in 46% of patients, particularly in patients who were obese.¹
- Skin tags increase in frequency through the fifth decade of life so that as many as 59% of individuals have them by the time they are 70 years old; however, the increase slows after age 50 years.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Three types of skin tags are described:¹
 - Small, furrowed papules of approximately 1 to 2 mm in width and height, located mostly on the neck and the axillae (**Figure 157-1**).
 - Single or multiple filiform lesions of approximately 2 mm in width and 5 mm in length occurring elsewhere on the body (**Figure 157-2**).
 - Large, pedunculated tumor or nevus, bag-like, soft fibromas that occur on the lower part of the trunk (**Figure 157-3**).
- Etiology is unknown, but it is theorized that skin tags occur in localized areas with a paucity of elastic tissue resulting in sessile or atrophic lesions. In addition, hormone imbalances appear to facilitate their development (e.g., high levels of estrogen and progesterone seen during pregnancy) and other factors including epidermal

FIGURE 157-1 Many skin tags and acanthosis nigricans on the neck of a man with diabetes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 157-2 Filiform pedunculated skin tags on the eyelids. These were removed with a radiofrequency loop after local anesthesia with lidocaine and epinephrine to minimize bleeding. (Courtesy of Richard P. Usatine, MD.)

growth factor, tissue growth factor- α , and infection (e.g., human papillomavirus) have been implicated as cofactors.

- Acrochordons also appear to be associated with impaired carbohydrate metabolism and diabetes mellitus (**Figure 157-1**).²
- Pedunculated lesions may become twisted, infarcted, and fall off spontaneously.
- Very rarely neoplasms are found at the base of skin tags. In a study of consecutive cutaneous pathology reports, 5 of 1335 clinically diagnosed fibroepithelial polyp specimens were malignant (i.e., 4 were basal cell carcinomas and 1 was squamous cell carcinoma in situ).³ There is selection bias in this study because most skin tags are not sent to the pathologist.

DIAGNOSIS

CLINICAL FEATURES

- Small, soft, usually pedunculated lesions.
- Skin colored or hyperpigmented.
- Most vary in size from 2 to 5 mm, but larger ones may be seen.
- Usually asymptomatic, but can be pruritic or become painful and inflamed by catching on clothing or jewelry.

TYPICAL DISTRIBUTION

- Most typically seen on the neck and in the axillae (**Figure 157-1**), but any skin fold may be affected. They are also seen on the trunk (**Figure 157-3**), the abdomen, and the back.

ANCILLARY TESTING

- Dermatoscopy may be a useful diagnostic tool to analyze acrochordon-like lesions in people with basal cell syndromes to facilitate early diagnosis and treatment.⁴

BIOPSY

- Not usually indicated unless the diagnosis is not clear. Typical skin tags do not need to be sent to pathology upon removal. Skin tags, on histology, are characterized by acanthotic, flattened, or frond-like epithelium. A papillary-like dermis is composed of loosely arranged collagen fibers and dilated capillaries and lymphatic vessels.

DIFFERENTIAL DIAGNOSIS

Lesions that can be confused with skin tags include:

- Warts—Cutaneous neoplasm caused by papilloma virus. Sessile, dome-shaped lesions approximately 1 cm in diameter with hyperkeratotic surface. Paring usually demonstrates a central core of keratinized debris and punctate bleeding points.
- Neurofibromas—Benign Schwann cell tumors; cutaneous tumors tend to form multiple, soft pedunculated masses (**Figure 157-4**).
- Epidermal hyperplasia in melanocytic nevi (also called keratotic melanocytic nevus [KMN])—Although most common moles are round, tan to brown, less than 6 mm, and flat to slightly elevated, some nevi have overlying hyperplastic epidermis resembling skin

FIGURE 157-3 Large pedunculated bag-like soft fibroma on the trunk. This is a large acrochordon or fibroepitheliomatous polyp. Local anesthetic was given prior to excision. (Courtesy of Richard P. Usatine, MD.)

FIGURE 157-4 Multiple soft neurofibromas on the neck of a patient with neurofibromatosis. (Courtesy of Richard P. Usatine, MD.)

tags. In a study of melanocytic nevi submitted for pathology over an 8-month period, 6% were KMN, most often located on the trunk (76%).⁵ Dermal nevi, can be pedunculated but they are usually larger than skin tags and may appear warty above the stalk.

- Basal cell carcinomas in certain syndromes.^{4,6}

MANAGEMENT

Skin tags may be removed for cosmetic reasons or because of irritation in a number of ways:

- Small lesions may be snipped with a sharp iris scissor with or without anesthesia (**Figure 157-5**).
- Larger skin tags and fibromas may be removed with shave excision after injecting with lidocaine and epinephrine.
- If there is any bleeding, aluminum chloride on a cotton-tipped applicator is applied for hemostasis.
- Electrodesiccation with or without anesthesia works for very tiny skin tags too small to grab with the forceps.
- Skin tags on the eyelids may be removed with a radiofrequency loop after local anesthesia with lidocaine and epinephrine to minimize bleeding.
- Cryotherapy can be applied directly to the skin tag with a Cryogun or a cotton-tipped applicator. One preferred method involves dipping forceps into liquid nitrogen and then grasping the skin tag until it turns white. This allows you to grasp the skin tag without freezing the skin around it. This is especially helpful on the eyelids. A special cryo forceps is made by Brymill, Inc. that has more metal at the end to hold the cold longer (**Figure 157-6**). This is a very efficient way to treat multiple skin tags quickly.
- An adhesive patch that applies pressure to the base of a skin tag was found effective in 65% of skin tags in one case series.⁷
- Most insurance companies will not pay for the cosmetic removal of skin tags.
- To avoid large healthcare costs, only send suspicious looking skin tags to the pathologist.

FOLLOW-UP

- Follow-up is not usually necessary.

PATIENT EDUCATION

- Advise patients that these are benign growths that can be removed if irritation occurs or for cosmetic purposes. Patients who are overweight should be encouraged to lose weight for their general health and to avoid new skin tags.

PATIENT RESOURCES

- <http://www.nlm.nih.gov/medlineplus/ency/article/000848.htm>.

158 SEBORRHEIC KERATOSIS

Mindy Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

An elderly woman noted a growth of a lesion on her chest (**Figure 158-1**). She was afraid that it might be melanoma. Her family physician recognized the typical features of a seborrheic keratosis (SK) (stuck-on with visible horn cysts) and attempted to reassure her. Dermoscopy was performed and the features were so typical of an SK; the physician was able to convince the patient to not have a biopsy (**Figure 158-2**). The black comedonal-like openings and white milia-like cysts are typical of an SK and can be seen with the naked eye and magnified with a dermatoscope.

INTRODUCTION

- A SK is a benign skin tumor and a form of localized hyperpigmentation as a result of epidermal alteration; it develops from the proliferation of epidermal cells, although the cause is unknown.

EPIDEMIOLOGY

- Most common benign tumor in older individuals; frequency increases with age.
- In an older study of individuals older than age 64 years in North Carolina, 88% had at least one SK. Ten or more SKs were found in 61% of the black men and women, 38% of the white women, and 54% of the white men in the study.¹
- In an Australian study performed in 2 general practices, 23.5% (40 out of 170) of individuals between ages 15 and 30 years had at least 1 SK; prevalence and size increased with age.²
- Approximately half of cases of multiple SKs occur within families, with an autosomal dominant mode of inheritance.³

ETIOLOGY AND PATHOPHYSIOLOGY

- In pigmented SKs, the proliferating keratinocytes secrete melanocyte-stimulating cytokines triggering activation of neighboring melanocytes.³
- A high frequency of mutations have been found in certain types of SKs in the gene encoding the tyrosine kinase receptor fibroblast growth factor receptor 3 (FGFR3).³ One study found that FGFR3 and transcription factor forkhead box N1 (FOXN1) were highly expressed in SKs but close to undetectable in squamous cell skin cancer.⁴ This may represent a positive regulatory loop between FGFR3 and FOXN1 that underlies a benign versus malignant skin tumor phenotype.
- Reticulated SKs, usually found on sun-exposed skin, may develop from solar lentigines.³

FIGURE 158-1 Seborrheic keratosis with associated horn cysts. (Courtesy of Richard P. Usatine, MD.)

FIGURE 158-2 Dermoscopy of the seborrheic keratosis in the previous figure showing comedo-like openings (black-like blackheads) and milia-like cysts (white-like milia). (Courtesy of Richard P. Usatine, MD.)

- Multiple eruptive seborrheic keratoses (the sign of Leser-Trélat) can be associated with internal malignancy (most often adenocarcinoma of the GI tract) (**Figure 158-3**),⁵ although this association has been questioned.⁶
- An eruption of seborrheic keratoses may develop after an inflammatory dermatosis such as severe sunburn or eczema.³ There is also a report of exacerbation of a SK by topical fluorouracil.⁷

DIAGNOSIS

SKs have a variety of appearances.

CLINICAL FEATURES

- Typically oval or round brown plaques with adherent greasy scale (**Figure 158-4**).
- Color ranges from black to tan (**Figures 158-4 to 158-6**).
- Most often have a velvety to finely verrucous surface and appear to be “stuck on.”
- Some are so verrucous they can appear to be warty (**Figure 158-6**).
- Lesions may be large (up to 35 × 15 cm), pigmented, and have irregular borders (**Figure 158-5**).
- Lesions can also be flat (**Figure 158-7**).
- Many lesions show keratotic plugging of the surface (**Figures 158-1 and 158-2**).
- May have surface cracks and associated horn cysts (keratin-filled cystic structures). The dermoscopy terms for the horn cysts are comedo-like openings and milia-like cysts (**Figures 158-1 and 158-2**; see Appendix C, Dermoscopy).
- Occasionally, lesions become irritated and can itch, grow, and bleed; secondary infection may occur.
- Variants of SKs include:
 - Dermatitis papulosa nigra—Consists of multiple brown-black dome-shaped, smooth papules found on the face in young and middle-age persons of color, predominantly African Americans (**Figures 158-8 and 158-9**).
 - Stucco keratosis—Consists of large numbers of superficial gray-to-light brown flat keratotic lesions usually on the tops of the feet, the ankles, and the back of the hands and forearms (**Figure 158-10**).

TYPICAL DISTRIBUTION

- Trunk, face, back, abdomen, extremities; not present on the palms and soles or on mucous membranes. May be present on the areola and breasts (**Figures 158-11 and 158-12**).
- Dermatitis papulosa nigra is found on the face, especially the upper cheeks and lateral orbital areas (**Figures 158-8 and 158-9**).

IMAGING

- No imaging studies are needed unless there is a sudden appearance of multiple seborrheic keratoses as in the sign of Leser-Trélat (**Figure 158-3**). These are associated with adenocarcinoma of the GI tract, lymphoma, Sézary syndrome, and acute leukemia.^{3,8}

FIGURE 158-6 Seborrheic keratosis with verrucous appearance on the forehead. (Courtesy of Richard P. Usatine, MD.)

FIGURE 158-9 Dermatitis papulosa nigra on the cheeks and in the hair line. The patient was treated effectively with cryotherapy and had a great cosmetic result. (Courtesy of Richard P. Usatine, MD.)

BIOPSY

- Should be performed if there is a suspicion of melanoma (**Figures 158-7** and **158-13**). Some melanomas resemble SKs and a biopsy is needed to avoid missing the diagnosis of melanoma. Do not freeze or curette a suspicious SK; these need surgical intervention to send tissue to the pathologist.

DIFFERENTIAL DIAGNOSIS

- Melanoma—When keratin plugs are visible in the surface of the SK, this helps to distinguish it from a melanoma. **Figure 158-7** is a SK that has the ABCDE features (Asymmetry, Border irregular, Color variation, Diameter >6 mm, Evolving) of melanoma (Chapter 172, Melanoma). A biopsy was performed and the lesion was proven to be benign. In **Figure 158-13**, a possible SK turned out to be a melanoma in situ.
- Solar lentigo—Flat, uniformly medium or dark brown lesion with sharp borders (Chapter 168, Lentigo Maligna). These are flat and seen in sun-exposed areas, typically on the face or back of the hands. Also called liver spots, these hyperpigmented areas are not palpable, whereas a SK is a palpable plaque even when the SK is thin (**Figure 158-7**).
- Wart—Cutaneous neoplasm caused by papilloma virus (Chapter 131, Common Warts). Sessile, dome-shaped lesions approximately 1 cm in diameter with hyperkeratotic surface. Paring usually demonstrates central core of keratinized debris and punctate bleeding points.
- Pigmented actinic keratosis (AK)—Although most AKs are non-pigmented and don't look like an SK, occasionally a biopsy of an unknown pigmented plaque will be a pigmented AK secondary to sun damage (Chapter 166, Actinic Keratosis and Bowen Disease).
- An inflamed SK may be confused with a malignant melanoma or a squamous cell carcinoma and should be biopsied to determine the diagnosis.
- Even a basal cell carcinoma (BCC) can have features that suggest a SK (**Figure 158-14**) (Chapter 170, Basal Cell Carcinoma).

MANAGEMENT

- Cryosurgery with liquid nitrogen, with a 1-mm halo, is a quick and easy treatment. The risks include pigmentary changes, incomplete resolution, and scarring. Hypopigmentation is the most common complication of this treatment, especially in dark-skinned individuals.
- Removal of benign lesions by curettage assures complete removal without taking the normal tissue below.
- Light electrofulguration can make the curettage so easy that it can be accomplished with a wet gauze pad.
- If the diagnosis is uncertain but there are no features suggesting a melanoma, a SK may be removed by shave biopsy and the tissue sent to pathology.
- If melanoma or other skin cancers are suspected, perform a full-thickness biopsy by punch or elliptical excision and send to pathology.

FIGURE 158-11 Multiple seborrheic keratoses on the areola of a 46-year-old woman. Cryotherapy cleared the seborrheic keratoses easily. (Courtesy of Richard P. Usatine, MD.)

FIGURE 158-12 Waxy seborrheic keratoses on the breasts of this 70-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FOLLOW-UP

- Some experts suggest follow-up for patients with multiple SKs because malignant tumors can develop elsewhere on the body and rarely within a SK.^{3,8} SOR C

PATIENT EDUCATION

- Reassure patients that SKs are benign lesions that do not become cancer. Although these SKs may grow larger and thicker with time, this is not dangerous.
- Unless the SK is suspicious for cancer or inflamed, removal is for cosmetic purposes only and is often not covered by insurance.
- Although SKs may resolve on occasion, spontaneous resolution does not ordinarily occur.

159 SEBACEOUS HYPERPLASIA

Mindy Smith, MD, MS

PATIENT STORY

A 65-year-old man noted a new growth on his face for 1 year (**Figure 159-1**). On close examination, the growth was pearly with a few telangiectasias. The doughnut shape and presence of sebaceous hyperplasia scattered on other areas of the face were reassuring that this may be nothing but benign sebaceous hyperplasia. To reassure the patient and to remove the lesion a shave biopsy was performed to rule out basal cell carcinoma (BCC). The patient was relieved when the pathology result was in fact sebaceous hyperplasia. Additionally, he was pleased with the cosmetic result.

INTRODUCTION

Sebaceous hyperplasia (SH) is a common, benign condition of sebaceous glands consisting of multiple asymptomatic small yellow papules with a central depression. The sebaceous lobules of SH are greater in number and higher in the dermis than normal sebaceous glands and only 1 gland appears enlarged.¹ Consequently, the term *hyperplasia* appears to be a misnomer, and SH is more accurately classified as a hamartoma (disorganized overgrowth of tissue normally found at that site).¹

EPIDEMIOLOGY

- SH occurs in approximately 1% to 26% of the adult population; the latter number is from a population study of hospitalized patients with a mean age of 82 years.¹
- The prevalence of SH is increased in those with immunosuppression by 10-fold to 30-fold¹; for example, 10% to 16% of patients receiving long-term immunosuppression with cyclosporine in one study had SH.²
- SH has also been reported in infants where they are considered physiologic,³ and in young adults who may have a family history of SH.¹
- SH has been reported overlying other skin lesions including neurofibromas, melanocytic nevi, verruca vulgaris, and skin tags.¹
- Rare forms of SH include giant linear (up to 5 cm in diameter) and functional familial (also called premature or diffuse SH); the latter occurring typically around puberty as thick plaque-like lesions with pores resembling an orange peel.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Sebaceous glands, a component of the pilosebaceous unit, are found throughout the skin, everywhere that hair is found. The greatest number is found on the face, chest, back, and the upper outer arms.

FIGURE 159-1 Large single lesion of sebaceous hyperplasia that was removed by shave biopsy to confirm that it was not a basal cell carcinoma. Doughnut shape visible. (Courtesy of Richard P. Usatine, MD.)

- The glands are composed of acini attached to a common excretory duct. In some areas, these ducts open directly to the epithelial surface, including the lips and buccal mucosa (i.e., Fordyce spots), glans penis or clitoris (i.e., Tyson glands), female areolae (i.e., Montgomery glands), and eyelids (i.e., meibomian glands).¹
- Sebaceous glands are highly androgen sensitive and become increasingly active at puberty and reach their maximum by the third decade of life.
- The cells that form the sebaceous gland, sebocytes, accumulate lipid material as they migrate from the basal layer of the gland to the central duct where they release the lipid content as sebum. In younger individuals, turnover of sebocytes occurs approximately every month.
- With aging, the turnover of sebocytes slows; this results in crowding of primitive sebocytes within the sebaceous gland, causing a benign hamartomatous enlargement called SH.¹
- Genetic factors include overexpression of the aging-associated gene Smad7 and parathormone-related protein.⁴
- There is no known potential for malignant transformation, but SH may be associated with nonmelanoma skin cancer in patients following organ transplantation.

RISK FACTORS

- Associated with Muir-Torre syndrome (concurrent or sequential development of a sebaceous neoplasm and an internal malignancy or multiple keratoacanthomas, an internal malignancy, and a family history of Muir-Torre syndrome).
- Immunosuppression
- Ultraviolet radiation⁴

DIAGNOSIS

CLINICAL FEATURES

- Lesions appear as yellowish, soft, small papules ranging in size from 2 to 9 mm (**Figures 159-1 to 159-3**).¹
- Surface varies from smooth to slightly verrucous.
- Lesions can be single or multiple.
- Increasing number of lesions with aging; higher frequencies after 40 to 50 years of age.¹
- In functional familial SH, lesions may appear thick and plaque-like, with pores that resemble an orange peel; the skin in these patients is quite oily.¹
- Lesions may become red and irritated and bleed after scratching, shaving, or other trauma and may be associated with telangiectasias.
- Central umbilication (doughnut shape) from which a small amount of sebum can sometimes be expressed (**Figures 159-1 to 159-3**).

TYPICAL DISTRIBUTION

- Most commonly located on the face, particularly the nose, cheeks, and forehead. May also be found on the chest, areola, mouth, and, rarely, the vulva.^{1,5}

FIGURE 159-2 Multiple lesions of sebaceous hyperplasia on the cheek and chin. Simultaneous appearance of multiple lesions makes them less likely to be basal cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 159-3 Large sebaceous hyperplasia on the forehead with telangiectasias. Doughnut shape visible. (Courtesy of Richard P. Usatine, MD.)

IMAGING

- Dermoscopy may aid in distinguishing between nodular BCC and SH; a vascular pattern with orderly winding, scarcely branching vessels extending toward the center of the lesion is specific for hyperplastic sebaceous glands.⁶

BIOPSY

- Not usually necessary unless concerned about BCC.

DIFFERENTIAL DIAGNOSIS

- Nodular BCC—These lesions can appear as waxy papules with a central depression that may ulcerate, most commonly located on the head, neck, and upper back. They may have a pearly appearance, surface telangiectasias, and bleed easily (**Figures 159-4 and 159-5**).
- Fibrous papule of the face is a benign, firm, papule of 1 to 5 mm that is usually dome-shaped and indurated with a shiny, skin-colored appearance. Most lesions are located on the nose and, less commonly, on the cheeks, chin, neck, and, rarely, the lip or forehead.
- Milia are common, benign, keratin-filled cysts (histologically identical to epidermoid cysts) that occur in persons of all ages. They are 1 to 2 mm, superficial, uniform, pearly white to yellowish, domed lesions usually occurring on the face (**Figure 159-6**).
- Molluscum contagiosum are firm, smooth, usually 2- to 6-mm umbilicated papules that may be present in groups or widely disseminated on the skin and mucosal surfaces. The lesions can be flesh colored, white, translucent, or even yellow in color. Lesions generally are self-limited but can persist for several years (Chapter 130, Molluscum Contagiosum).
- Syringoma is a benign adnexal neoplasm formed by well-differentiated ductal elements. They are 1- to 3-mm skin-colored or yellowish dermal papules with a rounded or flat top arranged in clusters, and symmetrically distributed primarily on the upper parts of the cheeks and lower eyelids (**Figure 159-6**).
- Xanthomas are deposits of lipid in the skin or subcutaneous tissue that manifest clinically as yellowish papules, nodules, or tumors. They are usually a consequence of primary or secondary hyperlipidemia and occur in patients older than age 50 years. The lesions are soft, velvety, yellow, flat, polygonal papules that are asymptomatic and usually bilateral and symmetric (Chapter 223, Hyperlipidemia).

MANAGEMENT

SH does not require treatment but can be removed for cosmetic purposes or if it becomes irritated. Evidence supporting treatment comes primarily from case series.

- Options for removal include cryotherapy, electrodesiccation, topical chemical treatments (e.g., with bichloroacetic acid or trichloroacetic acid), oral isotretinoin (10 to 40 mg a day for 2 to 6 weeks), laser treatment (e.g., with argon, carbon dioxide, or pulsed-dye laser), photodynamic therapy (i.e., combined use of

FIGURE 159-4 Basal cell carcinoma on the forehead that could be mistaken for sebaceous hyperplasia. (Courtesy of Richard P. Usatine, MD.)

FIGURE 159-5 Close-up of same basal cell carcinoma on the forehead that shows irregular distribution of telangiectasias and lack of the doughnut shape. (Courtesy of Richard P. Usatine, MD.)

FIGURE 159-6 Syringomas and milia on the lower eyelid of a 23-year-old male. The milia are the white round epidermal cysts and the syringomas are flesh colored and larger. (Courtesy of Richard P. Usatine, MD.)

5-aminolevulinic acid and visible light),⁷ shave excision, and punch excision.¹ Complications of these therapies include atrophic scarring and changes in pigmentation.

FOLLOW-UP

No follow-up is needed.

FIGURE 159-7 Single, large, elevated lesion of sebaceous hyperplasia on the nose of a 51-year-old man with rosacea. A shave biopsy ruled out basal cell carcinoma and gave the definitive diagnosis of sebaceous hyperplasia. The cosmetic result was excellent. (Courtesy of Richard P. Usatine, MD.)

160 DERMATOFIBROMA

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A 25-year-old woman reports a firm nodule on her leg that gets in the way of shaving her leg (**Figure 160-1**). Upon questioning, the nodule may have started there after she cut her leg shaving 1 year ago. She is worried it could be a cancer and wants it removed. Close observation showed a brown halo and a firm nodule that dimpled down when pinched. A diagnosis of a dermatofibroma (DF) was made and the choices for treatment were discussed.

INTRODUCTION

DF is a benign fibrohistiocytic tumor, usually found in the mid dermis, composed of a mixture of fibroblastic and histiocytic cells. These scar-like nodules are most commonly found on the legs and arms of adults.

SYNONYMS

Also called benign fibrous histiocyoma.

EPIDEMIOLOGY

- Occurs more often in women (male-to-female ratio is 1:4).¹
- Found in patients of all races.
- Approximately 20% occur in patients younger than age 17 years.¹ In one case series, 80% occurred in people between the ages of 20 and 49 years.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Uncertain etiology—Nodule may represent a fibrous reaction triggered by trauma, a viral infection, or insect bite; however, DFs show clonal proliferative growth seen in both neoplastic and inflammatory conditions.³
- Multiple DFs (i.e., >15 lesions) have been reported associated with systemic lupus erythematosus, HIV infection, Down syndrome, Graves disease, or leukemia, and may represent a worsening of immune function.¹ A case of familial eruptive DFs has also been reported associated with atopic dermatitis.⁴

DIAGNOSIS

CLINICAL FEATURES

- Firm to hard nodule; skin is freely movable over the nodule, except for the area of dimpling.

FIGURE 160-1 Dermatofibroma on the leg of a 25-year-old woman that may have begun after she cut her leg shaving 1 year ago. Note the brown halo, pink hue, and raised center. (Courtesy of Richard P. Usatine, MD.)

- Color of the overlying skin ranges from flesh to gray, pink, red, blue, brown, or black (**Figures 160-2 and 160-3**), or a combination of hues (**Figure 160-4**).
- Dimples downward when compressed laterally because of tethering of the overlying epidermis to the underlying nodule (**Figure 160-3**).
- Usually asymptomatic but may be tender or pruritic.
- Size ranges from 0.3 to 10 mm; usually less than 6 mm. Rarely, DFs grow to larger than 5 cm.⁵
- May have a hyperpigmented halo and a scaling surface (**Figure 160-4**).
- DFs can rarely be located entirely within subcutaneous tissue.⁶

IMAGING

- Dermoscopy is a useful adjunctive diagnostic technique for DF (**Figure 160-5**). Although the most common finding is a peripheral pigment network with a central white area (34.7% of cases), 10 dermoscopic patterns have been identified; in a large case series, pigment network was observed in 71.8% (3% atypical pigment network).⁷ (See Appendix C: Dermoscopy.)

TYPICAL DISTRIBUTION

- May be found anywhere, but usually on the legs and arms, especially the lower legs. In one case series, 70% were on the lower extremities.²

BIOPSY

- A punch biopsy can be both diagnostic and therapeutic. DFs have been reported with overlying basal cell carcinoma and associated melanoma.^{8,9}
- Histologically, DFs can be fibrocollagenous (40.1%), histiocytic (13.1%), cellular (11.5%), aneurysmal (7.4%), angiomatous (6.5%), sclerotic (6.5%), monster (4.9%), palisading (1.6%), keloidal (0.8%), or mixed type (7.3%).² Also reported are ossifying DFs¹⁰ and a signet-ring cell DF.¹¹
- Electron microscopy and immunohistochemistry may be needed to differentiate atypical or pigmented DFs from other lesions.⁷

DIFFERENTIAL DIAGNOSIS

DFs may be confused with the following malignant tumors; diagnosis based on histology and excision should be undertaken for enlarging or ulcerating tumors:

- Dermatofibrosarcoma protuberans—A low-grade malignant fibrotic tumor of the skin and subcutaneous tissues (**Figure 160-6**). A punch biopsy will provide adequate tissue to make the diagnosis.
- Pseudosarcomatous DF—A rare connective tissue tumor arising on the trunk and limbs in young adults.
- Malignant fibrous histiocytoma—A common soft-tissue sarcomas occurring in the extremities. Presentation as a primary cutaneous lesion is rare and more often presents as a metastasis from another location such as the breast.

FIGURE 160-2 Dermatofibroma on the thigh of black woman. Note the darker brown halo around the lighter center. (Courtesy of Richard P. Usatine, MD.)

FIGURE 160-3 Pinch test showing a deep dimpling of this dermatofibroma on the buttocks. (Courtesy of Richard P. Usatine, MD.)

Many benign lesions have a similar appearance, including:

- Pigmented seborrheic keratosis—May be macular and often larger than DF. Distinguished by surface cracks, verrucous features, stuck-on appearance, and adherent greasy scale (Chapter 158, Seborrheic Keratosis).
- Epidermal inclusion cyst—Sharply circumscribed, skin-colored nodule often with a central punctum. Most common on face, neck, or trunk. Composed of stratified epithelium surrounding a mass of keratinized material that has a foul odor when it drains.
- Hypertrophic scar—Occurs within previous wounds or lacerations.
- Neurofibroma—Benign Schwann cell tumors; single lesions are seen in normal individuals. Cutaneous tumors tend to form multiple, soft, pedunculated masses, whereas subcutaneous nodules are skin-colored soft nodules attached to peripheral nerves. The latter show similar invagination as DF (Chapter 235, Neurofibromatosis).

MANAGEMENT

- No treatment is necessary unless the diagnosis is questioned or symptoms warrant.
- Punch excision or shave excision may be used for small lesions; with the latter technique, the healed area may remain hard as a result of remaining fibrous tissue.
- Larger lesions may require an elliptical (fusiform) excision, down to the subcutaneous fat.
- One author noted that DFs occurring on the face often have involvement of deeper structures and an increased rate of local recurrences and therefore recommend excision with wider margins in comparison with DFs occurring on the extremities.¹²
- Cryotherapy has also been used, but the cure rate is low and lesions may recur.
- Several case reports found success in treating multiple DFs with carbon dioxide laser¹³ or isotretinoin.¹⁴

PROGNOSIS

- Although DFs are usually unchanging and persist indefinitely, there are reports of spontaneous regression.¹⁵
- Following excision, DFs have a low recurrence rate of less than 2%, with higher recurrence believed to occur in cellular, aneurysmal, and atypical types.^{7,10}
- A higher rate of recurrence has been noted in the subcutaneous and deep types, and in lesions located on the face, in which a recurrence rate of 15% to 19% has been reported.^{16,17}

PATIENT EDUCATION

- DFs are best left alone if they are relatively asymptomatic and stable.

PATIENT RESOURCES

- www.aocd.org/skin/dermatologic_diseases/DF.html.

161 PYOGENIC GRANULOMA

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A 20-year-old woman, who was being seen by her family physician for her prenatal care, presents to the office with a new growth on her lip. She stated that the growth on her lip bled very easily but was not painful. She was diagnosed with a pyogenic granuloma (PG) and preferred to wait until her pregnancy was over to have it removed. The lesion did not regress spontaneously after pregnancy and was surgically excised.

INTRODUCTION

PG is the name for a common, benign, acquired, vascular neoplasm of the skin and mucous membranes.

SYNONYMS

The term *lobular capillary hemangioma* has been suggested because PG is neither pyogenic (purulent bacterial infection) nor a granuloma.¹

EPIDEMIOLOGY

- Most often seen in children and young adults (0.5% of children's skin lesions); 42% of cases occur by 5 years of age and approximately 1% are present at birth.¹
- Oral lesions occur most often in the second and third decade, more commonly in women (female-to-male ratio is 2:1).¹
- Also common during pregnancy.
- PG has also been reported in the GI tract, the larynx, and on the nasal mucosa, conjunctiva, and cornea.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown but may be the result of trauma, infection, or preceding dermatoses.
- Consists of dense proliferation of capillaries and fibroblastic stroma that is infiltrated with polymorphonuclear leukocytes.
- Multiple PGs have been reported at burn sites and following use of oral contraceptives, protease inhibitors, and topical application of tretinoin for acne.²
- PGs are known to regress following pregnancy. Vascular endothelial growth factor (VEGF) was found in one study to be high in the granulomas during pregnancy, was almost undetectable after parturition, and was associated with apoptosis of endothelial cells and regression of granuloma.³

FIGURE 161-1 Pyogenic granuloma on the lower lip arising during pregnancy. (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

RISK FACTORS

- Trauma (up to 50%) or chronic irritation.¹
- Multiple lesions can follow manipulation of a primary lesion.⁴
- Pregnancy or use of oral contraceptives for oral PGs; postulated caused by imbalance between angiogenesis enhancers and inhibitors.¹
- Infection with *Bartonella*.¹

DIAGNOSIS

CLINICAL FEATURES

- Usually solitary, erythematous, dome-shaped papule or nodule that bleeds easily (**Figures 161-1 to 161-8**); rarely causes anemia. Satellite lesions may rarely occur.
- Prone to ulceration, erosion, and crusting.
- Size ranges from a few millimeters to several centimeters (average size is 6.5 mm).¹
- Rapid growth over a period of weeks to maximum size.
- Variants include cutaneous, oral mucosal (granuloma gravidarum), satellite, subcutaneous, intravenous, and congenital types.¹

TYPICAL DISTRIBUTION

- Cutaneous PG most often found on the head and neck (62.5%) specifically the gingiva, lips as in **Figure 161-1**, nose (**Figure 161-2**), and face, trunk (20%) and extremities (18%) (**Figures 161-3 to 161-6**).¹
- Pregnancy PG occurs most commonly along the maxillary intraoral mucosal surface (**Figure 161-1**).

IMAGING

- Reddish homogeneous area surrounded by a white collarette is the most frequent dermoscopic pattern in PGs (85%).⁵ In more advanced lesions, white lines that intersect the central areas may be seen that are likely fibrous septa.

BIOPSY

- Early lesions resemble granulation tissue (numerous capillaries and venules with endothelial cells arrayed radially toward the skin surface; stroma is edematous).¹
- The mature PG exhibits a fibromyxoid stroma separating the lesion into lobules. Proliferation of capillaries is present, with prominent endothelial cells. The epidermis exhibits inward growth at the lesion base.¹
- A regressing PG has extensive fibrosis.

DIFFERENTIAL DIAGNOSIS

PG may be confused with a number of cutaneous malignancies, including atypical fibroxanthoma, basal cell carcinoma, Kaposi carcinoma, metastatic cutaneous lesions, squamous cell carcinoma, and amelanotic melanoma (**Figure 161-7**). It is especially important to

FIGURE 161-2 Pyogenic granuloma on the nose in a young adult. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-3 Large pyogenic granuloma on the hand of a 33-year-old man present for 3 months. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-4 Large pyogenic granuloma on the finger of a 22-year-old man present for 4 months. He was sent out of multiple clinical settings untreated until we excised this. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-5 Small pyogenic granuloma on the finger of a 17-year-old boy for 2 months. It started with a small injury to the finger. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-6 Pyogenic granuloma on the leg for 6 months before the patient presented for treatment. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-7 Amelanotic melanoma on the nose that could be confused with a pyogenic granuloma. Always send what you suspect to be a PG to the pathologist. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

send the excised lesion that appears to be a PG for pathology to make sure that a malignancy is not missed.

Benign tumors that may be confused with PG include:

- Cherry hemangioma—Small, bright-red, dome-shaped papules that represent benign proliferation of capillaries (**Figure 161-8**).
- Fibrous papule of the nose is a benign tumor of the nose. Most are skin colored and not confused with PG. A benign clear cell variant of a fibrous papule can closely resemble a PG as seen in **Figure 161-9**.
- Bacillary angiomatosis—A systemic infectious disease caused by two *Bartonella* species. Globular angiomatous papules appear like PG (**Figure 217-6**). Nodules affect all age groups and may reach 10 cm in size. This infection is more likely to occur in persons with AIDS. Weight loss and lymphadenopathy may occur.

MANAGEMENT

Removal of the lesion is indicated to alleviate any bleeding or discomfort, for cosmetic reasons, or when the diagnosis is uncertain.

NONPHARMACOLOGIC

- Untreated PGs eventually atrophy, become fibromatous, and slowly regress, especially if the causative agent is removed.

MEDICATIONS

- A case of successful treatment of a recurrent PG was reported using a 14-week course of twice-weekly imiquimod 5% topical application.⁶ **SOR C**

PROCEDURES

A number of procedures have been used for elimination of PGs; data are limited to case series reports.⁷

- Simple surgical excision has a low recurrence rate (<4%) but is associated with scarring (55%).⁷ **SOR C**
- Removal can be accomplished with shave excision and electrodesiccation; the latter reduces recurrence (approximately 10%) and scarring appears less than with either simple excision (31%) or cauterization alone (43.5%).^{1,7} PGs bleed extensively when manipulated or cut. It is important to use lidocaine with epinephrine, wait 10 minutes for the epinephrine to work, and have an electrosurgery device to control bleeding. Cut the PG off with a blade and send to pathology. Curretting the base will also help stop the bleeding and prevent recurrence. The base is curetted and electrodesiccated until the bleeding stops. **SOR C**
- Both cryosurgery and laser surgery often require more than one treatment and rates of scarring may be high (12% to 42% and 44%, respectively).^{1,7} **SOR C**
- In one case series, sclerotherapy was reported to leave no scarring or recurrence.⁷ **SOR C**

PROGNOSIS

- PG develops over weeks and growth typically stabilizes over several months.¹ Eventually, it shrinks to become a fibrotic “angioma.”

FIGURE 161-8 Hemangioma on the lip of a 67-year-old man. By appearance alone this is hard to differentiate from a pyogenic granuloma (lobular capillary hemangioma). This did not bleed extensively at time of excision (and the pathology result confirmed that this was a hemangioma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 161-9 Vascular growth on the nose of a pregnant woman that appears to be a pyogenic granuloma. Biopsy revealed a benign clear cell variant of a fibrous papule. (Courtesy of Richard P. Usatine, MD.)

Some nodules spontaneously infarct and involute. In one pediatric retrospective case series with telephone follow-up, 4 untreated patients had spontaneous resolution within 6 to 18 months with no recurrences.⁸

- Congenital PG is an uncommon disseminated variant that presents with multiple lesions, is similar in appearance to the cutaneous form, and is present at birth. The condition appears to follow a benign course, with spontaneous resolution over 6 to 12 months.¹

PATIENT EDUCATION

- Explain to patients that lesions may resolve spontaneously and that multiple successful treatments are available (note that most patients will be grateful to have treatment that day as the lesion tends to be a great nuisance by bleeding easily and having an undesirable appearance).
- Once treated, if the lesion begins to recur, patients should follow-up quickly before the lesion gets larger and harder to treat.

FOLLOW-UP

In 2 weeks to receive the result of the pathology and to check wound healing.

SECTION 10 NEVI

162 BENIGN NEVI

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A young woman comes to the office because her husband has noted that the moles on her back are changing (**Figure 162-1**). A few have white halos around the brown pigmentation and some have lost their pigment completely, with a light area remaining. She has no symptoms but wants to make sure these are not skin cancers. Halo nevi are an uncommon variation of common nevi. These appear benign and the patient is reassured.

INTRODUCTION

Most nevi are benign tumors caused by the aggregation of melanocytic cells in the skin. However, nevi can occur on the conjunctiva, sclera and other structures of the eye. There are also nonmelanocytic nevi that are produced by other cells as seen in Becker nevi and comedonal nevi. Although most nevi are acquired, many nevi are present at birth.

SYNONYMS

Moles.

EPIDEMIOLOGY

- Acquired nevi are common lesions, forming during early childhood; few adults have none.
- Prevalence appears to be lower in dark-skinned individuals.
- Present in 1% of neonates increasing through childhood and peaking at puberty; new ones may continue to appear in adulthood. In a population study of children (N = 180, ages 1 to 15 years) in Barcelona, the mean number of nevi was 17.5.¹
- Adults typically have 10 to 40 nevi scattered over the body. In a population study in Germany, 60.3% of 2823 adults (mean age: 49 years; 50% women) exhibited 11 to 50 common nevi and 5.2% had at least 1 atypical nevus.²
- The peak incidence of melanocytic nevi (MN) is in the fourth to fifth decades of life; the incidence decreases with each successive decade.³

FIGURE 162-1 A. Multiple halo nevi on the back. B. Close-up of a halo nevus in transition. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Benign tumors composed of nevus cells derived from melanocytes, pigment-producing cells that colonize the epidermis.
- MN represent proliferations of melanocytes that are in contact with each other, forming small collections of cells known as nests. Genetic mutations present in common nevi as well as in melanomas include BRAF, NRAS, and *c-kit*.⁴
- Sun (UV) exposure, skin-blistering events (e.g., sunburn), and genetics play a role in the formation of new nevi.³
- Nevi commonly darken and/or enlarge during pregnancy. Melanocytes have receptors for estrogens and androgens and melanogenesis is responsive to these hormones.³
- Three broad categories of MN are based on location of nevus cells²:
 - Junctional nevi—Composed of nevus cells located in the dermo-epidermal junction; may change into compound nevi after childhood (except when located on the palms, soles, or genitalia) (**Figure 162-2**).
 - Compound nevi—A nevus in which a portion of nevus cells have migrated into the dermis (**Figure 162-3**).
 - Dermal nevi—Composed of nevus cells located within the dermis (usually found only in adults). These are usually raised and have little to no visible hyperpigmentation (**Figures 162-4 and 162-5**).
- Special categories of nevi:
 - Halo nevus—Compound or dermal nevus that develops a symmetric, sharply demarcated, depigmented border (**Figure 162-1**). Most commonly occurs on the trunk and develops during adolescence. Repigmentation may occur.
 - Blue nevus—A dermal nevus that contains large amounts of pigment so that the brown pigment absorbs the longer wavelengths of light and scatters blue light (Tyndall effect) (**Figure 162-6**). Blue nevi are not always blue and color varies from tan to blue, black, and gray. Types of blue nevi include amelanotic, desmoplastic, atypical, and malignant variants; genetic mutations seen in blue nevi are often different than those seen in common nevi and include the G α q class of G-protein α subunits, Gnaq, and Gna11 proteins.⁴ The nodules are firm because of associated stromal sclerosis. Usually appears in childhood on the extremities, dorsum of the hands and face. A rare variant, the cellular blue nevus is large (>1 cm), frequently located on the buttocks, and may undergo malignant degeneration.
 - Nevus spilus—Hairless, oval, or irregularly shaped brown lesion with darker brown to black dots containing nevus cells (**Figure 162-7**). May appear at any age or be present at birth; unrelated to sun exposure.
 - Spitz nevus (formerly called benign juvenile melanoma because of its clinical and histologic similarity to melanoma)—Hairless, red, or reddish brown dome-shaped papules generally appearing suddenly in children, sometimes following trauma (**Figures 162-8 and 162-9**). The pink color is caused by increased vascularity. Most importantly, these should be fully excised with clear margins.
 - Nevus of Ota—Dark brown nevus that occurs most commonly around the eye and can involve the sclera (**Figure 162-10**).

FIGURE 162-2 Two benign junctional nevi on the arm of a 19-year-old woman. Note how these are flat macules. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-3 Benign compound nevus proven by biopsy on the back of a 35-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-4 Dermal nevus (intradermal melanocytic nevus)—dome shaped with some scattered pigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-5 Dermal nevus pedunculated with small telangiectasias. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-7 Nevus spilus on the leg of a young woman from birth. It appears benign and needs no intervention. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-6 Blue nevus on the left cheek that could resemble a melanoma with its dark color. In this case it was fully excised with a 5-mm punch with a good cosmetic result. Blue nevi are benign and do not need to be excised unless there are suspicious changes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-8 Spitz nevus that grew over the past year on the nose of this 18-year-old woman. It was fully excised with no complications. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-9 Spitz nevus on face of this 9-year-old boy. He very bravely allowed us to excise it with local anesthesia. (Courtesy of Richard P. Usatine, MD.)

- Both acquired and congenital MN hold some risk for the development of melanoma; the number of MN, especially more than 100, is an important independent risk factor for cutaneous melanoma.⁵

NONMELANOCYTIC NEVI

- Becker nevus—A brown patch often with hair located on the shoulder, back or submammary area, most often in adolescent men (**Figures 162-11** and **162-12**). The lesion may enlarge to cover an entire shoulder or upper arm. Although it is called a nevus, it does not actually have nevus cells and has no malignant potential. It is a type of hamartoma, an abnormal mixture of cells and tissues normally found in the area of the body where the growth occurs.
- Nevus depigmentosus is usually present at birth or starts in early childhood. There is a decrease number of melanosomes within a normal number of melanocytes. It typically has a serrated or jagged edge (**Figure 162-13**).
- Nevus anemicus—A congenital hypopigmented macule or patch that is stable in relative size and distribution. It occurs as a result of localized hypersensitivity to catecholamines and not a decrease in melanocytes. On diascopy (pressure with a glass slide) the skin is indistinguishable from the surrounding skin (**Figure 162-14**).
- Nevus comedonicus (comedonal nevus) is a rare congenital hamartoma characterized by an aggregation of comedones in one region of the skin (**Figure 162-15**).
- Epidermal nevi are congenital hamartomas of ectodermal origin classified on the basis of their main component: sebaceous, apocrine, eccrine, follicular, or keratinocytic. See Chapter 163, Congenital Nevi for a full discussion of this type of nevus.

Note nevus comedonicus and epidermal nevi tend to follow Blaschko lines, which come from embryologic development.

RISK FACTORS

- In the Barcelona study of children, male gender, past history of sunburns, facial freckling, and family history of breast cancer were independent risk factors for having a higher number of nevi.¹
- In one study among very light-skinned (and not darker skinned) children without red hair, children who develop tans have greater numbers of nevi.⁶
- Neonatal blue-light phototherapy is not related to nevus count.⁷

DIAGNOSIS

CLINICAL FEATURES

Most benign MN are tan to brown, usually less than 6 mm, with round shape and sharp borders.

- Junctional nevi—Macular or slightly elevated mole of uniform brown to black pigmentation, smooth surface, and a round or oval border (**Figure 162-2**). Most are hairless and vary from 1 to 6 mm.
- Compound nevi—Slightly elevated, symmetric, uniformly flesh colored or brown with a round or oval border, often becoming

FIGURE 162-10 Nevus of Ota on the face of this young woman since early childhood. It involved both eyes and the skin around both eyes. The scleral pigmentation looks blue. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-11 Becker nevus that developed during adolescence. Hair is frequently seen on this type of nonmelanocytic nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-12 Becker nevus on the back of a 16-year-old Hispanic boy for 2 years. While this nevus did not have hair, it did have increased acne within the area—another feature of the Becker nevus. (Courtesy of Richard P. Usatine, MD.)

more elevated with age (**Figure 162-3**). Hair may be present and a white halo may form.

- Dermal nevi (same as intradermal nevi)—Skin color or brown color that may fade with age; dome shaped is most common, but shapes vary, including polypoid, warty, and pedunculated. Often found on the face and may have telangiectasias (**Figures 162-4** and **162-5**). Size ranges from 1 to 10 mm.

TYPICAL DISTRIBUTION

- Most often above the waist on sun-exposed areas but may appear anywhere on the cutaneous surface; less commonly found on the scalp, breasts, or buttocks.
- Among the children in the Barcelona study, 61.1% had nevi on the face and neck, 17.2% on the buttocks, and 11.7% on the scalp; approximately one-third had congenital nevi (Chapter 163, Congenital Nevi).¹
- In an Australian study of white children, MN of all sizes were highest on the outer forearms, followed by the outer upper arms, neck, and face.⁸ Boys had higher densities of MN of all sizes on the neck than girls, and girls had higher densities of MN of 2 mm or greater on the lower legs and thighs than boys. Habitually sun-exposed body sites had higher densities of small MN and highest prevalence of larger MN.

IMAGING

- Dermoscopy can be a useful technique for diagnosing benign nevi. For MN, dermoscopic diagnosis relies on color; pattern (i.e., globular, reticular, starburst, and homogeneous blue pattern); pigment distribution (i.e., multifocal, central, eccentric, and uniform); and special sites (e.g., face, acral areas, nail, and mucosa), in conjunction with patient factors (e.g., history, pregnancy).⁹ (See Appendix C: Dermoscopy.)
- In the Barcelona study, the most frequent dominant dermoscopic pattern was the globular type with the homogeneous pattern predominating in the youngest children and the reticular pattern predominating in adolescents.¹

BIOPSY

Biopsy is necessary if you suspect melanoma or a Spitz nevus. A biopsy that cuts below the pigmented area is preferred if there is a reasonable suspicion for melanoma. This can be done with a scoop shave, a punch that gets the whole lesion, or an elliptical excision. If the patient wants a raised benign appearing nevus excised for cosmetic reasons, a shave excision may be adequate. Send all lesions (except skin tags) to the pathologist for examination, even when they appear benign, to avoid missing a melanoma.

DIFFERENTIAL DIAGNOSIS

Benign nevi may develop atypia or become melanoma. This should be suspected if a lesion has atypical features including asymmetry, border irregularity, color variability, diameter greater than 6 mm, and evolving (called the ABCDE approach [asymmetry, border irregularity, color irregularity, diameter >6 mm, evolution]). Any lesion that becomes symptomatic (e.g., itchy, painful, irritated, or

FIGURE 162-13 Nevus depigmentosus on the face of this young girl since birth. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-14 Nevus anemicus on the posterior neck. The localized hypersensitivity to catecholamines causes the area to stay lighter than the surrounding skin. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

bleeding), or develops a loss or increase in pigmentation, should be evaluated and biopsied if needed. Dermoscopy can be used to increase one's accuracy in distinguishing between benign and malignant lesions (see Appendix C, Dermoscopy).

- Melanomas are skin cancers that may develop from a preexisting nevus. The most important skill to develop is how to distinguish a benign nevus from a nevus that might be malignant melanoma. Because clinical appearance can be misleading, a biopsy is necessary when there is a reasonable suspicion for cancer (Chapter 172, Melanoma).
- Dysplastic or atypical nevi are variants that are relatively flat, thinly papular, and relatively broad. Often, the lesions exhibit target-like or fried egg-like morphology, with a central papular zone and a macular surrounding area with differing pigmentation (Chapter 165, Dysplastic Nevus).
- Seborrheic keratoses are benign growths that appear more with increasing age and are often hyperpigmented as seen with many nevi. These are more superficial and stuck-on in their appearance (Chapter 158, Seborrheic Keratosis).
- Labial melanotic macules are benign dark macules on the lip that are not nevi and not melanomas (**Figure 162-16**). They can be removed for cosmetic purposes.

MANAGEMENT

Nevi are generally only removed for cosmetic reasons or because of concern over changes in the lesion suggestive of dysplasia or melanoma.

- A full excisional biopsy with a sutured closure is usually the best means to diagnose a lesion if concern exists regarding the possibility of melanoma. If the lesion is found to be benign, no further treatment is usually required.
- Punch excision can be used to excise smaller lesions.
- Scoop shave—Unfortunately, if a punch biopsy is used to sample a larger lesion it may miss a melanoma in another part of the lesion. A broad scoop shave is better than a punch biopsy when a full elliptical excision is not possible or desirable (e.g., a large flat pigmented lesion on the face).
- Nevi removed for cosmesis are often removed by shave excision.³

If a Spitz nevus is suspected, either biopsy it now or schedule the patient for a full excision. The histopathology is too close to a melanoma to just watch it.

- Becker nevi and comedonal nevi do not become melanoma because they lack melanocytes. Therefore, there is no reason to excise them. Generally, these are large and the risks of excision for cosmetic reasons outweigh the benefits.

PREVENTION

- Sun protection to limit sunburn may help reduce the appearance of nevi. In a trial of 209 white children, children randomized to the sunscreen group, especially those with freckles, had significantly

FIGURE 162-15 Nevus comedonicus on the chest of this 15-year-old boy since birth. This is a congenital hamartoma with open comedones. It is not acne. (Courtesy of Richard P. Usatine, MD.)

FIGURE 162-16 Labial melanotic macule. These are benign but are not nevi. (Courtesy of Richard P. Usatine, MD.)

fewer new nevi on the trunk than did children in the control group at 3-year follow-up.¹⁰

PROGNOSIS

- Degeneration of common nevi into melanoma is very rare.
- Patients with multiple or large MN appear to have an increased risk of melanoma.³
- Nevi may recur or persist following removal; in one study, dysplastic MN were the most likely to persist.¹¹ In another study, of 61 benign nevi biopsy sites reexamined, two (3.3%) recurred.¹²

FOLLOW-UP

- Patients with multiple or sizable MN should be followed by an experienced clinician because they appear to have an increased lifetime risk of melanoma, with the risk increasing in rough proportion to the size and/or number of lesions.³

PATIENT EDUCATION

- Patients should be encouraged to use sunscreen to prevent skin cancer as well as to reduce the development of new nevi.
- Patients with multiple or sizable MN should be taught to look for and report asymmetry, border irregularity, new symptoms, and color and size changes.

163 CONGENITAL NEVI

Mindy A. Smith, MD, MS

PATIENT STORY

A small congenital nevus (**Figure 163-1**) was noted on this 6-month-old child by his new family physician during a routine examination. The parents acknowledged that it was present from birth and asked if it needed to be cut out. They were reassured that nothing needs to be done about it at this time.

INTRODUCTION

Congenital melanocytic nevi are benign pigmented lesions that have a wide variation in presentation and are composed of melanocytes, the pigment-forming cells in the skin (**Figures 163-1 to 163-7**).

SYNONYMS

- Garment nevus, bathing trunk nevus, giant hairy nevus, giant pigmented nevus, pigmented hairy nevus, nevus pigmentosus, nevus pigmentosus et pilosus, and Tierfell nevus.¹
- Tardive congenital nevus refers to a nevus with similar features to congenital nevi, but appears at age 1 to 2 years.

EPIDEMIOLOGY

- Congenital melanocytic nevi develop in 1% to 6% of newborns and are present at birth or develop during the first year of life.¹
- In an Italian prevalence study of more than 3000 children ages 12 to 17 years, congenital melanocytic nevi or congenital nevus-like nevi were found in 17.5%; most (92%) were small (<1.5 cm).²
- Congenital nevi are also seen in neurocutaneous melanosis, a rare syndrome characterized by the presence of congenital melanocytic nevi and melanotic neoplasms of the central nervous system.
- The development of melanoma within congenital nevi (**Figure 163-8**) is believed to occur at a higher rate than in normal skin. Estimates range from 4% to 10%, with smaller lesions having lowest risk.¹
 - In a systematic review, 46 of 651 patients with congenital melanocytic nevi (0.7%), who were followed for 3.4 to 23.7 years, developed melanomas, representing a 465-fold increased relative risk of developing melanoma during childhood and adolescence.³ The mean age at diagnosis of melanoma was 15.5 years (median: 7 years).
 - Patients with giant congenital melanocytic nevi appear to be at highest risk where subsequent melanoma has been reported in 5% to 7% by age 60 years.⁴ In one study, 70% of patients with a large congenital melanocytic nevus diagnosed with melanoma were diagnosed within the first 10 years of life.⁵

FIGURE 163-1 Small congenital nevus found on the foot of a 6-month-old child. The parents were counseled that this nevus does not need to be excised for the prevention of melanoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 163-2 Congenital nevus on the breast of a 24-year-old woman. It is verrucous, but entirely benign. (Courtesy of Richard P. Usatine, MD.)

- In a prospective study of 230 medium-size congenital nevi (1.5 to 19.9 cm) in 227 patients from 1955 to 1996, no melanomas occurred. The average follow-up period being 6.7 years to an average age of 25.5 years.⁶
- Other risk factors for melanoma include personal or family history of melanoma or other skin cancer, presence of multiple nevi, red hair, blue eyes, freckling, and history of radiation (see Chapter 172, Melanoma).¹

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of congenital nevi is unknown.
- Congenital nevi result from a proliferation of benign melanocytes in the dermis, epidermis, or both. Melanocytes of the skin originate in the neuroectoderm and migrate vertically to the skin and other locations such as the central nervous system and eye.¹ Defects in migration or maturation are hypothesized as causal.

DIAGNOSIS

Diagnosis is usually made based on clinical features and the history of the nevus being present at birth or develop during the first year of life.

CLINICAL FEATURES¹

- Variable mixtures of color including pink-red (primarily at birth), tan, brown, black, or multiple shades within a single lesion (**Figures 163-1 to 163-7**); color usually remains constant over time but the nevus will grow as the person grows.
- Shapes are also highly variable, including oval, round, linear, and random; lesions have irregular but well-demarcated borders (**Figures 163-1 to 163-8**). The pigment may fade off into surrounding skin (**Figures 163-3 and 163-4**).
- Nevi may become raised over time (**Figures 163-2 and 163-3**) and the skin surface ranges from smooth to pebbly to hyperkeratotic (eczema-like appearance).
- Macular portion usually found at edges.
- Frequently exhibit hypertrichosis (**Figure 163-5**).
- Heavily pigmented large congenital melanocytic nevi over a limb may be associated with underdevelopment of the limb.¹
- Lesions are classified by size in adulthood as:¹
 - Small (<1.5 cm) (**Figure 163-1**).
 - Medium (1.5 cm to 19 cm) (**Figures 163-2 and 163-3**).
 - Large (>20 cm) (**Figures 163-5 to 163-7**). Giant nevi are often surrounded by several smaller satellite nevi (**Figures 163-5 to 163-7**).
 - Lesions on a child's head of less than 9 cm or body of greater than 6 cm are considered large based on likely eventual growth.¹

IMAGING

- Dermoscopy findings depend on the age and location. In one study, the globular pattern was most common in children younger than age 11 years and on the trunk.⁷ The majority of reticular lesions

FIGURE 163-3 A benign hairy congenital nevus on the upper buttocks of a 7-year-old boy. The parents requested a consult with plastic surgery to discuss removal. (Courtesy of Richard P. Usatine, MD.)

FIGURE 163-7 Giant congenital bathing trunk nevus surrounded by satellite nevi in a 7-year-old Hispanic boy. The patient was referred to plastic surgery so that his parents might consider a staged removal of this large nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 163-6 Infant born with large bathing trunk nevus covering most of the back and chest. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 163-8 Melanoma arising in an acquired nevus showing features of central regression and a new elevated nodule. These are the same features that make a congenital nevus suspicious for melanoma. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

were located on the limbs and the variegated pattern was the most specific for congenital nevi.

- MRI of the central nervous system can be a useful diagnostic tool in patients suspected of having neurocutaneous melanosis; one author recommended a screening MRI for patients with giant congenital melanocytic nevi.⁸

TYPICAL DISTRIBUTION

- Congenital nevi can be found anywhere on the body.

BIOPSY

- Although there are many histologic subtypes, distinguishing histologic features of congenital nevi include:¹
 - Involvement by nevus cells of deep dermal appendages and neurovascular structures (e.g., hair follicles, sebaceous glands, arrector pili muscles, and within walls of blood vessels).
 - Infiltration of nevus cells between collagen bundles.

DIFFERENTIAL DIAGNOSIS

- Becker nevus—A brown macule, patch of hair, or both on the shoulder, back, or submammary area that develops in adolescence. The border is irregular and the lesion may enlarge to cover an entire shoulder or upper arm. It is a type of hamartoma and is not a melanocytic nevus (see Chapter 162, Nevus).
- Café-au-lait spots—Coffee-and-milk-colored patch that can be present at birth or develop during early childhood. Although a number of large café-au-lait spots are associated with neurofibromatosis, a few of them can occur in completely unaffected children. These light-brown patches have increased melanin but are not nevi (see Chapter 234, Neurofibromatosis).

MANAGEMENT

The management of congenital nevi depends on size and location of the lesion (difficulty in monitoring), associated symptoms, the age of the patient, the effect on cosmesis, and the potential for malignant transformation.

- For small- and medium-size congenital melanocytic nevi, the risk of malignant transformation is small and prophylactic removal is not recommended. For cosmesis, treatments include surgical excision or laser treatment.
- Larger congenital nevi can be surgically removed but may require tissue expanders, tissue grafts, and tissue flaps to close large defects. Excisions can also be staged in multiple steps. Because the melanocytes may extend deep into underlying tissues (including muscle, bone, and central nervous system), removing the cutaneous component may not eliminate the risk of malignancy.
 - There is also concern that surgical intervention may adversely affect congenital melanocytic nevi cells.⁹
- Laser treatment of the lesions has been performed with a number of different types of lasers.¹⁰ Because of the lack of penetrance to deeper tissue levels, long-term recurrence or malignant transformation is also an issue with these techniques.

- Careful life long follow-up with photographs is an acceptable approach, especially now with the affordability of digital cameras.
- Garment or bathing trunk nevi (**Figures 163-5 to 163-7**):
 - Approximately half of the melanomas that develop in bathing trunk nevi do so before age 5 years.¹¹ These melanomas can be missed by observation because they can have nonepidermal origins.
 - Surgical excision is recommended by some experts to prevent melanoma.¹¹ **SOR C**.
- Changes to watch for that call for a biopsy include:
 - Partial regression (depressed white areas).
 - Inflammation.
 - Rapid growth or color change.
 - Development of a firm nodule (**Figure 163-8**).

PATIENT EDUCATION

- All patients should be told about the importance of protection from UV light exposure. This is especially important in people with giant congenital nevi, because they at a significantly increased risk of melanoma.
- Patients (or their parents) should be taught to look for signs of melanoma (ABCDE) (asymmetry, border irregularity, color irregularity, diameter >6 mm, evolution).

FOLLOW-UP

- Patients with giant congenital nevi or multiple congenital nevi may benefit from consultation with a neurologist, pediatrician, or both, because of the risk of neurocutaneous melanosis and its neurologic manifestations or obstructive hydrocephalus.
- Bathing trunk nevi can also be associated with spina bifida, meningocele, and neurofibromatosis.¹¹
- Because patients with all forms of congenital nevi, especially giant congenital melanocytic nevi, have an increased risk of developing melanoma, physicians should consider baseline photography and regular follow-up with an experienced clinician for these patients.

164 EPIDERMAL NEVUS AND NEVUS SEBACEOUS

Mindy A. Smith, MD, MS

PATIENT STORY

A 15-year-old boy is brought in by his mother with a concern about growth of his birthmark. It has become somewhat more raised and bumpy in the past year (**Figure 164-1**). The adolescent reports no symptoms and is not worried about the appearance. He is otherwise healthy with no neurologic symptoms. The joint decision of the family and the doctor was to not excise the epidermal nevus at this time. He may choose to have this removed by a plastic surgeon in the future.

INTRODUCTION

- Epidermal nevi (EN) are congenital hamartomas of ectodermal origin classified on the basis of their main component: sebaceous, apocrine, eccrine, follicular, or keratinocytic.
- Nevus sebaceous (NS) is a hamartoma of the epidermis, hair follicles, and sebaceous and apocrine glands. A hamartoma is the disordered overgrowth of benign tissue in its area of origin.

SYNONYMS

- EN syndrome is also called Solomon syndrome and is a neurocutaneous disorder characterized by EN and an assortment of neurologic and visceral manifestations.
- NS is also called sebaceous nevus and nevus sebaceus of Jadassohn (**Figure 164-2**).
- An inflammatory linear verrucous epidermal nevus (ILVEN) (**Figure 164-3**) can be part of an epidermal nevus syndrome but some affected persons only have the cutaneous EN.

EPIDEMIOLOGY

- EN are uncommon (approximately 1% to 3% of newborns and children), sporadic, and usually present at birth, although they can appear in early childhood (**Figure 164-4**).
- EN are associated with disorders of the eye, nervous, and musculoskeletal systems in 10% to 30% of patients; in one study, 7.9% of patients with EN had 1 of the 9 syndromes—an estimated 1 per 11,928 pediatric patients.¹
- In another review of 131 cases of EN, most (60%) had noninflammatory EN, one third had NS, and 6% had ILVEN.²
- NS is usually present at birth or noted in early childhood (**Figure 164-5**).³ Most cases are sporadic but familial cases have been reported.²
- Linear NS is estimated to occur in 1 per 1000 live births.⁴

FIGURE 164-1 Epidermal nevus on the face of a teenager. This nevus has been present since birth, and the patient is otherwise healthy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-2 Nevus sebaceous on the scalp of a 14-year-old boy. (Courtesy of Richard P. Usatine, MD.)

- Linear NS syndrome includes a range of abnormalities, including the central nervous system (CNS); patients with CNS involvement typically have cognitive impairment and seizures³; other organ systems, including the cardiovascular, skeletal, ophthalmologic, and urogenital systems, may be involved.

ETIOLOGY AND PATHOPHYSIOLOGY

- EN histologically display hyperkeratosis and papillomatosis, similar microscopically to seborrheic keratosis (see Chapter 158, Seborrheic Keratosis).² Also similar to seborrheic keratosis, some EN of keratinocyte differentiation (approximately one third) have been found to have a mutation in the fibroblast growth factor receptor 3 (FGFR3) gene.
- Nine EN syndromes have been reported and are described in the referenced article.⁵
- EN frequently have a linear pattern that follows Blaschko lines (**Figures 164-1, 164-3, and 164-4**), which are believed to represent epidermal migration during embryogenesis.
- EN tend to become thicker, verrucous (**Figure 164-4**), and hyperpigmented at puberty.²
- Similarly, NS demonstrates stages of evolution paralleling the histologic differentiation of normal sebaceous gland:⁶
 - Infancy and young children—Smooth to slightly papillated, waxy, hairless thickening (**Figure 164-5**).
 - Puberty—Epidermal hyperplasia resulting in verrucous irregularity of the surface covered with numerous closely aggregated yellow-to-brown papules (**Figure 164-6**).
 - Development of secondary appendageal tumors (**Figures 164-7 and 164-8**) occurs in 20% to 30% of patients, most are benign (most commonly basal cell epithelioma or trichoblastoma), but single (most commonly basal cell carcinoma) or multiple malignant tumors of both epidermal and adnexal origins may be seen and metastases have been reported.² Rarely, these malignancies are seen in childhood.
- NS was shown to have a high prevalence of human papillomavirus DNA and authors postulate that human papillomavirus (HPV) infection of fetal epidermal stem cells could play a role in the pathogenesis.⁷

MAKING THE DIAGNOSIS

Clinical features of EN

- EN are linear, round, or oblong; well-circumscribed; elevated; and flat-topped (**Figures 164-1 and 164-4**).
- Color is yellow-tan to dark brown.
- Surface is uniform velvety or warty (**Figures 164-4 and 164-5**).
- ILVEN, a less common type of EN, is pruritic and erythematous (**Figure 164-3**).

Clinical features of NS

- NS has an oval to linear shape ranging from 0.5 × 1 cm to 7 × 9 cm.
- NS is usually a solitary, smooth, waxy, hairless thickening noted on the scalp at birth or in early childhood (**Figures 164-2 and 164-6**).

FIGURE 164-3 Inflammatory linear verrucous epidermal nevus (ILVEN) on the trunk of an adult man. Topical steroids were not helpful in diminishing his pruritus. (Courtesy of Robert T. Gilson, MD.)

FIGURE 164-4 Linear epidermal nevus on the neck that appeared in early childhood. The patient had no neurologic, musculoskeletal, or vision problems. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-5 Nevus sebaceous behind the ear of an infant. Note the light color and the subtle presentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-8 Nevus sebaceous with a benign tumor identified as a syringocystadenoma papilliferum by shave biopsy. Patient was referred for full removal of the nevus sebaceous. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-6 Nevus sebaceous on the scalp of a teenage female that is verrucous and brown. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-7 Nevus sebaceous on the scalp of a young woman. The patient reported a new area of elevation and bleeding. A biopsy showed no malignant transformation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-9 Extensive epidermal nevus following Blaschko lines on the trunk of this boy. Note how the lines are similar to the patient with inflammatory linear verrucous epidermal nevus (ILVEN) in Figure 164-2. (Courtesy of Rick Hodes, MD.)

- Early NS may be pink, orange, yellow, or tan; later lesions can appear verrucous and nodular (**Figure 164-5**).

TYPICAL DISTRIBUTION

- EN occur most commonly on the head and neck followed by the trunk and proximal extremities; only 13% have widespread lesions (**Figure 164-9**). Lesions may spread beyond their original distribution with age.
- NS are commonly found on the scalp followed by forehead and retroauricular region (**Figures 164-2 and 164-5 to 164-8**) and rarely involves the neck, trunk, or other areas.

BIOPSY

- Biopsy is the most definitive method for diagnosing these nevi. A biopsy is not needed if the clinical picture is clear and no operative intervention is planned. A shave biopsy should provide adequate tissue for diagnosis because the pathology is epidermal and in the upper dermis.
 - Histologic features of epidermolytic hyperkeratosis within an EN are associated with mutations in the keratin gene that may be transmitted to offspring; widespread cutaneous involvement may be seen.²

DIFFERENTIAL DIAGNOSIS

- Linear lichen planus (**Figure 164-10**)—Discrete, pruritic, violaceous papules are arranged in a linear fashion, usually extending along an entire limb.
- Syringoma (**Figure 164-11**)—Benign adnexal tumor derived from sweat gland ducts. Autosomal dominant transmission, soft, small, skin-colored to brown papules develop during childhood and adolescence, especially around the eyes, but may be found on the face, neck, and trunk.
- Lichen striatus—Discrete pink, tan, or skin-colored asymptomatic papules in a linear band that suddenly appear. The papules may be smooth, scaly, or flat topped. It is mostly seen in children. Although it is most commonly seen on an extremity, it can appear on the trunk (**Figure 164-12**). It can resemble a linear EN but lichen striatus will spontaneously regress within 1 year.
- Linear porokeratosis—Characterized by small, annular, hypertrophic verrucous plaques with a linear morphology usually limited to a single extremity. The annular morphology and dermatomal distribution should help distinguish this condition from EN and NS.

MANAGEMENT

MEDICATIONS

- There are no proven topical methods for treatment of these lesions. Topical retinoids may improve lesion appearance but recurrence is common.²

PROCEDURES

- Destructive modalities for EN, such as electrodesiccation and cryotherapy, may temporarily improve the appearance of the lesion, but recurrence is frequent.²

FIGURE 164-10 Lichen planus on the flexor aspect of the forearm in a linear pattern resembling a linear epidermal nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-11 Syringoma on the lower eyelid. (Courtesy of Richard P. Usatine, MD.)

FIGURE 164-12 Lichen striatus that appeared suddenly on the arm of a young boy. (Courtesy of Richard P. Usatine, MD.)

- Carbon dioxide laser is an alternative option for EN; however, scarring and pigment changes are potential permanent complications, especially in patients with darker skin types.⁸ This treatment does not completely remove NS and there is recurrence risk.²
- Surgical excision is an option that may be complicated by scarring.
- Because of the potential for malignant transformation particularly following puberty, some authors recommend early complete plastic surgical excision for NS; **SOR**  reconstructive surgery may be needed.
- Excision of large lesions may require reconstructive surgery with a rotation flap to close.⁹

PROGNOSIS

- There are reports of spontaneous improvement in patients with widespread involvement of EN.
- Malignant potential is low in EN.²
- Malignant potential in NS is uncertain. Reports range from 0% to 2.7%.²
 - Early reports suggested a high rate of developing basal cell carcinomas, whereas more recent studies identified trichoblastoma and syringocystadenoma papilliferum in NS, usually in adulthood.²
 - In a retrospective analysis of 757 cases of NS from 1996 to 2002 in children age 16 years or younger, investigators found no malignancies and question the need for prophylactic surgical removal.¹⁰
 - Squamous cell carcinoma has also been described in a NS.¹¹

FOLLOW-UP

- Patients with NS should be examined for other associated findings. Consider a consultation with a neurologist and/or ophthalmologist.
 - In a study of 196 subjects with NS examined for clinical neurologic abnormalities, only 7% had abnormalities.¹² Abnormal exams were more frequent in individuals with extensive nevi (21% vs. 5%) and a centropalmar location (21% vs. 2%). The patients depicted in this chapter had no neurologic abnormalities.

165 DYSPLASTIC NEVUS

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A 44-year-old man presents with concern over a mole on his back that his wife says is growing larger and more variable in color. The edges are irregular and the color almost appears to be “leaking” into the surrounding skin. He reports no symptoms related to this lesion. On physical exam, the nevus is 9 mm in diameter with asymmetry and variations in color and an irregular border (**Figure 165-1**). A full-body skin exam did not demonstrate any other suspicious lesions. Dermoscopy showed an irregular network with multiple asymmetrically placed dots off the network (**Figure 165-2**). A scoop saucerization was performed with a DermaBlade taking 2-mm margins of clinically normal skin (**Figure 165-3**). Although this could have been an early thin melanoma, the pathology showed a completely excised compound dysplastic nevus with no signs of malignancy. No further treatment was needed except yearly skin exams to monitor for melanoma.

INTRODUCTION

Dysplastic nevi (DN)/atypical moles are acquired melanocytic lesions of the skin whose clinical and histologic definitions are controversial and still evolving. These lesions have some small potential for malignant transformation and patients with multiple DN have an increased risk for melanoma.¹

The presence of multiple DN is a marker for increased melanoma risk just as red hair is, and, analogously, cutting off the red hair or cutting out all the DN does not change that risk of melanoma. The problem with DN is that any one lesion that is suspicious for melanoma must be biopsied to avoid missing melanoma, not to prevent melanoma from occurring in that nevus in the future.

SYNONYMS

Atypical nevus, atypical mole, Clark nevus, nevus with architectural disorder, and melanocytic atypia.¹

EPIDEMIOLOGY

- Two percent to 9% of the population has atypical moles (AMs).^{2,3} In a Swedish case-control study, 56% of cases (121 patients with melanoma) and 19% of 310 control subjects had nevi fulfilling the clinical criteria for DN.⁴ Among patients with melanoma, the rate of DN ranges from 34% to 59%.³ DN are uncommon in children; in a study of Swedish children (N = 524), none had DN.⁵ In another study of pathology reports from nevi removed from

FIGURE 165-1 Growing 9-mm compound dysplastic nevus on the back of a 44-year-old man. There is asymmetry and variations in color and an irregular border. (Courtesy of Richard P. Usatine, MD.)

FIGURE 165-2 Dermoscopy of this compound dysplastic nevus shows an irregular network with multiple asymmetrically placed dots off the network. (Courtesy of Richard P. Usatine, MD.)

patients younger than 18 years old, 3 of 199 nevi submitted for histologic analysis met the histologic criteria for DN.⁶

- Individuals with fair skin types are at higher risk of DN.³
- The sudden eruption of benign and atypical melanocytic nevi has been reported and is associated with blistering skin conditions and a number of disease states, including immunosuppression. Subsets of patients with immunosuppression have increased numbers of nevi on the palms and soles.⁷
- The National Institute of Health Consensus Conference on the diagnosis and treatment of early melanoma defined a syndrome of familial atypical mole and melanoma (FAMM). The criteria of FAMM syndrome are:⁸
 - The occurrence of malignant melanoma in one or more first- or second-degree relatives.
 - The presence of numerous (often >50) melanocytic nevi, some of which are clinically atypical.
 - Many of the associated nevi show certain histologic features (see below under BIOPSY).

ETIOLOGY AND PATHOPHYSIOLOGY

- Most DN are compound nevi (**Figure 165-1**) possessing a junctional and intradermal component (see Chapter 162, Nevus).¹ The junctional component is highly cellular and consists of an irregular distribution of melanocytes arranged in nests and lentiginous patterns along the dermoepidermal junction. The dermal component, located at the center, consists of nests and strands of melanocytes with distinct sclerotic changes.¹
- DN exhibit a host response consisting of irregular rete ridge elongation, subepidermal sclerosis, proliferation of dermal capillaries, and a perivascular, lymphohistiocytic inflammatory infiltrate.¹
- Individuals with DN may have deficient DNA repair, and DN lesions are associated with overexpression of pheomelanin (pigment produced by melanocytes), which may lead to increased oxidative DNA damage and tumor progression.⁹

DIAGNOSIS

CLINICAL FEATURES

- Variable mixtures of color including tan, brown, black, and red within a single lesion (**Figures 165-4** and **165-5**).
- Irregular, notched borders; pigment may fade off into surrounding skin (**Figure 165-5**).
- Flat or slightly raised (**Figures 165-4** to **165-6**) with the macular portion at edge. Not verrucous or pendulous.
- Lesions frequently surrounded by a reddish hue from reactive hyperemia making them appear target-like.
- Usually larger than 6 mm; may be larger than 10 mm (**Figures 162-1** and **162-4**).
- Patients with FAMM syndrome may have more than 100 lesions, far greater than the average number of common moles (<50) in most individuals.

FIGURE 165-3 A scoop saucerization was performed with a DermaBlade taking 2-mm margins of clinically normal skin. Although this could have been an early thin melanoma, the pathology showed a completely excised compound dysplastic nevus with no signs of malignancy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 165-4 Dysplastic nevus in a woman with malignant melanoma in a different region of her body. The size was greater than 6 mm and there was variation in color. This was fully excised to make sure there was no melanoma present. (Courtesy of Richard P. Usatine, MD.)

TYPICAL DISTRIBUTION

- Usually on sun-exposed areas, especially the back (**Figure 165-5**); may be found on sites where nevi are usually absent or rare such as the scalp, breasts, genital skin, buttocks, palm (**Figure 165-6**), and dorsa of feet.

IMAGING

- Although eccentric peripheral hyperpigmented and multifocal hyper- or hypopigmented types are more commonly seen in melanoma, no digital dermatoscopic criteria have been identified that can clearly distinguish DN from in situ melanomas.¹⁰ However, dermoscopy increases diagnostic sensitivity and specificity of cutaneous melanoma from 60% to greater than 90%, especially using pattern recognition.³

BIOPSY

- The importance of histology is to distinguish DN from melanoma. Although not universally accepted, the World Health Organization Melanoma Program proposed a list of characteristics/criteria with individual lesions requiring two major and two minor criteria to be classified as a DN:³
 - Major criteria are basilar proliferation of atypical nevomelanocytes and organization of this proliferation in a lentiginous or epithelioid cell pattern.
 - Minor criteria are: (a) the presence of lamellar fibrosis or concentric eosinophilic fibrosis, (b) neovascularization, (c) inflammatory response, and (d) fusion of rete ridges. These established criteria yielded 92% mean concordance overall by panel members.

DIFFERENTIAL DIAGNOSIS

- Melanocytic nevi—Most common moles are tan to brown, smaller than 6 mm, round in shape, and with sharp borders (see Chapter 162, Nevus).
- Melanoma—Skin cancer is often asymmetric, with irregular border and varied colors. It is usually larger than 6 mm in diameter (see Chapter 172, Melanoma).

MANAGEMENT

NONPHARMACOLOGIC

- Obtain a family history of DN and melanoma for patients presenting with DN.
- Because of the low risk of any one DN developing malignant transformation, the prophylactic removal of all DN is not recommended. **SOR** **C**

MEDICATIONS

- Of the medications tested, including topical 5-fluorouracil, systemic isotretinoin, topical tretinoin with or without hydrocortisone, and topical imiquimod, none completely destroy DN.³

PROCEDURES

- Removal of at least one lesion is reasonable to histologically confirm the diagnosis and rule out melanoma. This should be accomplished

FIGURE 165-5 Dysplastic nevus on the chest of a 30-year-old man. A shave biopsy successfully removed the whole lesion and confirmed that it was not melanoma. Although it was less than 6 mm, it had irregular borders and variation of color. (Courtesy of Richard P. Usatine, MD.)

FIGURE 165-6 Junctional dysplastic nevus on the palm of a 43-year-old Hispanic man. Dermoscopically there was pigment on the top of the skin ridges making this suspicious for melanoma. Fortunately, the punch biopsy showed a dysplastic nevus only. (Courtesy of Richard P. Usatine, MD.)

with excisional biopsy and histologic confirmation of DN versus melanoma. DN is usually removed with conservative surgical margins (about 2 mm) to provide adequate tissue for the pathologist.³ **SOR** **C**

- Scoop saucerizations (deep shave biopsy with a DermaBlade or razor blade) including at least a 2-mm margin of clinically normal skin surrounding the pigmented lesion is a rapid and acceptable method of excision for pathology (**Figure 165-7**).

PREVENTION

- Avoid direct sunlight.

PROGNOSIS

- DNs appear to be dynamic throughout adulthood. In a study of the natural history of DN, investigators found that 51% of all evaluated nevi (297 of 593) showed clinical signs of change during an average follow-up of 89 months.¹¹ New nevi were common in adulthood, continuing to form in more than 20% of patients older than age 50 years, and some nevi disappeared.
- The risk of a melanoma arising within a DN is estimated at 1:3000 per year.¹ However, there is also an increased risk of melanoma arising elsewhere on the skin in patients with DN; the actual incidence rate is uncertain and ranges from 0.5% to 46%.³ There is also a substantially increased risk of melanoma associated with the number of atypical nevi (relative risk [RR] = 6.36; 95% confidence interval [CI]: 3.80, 10.33; for 5 versus 0).¹²
- In one case-control study, the estimated 10-year cumulative risk for developing melanoma in patients with AM syndrome was 10.7% (versus 0.62% in a control population).¹³

FOLLOW-UP

- Patients with DN should have regular skin examinations with biopsy performed of any suspicious lesions (**Figure 165-7**).³
- Consider total-body photographs for monitoring (**Figures 165-8** and **165-9**).³ In a study of 50 patients with 5 or more DN, the use of baseline digital photographs improved the diagnostic accuracy of skin self-examination on the back, chest, and abdomen, and improved detection of changing and new moles.¹⁴ Individual DN can be monitored more precisely with digital dermoscopic photos added to the skin photographs (**Figure 165-9**).
- MelaFind, a lesion imaging device using multispectral imaging analysis, may be helpful in differentiating DN from melanoma.¹⁵ It is a very expensive computerized device that is not affordable in a primary care office.
- Patients with numerous DN and who have a family history of melanoma are at a higher risk of developing melanoma and should be encouraged to have regular follow-up with a provider skilled in detecting melanoma.

FIGURE 165-7 Scoop saucerization of a suspicious pigmented lesion that turned out to be a dysplastic junctional nevus with moderate atypia. The whole lesion was successfully excised with this deep shave. (Courtesy of Richard P. Usatine, MD.)

FIGURE 165-8 Multiple dysplastic nevi on the back of a young physician. Multiple biopsies have all been negative, so patient is being followed by serial digital photography with numbering of the dysplastic nevi. (Courtesy of Richard P. Usatine, MD.)

- Patients with FAMM should also consider a baseline ophthalmologic examination because of a possible association between uveal melanoma and FAMM syndrome.³
- First-degree relatives of patients diagnosed with FAMM syndrome should be encouraged to be examined for DN and melanoma.

PATIENT EDUCATION

- Patients with DN should avoid excessive exposure to natural or artificial UV light and routinely use a broad-spectrum sunscreen with a sun protective factor of 30 or greater and/or sun-protective clothing.
- Patients should be taught self-examination to detect changes in existing moles and to recognize clinical features of melanomas. Patients should be taught to look for and report asymmetry, border irregularity, new symptoms (e.g., pain, pruritus, bleeding, or ulceration), and color and size changes.

SECTION 11 PRE CANCER/EARLY CANCER

166 ACTINIC KERATOSIS
AND BOWEN DISEASE

Richard P. Usatine, MD
Yu Wah, MD

PATIENT STORY

A 57-year-old woman presented with red and scaling skin on both arms (**Figure 166-1**) with a request for a prescription for 5-fluorouracil (5-FU). The patient had blue eyes and white hair and was found to have 2 basal cell carcinomas (BCCs) on her face and shoulder. The patient stated that 5-FU had helped her arms in the past, but that the scaly lesions had returned. She avoids sun exposure now, but acknowledges receiving too much sun exposure while growing up. Another course of 5-FU was prescribed for her arms to prevent new skin cancers from forming.

INTRODUCTION

Actinic keratoses (AKs) are precursors on the continuum of carcinogenesis toward squamous cell carcinomas (SCCs). However, each AK has a low risk of progression to malignancy and a high probability of spontaneous regression.¹ Bowen disease (BD) is SCC in situ confined to the epidermis.

SYNONYMS

AK is also known as solar keratosis. AK on the lips is known as actinic cheilitis (**Figure 166-2**). BD is also known as SCC in situ of the skin. SCC in situ involving the penis is known as erythroplasia of Queyrat (**Figure 166-3**).

EPIDEMIOLOGY

- AKs and BD are seen frequently in light-skinned individuals who have had significant sun exposure.
- The prevalence of AK is estimated at 11% to 25% in adults older than age 40 years in the northern hemisphere, and increases with age.¹ AKs are so common that they account for more than 10% of visits to dermatologists.
- The prevalence of BD is unknown.¹

ETIOLOGY AND PATHOPHYSIOLOGY

AKs and BD are both caused by cumulative UV exposure, most commonly from sunlight.

FIGURE 166-1 Actinic keratoses covering both arms and the dorsum of both hands in a fair-skinned woman who had significant sun exposure. Note that her left arm and hand are worse from driving a car and receiving more sun on the left arm. (Courtesy of Richard P. Usatine, MD.)

FIGURE 166-2 Actinic cheilitis involving lower lips. Note the erythema and scale caused by the sun damage. (Courtesy of Richard P. Usatine, MD.)

UV rays induce mutation of the tumor-suppressor gene P53. Subsequent proliferation of mutated atypical epidermal keratinocytes give rise to the clinical lesion of AK.² Multiple clinical and subclinical lesions may exist in an area of sun-damaged skin, a concept known as “field cancerization.”

AKs have the potential to become SCCs. The rate of malignant transformation has been variably estimated, but is probably no greater than 6% per AK over a 10-year period.³

In a large prospective cohort study, the risk of progression of AK to primary SCC (invasive or in situ) was 0.60% at 1 year and 2.57% at 4 years. Approximately 65% of all primary SCCs and 36% of all primary BCCs diagnosed in the study arose in lesions that previously were diagnosed clinically as AKs. Many AKs did resolve spontaneously, 55% AKs that were followed clinically were not present at 1 year and the 70% were not present at the 5-year follow-up.⁴

On a spectrum of malignant transformation, BD is SCC in situ before the SCC becomes invasive.

RISK FACTORS

- Total lifetime dose of UV radiation (natural sunlight, UV from tanning beds and radiation).¹
- Fair skin.¹
- Site-specific risk factors include tobacco for actinic cheilitis and human papilloma virus for genital and anal lesions.¹
- Exposure to immunosuppressive drugs, especially organ transplant recipients.
- Personal or family history of skin cancers.

DIAGNOSIS

CLINICAL FEATURES

AKs are rough scaly spots seen on sun-exposed areas (**Figure 166-1** to **166-6**). They may be found by touch, as well as close visual inspection of the patient’s skin. BD appears similar to an AK, but tends to be larger in size and thicker with a well-demarcated border (**Figure 166-7** and **166-8**).

TYPICAL DISTRIBUTION

Both lesions are seen in areas with greatest sun exposure such as the face, forearms, dorsum of hands, lower legs of women, and the balding scalp (**Figure 166-5**) and tops of the ears in men.

LABORATORY STUDIES

AKs that appear premalignant may be diagnosed by observation only and treated with destructive methods (e.g., excision, electrosurgery, or cryosurgery) without biopsy. BD requires a biopsy for diagnosis. BD or SCC should be biopsied prior to treatment. A shave biopsy should produce enough tissue for histopathology.

DIFFERENTIAL DIAGNOSIS

- Nummular eczema—a type of eczema in which the scaly patches are coin-shaped. The patches are often seen in patients who have already had some eczema or atopic conditions. The patches usually

FIGURE 166-3 Bowen disease of the penis also known as erythroplasia of Queyrat. Human papillomavirus is a risk factor in this location. (Courtesy of Richard P. Usatine, MD.)

FIGURE 166-4 Large actinic keratoses over the eyebrow of an older adult. A biopsy was performed to make sure this was not already Bowen disease or squamous cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 166-5 Actinic keratoses on the balding head of an older man. Hair loss results in less natural sun protection and is a risk factor for skin cancers on the scalp. The visible and palpable actinic keratoses were treated with cryotherapy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 166-7 Lesions on the arm of an older man with Bowen disease in the central lesion and actinic keratosis on the upper lesion. (Courtesy of Richard P. Usatine, MD.)

FIGURE 166-6 Actinic keratoses on the dorsum of the hand with some lesions suspicious for Bowen disease (squamous cell carcinoma in situ). (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 166-8 Bowen disease on the leg of an older woman. (Courtesy of Richard P. Usatine, MD.)

respond well to topical corticosteroids and are not related to sun damage (see Chapter 145, Atopic Dermatitis).

- Seborrheic keratoses—occur in aging adults but do not have any malignant potential. Typical seborrheic keratoses are brown in color and have a stuck on appearance. Seborrheic keratoses may look greasy or verrucous and have surface cracks. Their borders tend to be more well demarcated than AKs and their color is usually more brown than pink (see Chapter 158, Seborrheic Keratosis).
- Superficial BCCs—can look like an AK or BD. Look for the pearly and thready border that may distinguish a superficial BCC from an AK or BD. Histopathology is the proven method to diagnose (see Chapter 170, Basal Cell Carcinoma).
- When in doubt, perform a shave biopsy to differentiate between an AK, BD, SCC, and superficial BCC.

MANAGEMENT

ACTINIC KERATOSES

- No therapy or the application of an emollient is a reasonable option for mild AKs.⁵ **SOR A**
- Sun screen applied twice daily for 7 months may protect against development of AKs.² **SOR A**
- AKs are most often treated by cryosurgery using liquid nitrogen (**Figure 166-9**). It is simple, rapid, and inexpensive, and may be used as first-line treatment.¹ **SOR C** One metaanalysis showed a 2-month cure rate of 97.0% with 2.1% recurrences in 1 year.⁶
- Treating AKs with liquid nitrogen using a 1-mm halo freeze demonstrated complete response of 39% for freeze times of less than 5 seconds, 69% for freeze times greater than 5 seconds, and 83% for freeze times greater than 20 seconds.⁷ There is considerably more hypopigmentation caused by 20 seconds of freeze time. Determine the length of the freeze time based on the size and thickness of the lesion, using sufficient time for clearance while attempting to avoid hypopigmentation and scarring. **SOR B**
- Treat multiple AKs of the face, scalp, forearms, and hands topically with 5-FU, imiquimod, or diclofenac.^{1,5} **SOR A Table 166-1.**
- Topical 5-FU is an efficient therapeutic method and may be used for treatment of isolated, as well as large, areas of AK. It may be applied by the patient, and is inexpensive compared with other topical modalities.¹ **SOR A**
- 5-FU cream used twice daily for 3 to 6 weeks is effective for up to 12 months in clearance of the majority of AKs (**Figure 166-10**).⁵ **SOR A** Because of side-effects of soreness, less-aggressive regimens are often used, which may be effective, but have not been fully evaluated.⁵

FIGURE 166-9 Cryosurgery of large actinic keratosis. The outside border was marked with a 1- to 2-mm margin. (Courtesy of Richard P. Usatine, MD.)

TABLE 166-1 Comparison of Topical Agents for the Treatment of AK

Topical Agent for AK	Duration of Treatment	Irritation	Cost
5-fluorouracil generic 5%	3 to 6 weeks	High	Less than \$100
Diclofenac 3%	10 to 12 weeks	Moderate	More than \$130
Imiquimod	16 weeks	Moderate	More than \$400

- Diclofenac gel applied twice daily for 10 to 12 weeks has moderate efficacy with low morbidity in mild AKs.² **SOR B** There are few follow-up data to indicate the duration of benefit.² In one study, diclofenac 3% gel was as effective as 5-FU cream for AK of the face and scalp and diclofenac produced fewer signs of inflammation.⁸
- Imiquimod 5% cream has been demonstrated to be effective over a 16-week course of treatment, but studies have only measured 8 weeks of follow up.⁵ **SOR B** By weight, it is 19 times the cost of 5-FU. They have similar side effects.⁵
- One metaanalysis comparing imiquimod to 5-FU showed average complete clearance of AKs for each drug was 5-FU, $52 \pm 18\%$ and imiquimod, $70 \pm 12\%$.⁹
- Imiquimod applied topically for 12 to 16 weeks produced complete clearance of AKs in 50% of patients compared to 5% with vehicle (number needed to treat [NNT] = 2.2). Adverse events included erythema (27%), scabbing or crusting (21%), flaking (9%), and erosions (6%) (number needed to harm [NNH] = 3.2 to 5.9).¹⁰
- Because of its immunostimulatory properties, imiquimod cream must be used with caution in transplant patients on immunosuppression therapy.¹ **SOR C**
- Topical tretinoin has some efficacy on the face, with partial clearance of AKs, but may need to be used for up to a year at a time to optimize benefit.⁵ **SOR B**
- Cryosurgery was effective for up to 75% of lesions in trials comparing it with photodynamic therapy. It may be particularly superior for thicker lesions, but may leave scars.⁵ **SOR A**
- Photodynamic therapy (PDT) was effective in up to 91% of AKs in trials comparing it with cryotherapy, with consistently good cosmetic results. It may be particularly good for superficial and confluent AKs, but is likely to be more expensive than most other therapies. It is of particular value where AKs are numerous or when located at sites of poor healing, such as the lower leg.⁵ **SOR B**
- Other less accessible and expensive methods include lasers, dermabrasion, and chemical peels.
- Investigational treatment—ingenol mebutate. A short 2 to 3 days of treatment with daily topical ingenol mebutate from the sap of *Euphorbia peplus* plant, showed promising efficacy with a favorable safety profile in several randomized controlled trials (RCTs). One multicenter RCT showed 34.1% to 42.2% complete clearance of AKs with ingenol mebutate gel 0.05% for trunk and extremities, and 0.015% for face.¹¹ Another RCT with 0.05% gel showed a complete clearance of 71% of treated lesions.¹² Ingenol mebutate appears to have a dual mechanism of action by rapid lesion necrosis and subsequent immune mediated cellular cytotoxicity, providing efficacy with short treatment period.¹³

BOWEN DISEASE

- **Table 166-2** compares and summarizes the main treatment options.
- The risk of progression to invasive cancer is approximately 3%. This risk is greater in genital BD, and particularly in perianal BD. A high risk of recurrence, including late recurrence, is a particular feature of perianal BD and prolonged follow up is recommended for this variant.¹⁴ **SOR A**
- There is reasonable evidence to support use of 5-FU.¹⁴ **SOR B** It is more practical than surgery for large lesions, especially at potentially

FIGURE 166-10 **A.** Actinic keratoses reddened and crusted by the application of 5-fluorouracil topically twice daily. **B.** Face healed months after the course of 5-fluorouracil was completed. (Courtesy of Richard P. Usatine, MD.)

TABLE 166-2 Summary of the Main Treatment Options for Bowen Disease

Lesion Characteristics	Topical 5-FU	Topical Imiquimod*	Cryotherapy	Curettage	Excision	PDT	Radiotherapy	Laser†
Small, single/few, good healing site‡	4	3	2	1	3	3	5	4
Large, single, good healing site‡	3	3	3	5	5	2	4	7
Multiple, good healing site‡	3	4	2	3	5	3	4	4
Small, single/few, poor healing site‡	2	3	3	2	2	1–2	5	7
Large, single, poor healing site‡	3	2–3	5	4	5	1	6	7
Facial	4	7	2	2	4 [§]	3	4	7
Digital	3	7	3	5	2 [§]	3	3	3
Perianal	6	6	6	6	1 [¶]	7	2 to 3	6
Penile	3	3	3	5	4 [§]	3	2 to 3	3

5-FU, 5-fluorouracil; PDT, photodynamic therapy; 1, probably treatment of choice; 2, generally good choice; 3, generally fair choice; 4, reasonable but not usually required; 5, generally poor choice; 6, probably should not be used; 7, insufficient evidence available.

The suggested scoring of the treatments listed takes into account the evidence for benefit, ease of application or time required for the procedure, wound healing, cosmetic result, and current availability/costs of the method or facilities required. Evidence for interventions based on single studies or purely anecdotal cases is not included.

*Does not have a product license for Bowen disease.

†Depends on site.

‡Refers to the clinician's perceived potential for good or poor healing at the affected site.

§Consider micrographic surgery for tissue sparing or if poorly defined/recurrent.

¶Wide excision recommended.

poor healing sites, and has been used for “control” rather than cure in some patients with multiple lesions.⁸

- Topical imiquimod may be used off-label for BD for larger lesions or difficult/poor healing sites.¹⁴ **SOR B** However, it is costly and the optimum regimen has yet to be determined.¹⁴
- One prospective study suggests a superiority of curettage and electrodesiccation over cryotherapy in treating BD, especially for lesions on the lower leg (**Figure 166-11**).¹⁰ Curettage was associated with a significantly shorter healing time, less pain, fewer complications, and a lower recurrence rate when compared with cryotherapy.¹⁵

PREVENTION

- Protection from UV exposure by limiting outdoor activities, and using sunscreens and protective gears (hat, umbrella, long sleeve garments, etc).
- Avoid artificial tanning beds and tobacco.

PROGNOSIS

Prognosis of treated AK and BD is excellent.

FOLLOW-UP

Patients need skin examinations every 6 to 12 months to identify new precancers and cancers. **SOR** **C** More frequent examinations may be needed for those who have continued exposure to offending agents (eg. organ transplant recipients on immunosuppressant therapy), and those with history of recurrent skin malignancies.

PATIENT EDUCATION

Patients must understand that they acquired these conditions through cumulative sun damage, and they need to avoid further sun damage to minimize the likelihood of additional precancers and cancers. The sun damage is often from childhood and early adulthood, so the lesions are likely to form even with future sun protection. Self skin examination is recommended.

All topical treatments for AKs and BD will make the lesions look worse before they get better (**Figure 166-10**). The 5-FU treatments are often given with topical corticosteroid preparations to use after the treatment is over so as to minimize the symptoms of the inflammation.

PATIENT RESOURCE

- Skin Cancer Foundation has an excellent website with photos and patient information—<http://www.skincancer.org/ak/index.php>.

167 KERATOACANTHOMA

Alfonso Guzman, Jr. BSN, MD
Richard P. Usatine, MD

PATIENT STORY

A 71-year-old woman presented with a rapidly growing lesion on her face over the past 4 months (**Figure 167-1**). The lesion had features of a basal cell carcinoma with a pearly border and telangiectasias (**Figure 167-2**). Also the central crater with keratin gave it the appearance of a keratoacanthoma (KA). A shave biopsy was performed and the pathology showed squamous cell carcinoma (SCC)–KA type. A full elliptical excision with 4-mm margins was then performed.

INTRODUCTION

The KA is a unique epidermal tumor characterized by rapid, abundant growth and a spontaneous resolution, with the classic presentation in middle-aged, light-skinned individuals in hair-bearing, sun-exposed areas. In the late 1940s, Freudenthal of Wroclaw coined the term *keratoacanthoma*, owing to the considerable acanthosis observed in the tumor. Controversies have arisen since the 1950s about the real nature of the tumor; some KAs may metastasize, and there is debate over the relationship to SCC.^{1,2} Many dermatopathologists now classify this tumor as a subtype of SCC.

SYNONYMS¹

- Keratocarcinoma.
- Molluscum sebaceum.
- Molluscum pseudocarcinomatousum.
- Cutaneous sebaceous neoplasm.
- Self-healing squamous epithelioma.
- Intracutaneous cornifying epithelioma.
- Idiopathic cutaneous pseudoepitheliomatous hyperplasia.
- Verrugoma.

EPIDEMIOLOGY

- KA develops as a solitary nodule in sun-exposed areas.
- Seen more commonly later in life with a predilection for males.¹
- Develops rapidly within 6 to 8 weeks.
- May spontaneously regress after 3 to 6 months or may continue to grow and rarely metastasize.³

ETIOLOGY AND PATHOPHYSIOLOGY

- KAs share features such as infiltration and cytologic atypia with SCCs.

FIGURE 167-1 Pearly keratoacanthoma with telangiectasias and a central keratin core on the face of a 71-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 167-2 Close-up of the keratoacanthoma with telangiectasias and a central keratin core on the face of the woman in **Figure 167-1**. (Courtesy of Richard P. Usatine, MD.)

- KAs have been reported to metastasize.
- KA is considered to be a variant of SCC, called SCC-KA type.
- Histologic criteria are not sensitive enough to discriminate reliably between KA and SCC.⁴

RISK FACTORS

- Ages 40s to 60s.
- Occurs on sun-exposed areas of skin.
- Light complexion.
- Male gender.

DIAGNOSIS

CLINICAL FEATURES

Solitary nodule in sun exposed areas. Often have a central keratin plug that resembles a volcano (**Figures 167-1 to 167-5**). KAs may grow rapidly (**Figure 167-6**). Rare cases of multiple eruptive KAs have been reported.¹

TYPICAL DISTRIBUTION

Face, arms, hands, and trunk (**Figures 167-3 and 167-5**). KAs can be found anywhere on the head and neck, including the ears (**Figures 167-6 and 167-7**).

LABORATORY STUDIES

Biopsy is the only reliable method to make the diagnosis. KAs are well-differentiated squamoproliferative skin lesions.

DIFFERENTIAL DIAGNOSIS

- Actinic keratoses are precancerous lesions found on sun-exposed areas that may progress to SCC. Because these lesions are generally flat they are rarely confused with KAs (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Cutaneous horn is a raised, keratinaceous lesion that can arise in actinic keratoses and in all types of nonmelanoma skin cancers. It generally does not have pearly raised skin around the keratin horn and therefore does not have the crater appearance of a KA (see Chapter 169, Cutaneous Horn).
- SCCs of the skin have many forms and KA is considered to be one type of SCC (see Chapter 171, Squamous Cell Carcinoma).

MANAGEMENT

- A shave biopsy may be used for diagnosis but is not an adequate final treatment. Options for definitive treatment should be discussed with patient.
- Although some KAs may regress spontaneously, there is no way to distinguish between these and the ones that are variants of SCC, which may go on to metastasize. Therefore, the standard of care is to remove or destroy the remaining tumor. **SOR C**

FIGURE 167-7 Keratoacanthoma on the ear. (Courtesy of Richard P. Usatine, MD.)

A

B

FIGURE 167-6 Two SCCs in a 65-year-old man. **A.** The SCC over the temple was a keratoacanthoma type, whereas the SCC on the neck was a well-differentiated SCC. **B.** Rapid growth occurred in both tumors over the 6-week period that the patient waited to have head and neck surgery. (Courtesy of Richard P. Usatine, MD.)

- Elliptically excise a KA with margins of 3 to 5 mm as you would a SCC.⁴ SOR C
- Smaller, less-aggressive KAs diagnosed with shave biopsy may be destroyed with curettage and desiccation or cryotherapy with 3- to 5-mm margins. SOR C
- Mohs surgery may be indicated for large or recurrent KAs or KAs located in anatomic areas with cosmetic or functional considerations.⁴ SOR C
- Multiple eruptive KAs have been treated with oral retinoids, methotrexate, and cyclophosphamide.¹ SOR C

PROGNOSIS

When compared to other skin cancers, prognosis is good. Excision is typically curative.⁵

FOLLOW-UP

Patients should perform their own skin exams and have yearly clinical skin examinations to examine for recurrence and the development of new skin cancers.

PATIENT EDUCATION

KA is similar to other nonmelanoma skin cancers in that it occurs on sun-exposed areas and patients that have one are at increased risk of developing new skin cancers. Therefore, sun avoidance and sun protection should be emphasized.

168 LENTIGO MALIGNA

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 65-year-old woman noted that a brown spot on her face was growing larger and darker (**Figure 168-1**). A broad shave biopsy showed lentigo maligna (LM) (melanoma in situ). The patient was referred for Mohs surgery for definitive treatment.

INTRODUCTION

LM begins as a tan-brown macule melanoma usually in sun-damaged areas of the skin in older individuals. It is a subtype of melanoma in situ.

SYNONYMS

Hutchinson melanotic freckle.

EPIDEMIOLOGY

- The incidence of LM is directly related to sun exposure. In the United States, the incidence is greatest in Hawaii, intermediate in the central and southern states, and lowest in the northern states.¹
- Generally, patients with LM are older than age 40 years, with a peak incidence between the ages of 65 and 80 years.²
- Persons with LM melanoma (LMM) tend to be older, fair-skinned persons with markers of actinic skin damage and prior skin cancers, and the incidence is increasing.³
- The lesions occur more commonly on the driver's side of the head and neck in men in Australia.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- LM is a subtype of melanoma in situ, a preinvasive lesion confined to the epidermis (**Figures 168-1 to 168-3**).
- It is caused by cumulative sun exposure and, therefore, seen later in life.
- LMM occurs when the lesion extends into the dermis (**Figure 168-4**).
- LM can be present for long periods (5 to 15 years) before invasion occurs, although rapid progression within months has been described.⁵
- The risk for progression to LMM appears to be proportional to the size of the lesion of LM.⁵

FIGURE 168-1 Lentigo maligna (melanoma in situ) on the face. (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 168-2 LM on the face, presenting as a single large evolving pigmented lesion with changing color. (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. 1998, St. Louis: Mosby.)

RISK FACTORS

- UV radiation exposure: risk increases with increased hours of exposure to sunlight, with the amount of actinic damage, and with a history of nonmelanoma skin cancer.
- Increased number of melanocytic nevi, including large or giant congenital nevi.
- Fair skin.
- History of severe sunburns.
- Porphyria cutanea tarda.
- Tyrosine-positive oculocutaneous albinism.
- Xeroderma pigmentosum.
- Occupational risk with sun exposure.

DIAGNOSIS

CLINICAL FEATURES

- Large pigmented patch with multiple colors, including brown, black, pink, and white (signifying regression) (**Figures 168-1 to 168-3**).
- May have ill-defined borders and microscopic extension that can determine the clinical borders and complete removal of the lesion difficult.
- One retrospective study revealed the four most important features of LM: asymmetric pigmented follicular openings, dark rhomboidal structures, slate-gray globules, and slate-gray dots with a sensitivity of 89% and a specificity of 96% (see Appendix 3, Dermoscopy).⁶

TYPICAL DISTRIBUTION

- Face, head, and neck. There is a predilection for the nose and cheek (**Figures 168-1 and 168-2**).

BIOPSY

- Complete excisional biopsy is rarely practical because these lesions are frequently large and are on the face (**Figure 168-1**). There is debate in the literature between doing broad shave biopsy, multiple punch biopsy, and incisional biopsy.⁷ The goal is to avoid sampling error and misdiagnosing a LM or LMM as a benign lesion.
- A lesion suspicious for LM or LMM can be biopsied using a broad scoop shave biopsy approach with a Derma blade or sharp razor blade (**Figure 168-4**).⁷ The goal is to sample the dermal–epidermal junction and still produce a good cosmetic result (especially if the lesion turns out to be benign).
- One option is multiple smaller biopsy samples of each morphologically distinct region of the lesion.⁷
- If an area suspicious for invasion is noted, or if there is an area of induration suspicious for associated desmoplastic melanoma, a deeper incisional biopsy of this area should be performed.⁷
- If sampling is incomplete, the presence of a solar lentigo, pigmented actinic keratosis, or reticulated seborrheic keratosis (SK) could mislead the pathologist and clinician to the wrong conclusion

FIGURE 168-3 LM on the ear (melanoma in situ). (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 168-4 LMM on the cheek. This lesion is invasive and no longer melanoma in situ. A partial broad scoop shave biopsy is a good way to make this diagnosis, as a full depth complete excisional biopsy would be prohibitively large and a punch biopsy might miss the diagnosis. (Courtesy of the Skin Cancer Foundation. For more information www.skincancer.org.)

that the incisional specimen is representative of the whole, and that no LM is present.⁷

- In a study of LM, contiguous pigmented lesions were present in 48% of the specimens obtained by broad shave biopsy or Mohs surgery. The most common lesion was a benign solar lentigo (30%), followed by pigmented actinic keratosis (24%).⁷ This should be kept in mind when interpreting biopsy results to avoid false negatives.

DIFFERENTIAL DIAGNOSIS

- Solar lentigo—These hyperpigmented patches are very common on the faces and the dorsum of the hands of persons with significant sun exposure and the incidence increases with age. A possible solar lentigo is more suspicious for LM or LMM when it is larger, more asymmetric, has irregular borders and has more variation in colors. Pigmented lesions with these characteristics should be biopsied to determine the correct diagnosis. Many fair-skinned individuals have a number of solar lentiginos making this a challenge. The use of dermoscopy and judicious biopsies is necessary to avoid missing LM and LMM (**Figures 168-5** and **168-6**).
- SKs are ubiquitous benign growths that occur more frequently with age. An early SK can be flat and easily resemble a solar lentigo or LM. The SKs on the back are less likely to be confused for LM, but a large flat SK on the face can easily be mistaken for a LM. More importantly, avoid missing a LM because it is assumed to be a flat early SK. When in doubt, biopsy the lesion with a quick and easy shave biopsy. Do not freeze a possible SK unless you are sure that it is truly benign (see Chapter 158, Seborrheic Keratosis).
- LMM is the feared outcome of missing an LM and not treating it properly. Any suspicious lesion requires biopsy. Don't be afraid to do a quick and easy shave biopsy rather than a full-thickness excision. If it turns out to be a LM or LMM, you can refer for definitive treatment and your biopsy technique does not change the prognosis. Early diagnosis does. LMM accounts for 4% to 15% of cutaneous melanoma (**Figure 168-4**) (see Chapter 172, Melanoma).

MANAGEMENT

- Therapy is directed toward preventing progression to invasive LMM.

NONSURGICAL

- Nonsurgical therapy for primary cutaneous melanomas should only be considered when surgical excision is not possible.
- Alternatives to surgery include topical imiquimod, cryosurgery, and observation. Efficacy of nonsurgical therapies for LM has not been fully established.⁸ **SOR** 

MEDICATIONS

- Topical imiquimod 5% cream has been described in multiple studies to be effective in treating LM, especially in patients who are not surgical candidates. It is an immune response modifier that is indicated for the treatment of actinic keratosis and superficial basal cell

FIGURE 168-5 Solar lentigo on the face of a middle-aged Hispanic woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 168-6 Dermoscopy of the solar lentigo in the previous figure. The moth-eaten appearing edges are typical of a solar lentigo. There are no suspicious patterns and a shave biopsy confirmed that it was benign. (Courtesy of Richard P. Usatine, MD.)

carcinomas. Studies are limited by highly variable treatment regimens and lack of long-term follow-up.⁸⁻¹⁰ **SOR B**

SURGICAL

- For melanoma in situ, wide excision with 0.5- to 1.0-cm margins is recommended. For LM histologic subtype may require larger than 0.5-cm margins to achieve histologically negative margins, because of characteristically broad subclinical extension.^{8,10} **SOR A**
- Standard therapy is margin controlled surgical excision with Mohs surgery or rush permanent sections.^{10,11} **SOR B**
- The perimeter technique is a method of margin-controlled excision of LM with rush permanent sections. The main advantage is that all margins are examined with permanent sections. The main drawback is that multiple operative sessions are required to complete the procedure.¹²
- Recommended margins for standard excision of melanoma in situ are 0.5 cm. This margin is often inadequate for LM because of the subclinical extension that can occur.¹⁰ The average margin required to clear LM in 90% to 95% of cases in one study was greater than 0.5 cm.¹¹ Consequently, margin-controlled excision of LM is recommended.¹¹ **SOR B**
- Cryosurgery may be used in patients who are not good surgical candidates. In a study of 18 such patients with LM, the lesions resolved clinically in all cases, with no recurrence or metastasis detected during a mean follow-up of 75.5 months.¹³ **SOR C** These patients were treated with two freeze-thaw cycles of liquid nitrogen under local anesthesia in a single sitting.

PREVENTION

- Because LMM is related to a lifetime of exposure to UV radiation, patients should limit sun exposure, especially between 10 AM and 4 PM. When in the sun, make sure to wear sunscreen with a high sun-protection factor (SPF) that blocks both UVA and UVB. It's also a good idea to protect skin by wearing a broad-brim hat and clothing that covers your arms and legs.

PROGNOSIS

- There is a 5% estimated lifetime risk of developing LMM in patients diagnosed with LM at age 45 years.⁵

FOLLOW-UP

- The National Comprehensive Cancer Network recommends that patients have regular clinical skin examinations at least yearly by their family physician or a dermatologist.¹⁴
- Regional lymph nodes should also be examined.

PATIENT EDUCATION

- Patients diagnosed with LM need to minimize sun exposure and do regular self-skin examinations.

169 CUTANEOUS HORN

Mindy A. Smith, MD, MS

PATIENT STORY

A 74-year-old man asks about a lesion on the back of his right ear (**Figure 169-1**). It has been present for approximately 5 years. Although the lesion does not bother him, his wife is concerned because it has been slowly growing. Shave biopsy revealed that the horn was from a basal cell carcinoma. The patient was referred for Mohs surgery to excise the remainder of the cancer.

INTRODUCTION

Cutaneous horn (cornu cutaneum) is a morphologic (not pathologic) designation for a hyperkeratotic protuberant mass rising above the skin, resembling the horn of an animal.

EPIDEMIOLOGY

- Relatively rare lesion, most often occurring on sun-exposed areas of the skin in elderly men; a recent Brazilian case series, however, found a higher prevalence in women.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Results from unusual cohesiveness of keratinized material from the superficial layers of the skin or deeply embedded in the cutis. Etiology is unknown but may be related to skin damage from sun exposure or trauma; infectious causes have also been reported including molluscum contagiosum and leishmaniasis.²
- Consists of marked retention of stratum corneum.
- May be benign, premalignant, or malignant (**Figures 169-1 to 169-3**) at the base; in 2 large series, 58.6% and 38.9% had malignant or premalignant base pathology.^{1,3}
- A history of other malignant or premalignant lesions, tenderness at the base, large size, older age, and location on the penis increase the risk of underlying malignancy.²⁻⁴
- Associated with many types of skin lesions (at the base) that can retain keratin and produce horns including actinic keratosis, warts (**Figures 169-4 and 169-5**), seborrheic keratosis (**Figures 169-6 and 169-7**), keratoacanthoma (**Figure 169-3**), sebaceous gland, and basal or squamous cell carcinoma (**Figures 169-1 to 169-3**). In the more recent case series, actinic keratosis was found in 83.8% of the premalignant cases and squamous cell carcinoma was found in 93.75% of the malignant cases.¹
- Rare cases have been described in association with metastatic renal cell carcinoma, lymphoma, dermatofibroma, pyogenic granuloma (**Figure 169-8**), and, recently, Kaposi sarcoma.⁵

FIGURE 169-1 Cutaneous horn on posterior right pinna arising in a basal cell carcinoma. (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 169-2 Cutaneous horn in a squamous cell carcinoma in situ just lateral to the eye. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Advanced age (>70 years).
- Sun/radiation exposure.

DIAGNOSIS

CLINICAL FEATURES

- Horn-like protuberance.
- Lesions are usually firm; have been described as flat, keratotic, nodular, pedunculated, and ulcerated.³
- Size may vary from a few millimeters to several centimeters; gigantic cutaneous horns (17 to 25 cm length and up to 2.5 cm width) have been reported, and in one series of 4 cases, all were benign.⁶
- Because of their height, cutaneous horns may be traumatized causing bleeding or pain.

TYPICAL DISTRIBUTION

- May occur on any area of the body; approximately 30% are found on the face (Figures 169-2, 169-6, and 169-7) and scalp and another 30% on the upper limbs.¹

BIOPSY

- The horn itself consists of concentric layers of cornified epithelial cells (hyperkeratosis). The base may display features of the associated pathologic etiology.

DIFFERENTIAL DIAGNOSIS

- Common warts are well-demarcated, rough, hard papules with an irregular papillary surface. Although they may form cylindrical projections, these often fuse to form a surface mosaic pattern; paring the surface exposes punctate hemorrhagic capillaries (see Chapter 131, Common Warts).

MANAGEMENT

- Shave excision, ensuring that the base of the epithelium is obtained for histologic examination, and send to pathology; if benign, may freeze remainder of the lesion.
- Excisional biopsy may also be performed, with wider margins (tumor-free margin of at least 3 mm) if suspected malignancy.

FOLLOW-UP

- Routine follow-up is not needed provided complete removal is accomplished for malignant and premalignant lesions; in one case series of 48 eyelid cutaneous horns, there was no recurrence over a mean of 21 months.⁷
- Patients with any skin cancer should be seen yearly for skin exams because one cancer puts them at higher risk for all skin cancers. **SOR C**

FIGURE 169-3 Cutaneous horn on the arm of a 65-year-old woman, which grew rapidly over 6 months. Biopsy revealed a squamous cell carcinoma of the keratoacanthoma type. (Courtesy of Richard P. Usatine, MD.)

FIGURE 169-4 A. Cutaneous horn on the hand of a 33-year-old man for 8 years. He clipped it with nail clippers many times but it always grew back. A shave excision successfully removed it and the pathology showed a viral wart at the base. B. Close-up of the cutaneous horn. (Courtesy of Richard P. Usatine, MD.)

SECTION 12 SKIN CANCER

170 BASAL CELL
CARCINOMA

Jonathan B. Karnes, MD
Richard P. Usatine, MD

PATIENT STORY

A 52-year-old woman presented to the office with a “mole” that had been increasing in size over the last year (**Figure 170-1**). This “mole” had been on her face for at least 5 years. The differential diagnosis of this lesion was a nodular basal cell carcinoma (BCC) versus an intra-dermal nevus. A shave biopsy confirmed it was a nodular BCC and the lesion was excised with an elliptical excision.

INTRODUCTION

Basal cell carcinoma is the most common cancer in humans. Usually found on the head and neck, it is generally slow growing and almost never kills or metastasizes when treated in a timely fashion. However, the treatment necessary to eliminate it is often surgical and may cause scarring and changes in appearance and/or function.

EPIDEMIOLOGY

- BCC is the most common skin cancer but the exact incidence is not known.¹
- Incidence of these cancers increases with age, related to cumulative sun exposure.
- Nodular BCCs—Most common type (70%) (**Figures 170-1 to 170-4**).
- Superficial BCCs—Next most common type (**Figures 170-5 and 170-6**).
- Sclerosing (or morpheaform) BCCs—The least common type (**Figures 170-7 and 170-8**).

Other clinical variants including pigmented, polypoid, giant, keloidal, linear, and fibroepithelioma of Pinkus have been recognized, but are less common to very rare.²

ETIOLOGY AND PATHOPHYSIOLOGY

- BCCs spread locally and very rarely metastasize.
- Basal cell nevus syndrome, also known as Gorlin syndrome, is a rare autosomal dominant condition in which affected individuals have multiple BCCs that may clinically mimic nevi (**Figure 170-9**).

FIGURE 170-1 Pearly nodular basal cell carcinoma on the face of a 52-year-old woman present for 5 years. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-2 Nodular BCC on the nasal ala of an 82-year-old woman. The nose is a very common location for a basal cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-3 Nodular BCC on the lower eyelid. Patient referred for Mohs surgery. The differential diagnosis is a hidrocystoma. This basal cell carcinoma is a firm nodule and a hidrocystoma is fluid-filled and softer. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-5 Superficial basal cell carcinoma on the back of a 45-year-old man who enjoys running in the California sun without his shirt. Note the diffuse scaling, thready border (slightly raised and pearly), and spotty hyperpigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-4 Large nodular basal cell carcinoma with an annular appearance on the face of a homeless woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-6 Superficial basal cell carcinoma on the arm of a fair-skinned welder mimicking nummular eczema. (Courtesy Jonathan B. Karnes, MD.)

RISK FACTORS

- Advanced age.
- Cumulative sun exposure.
- Radiation exposure.
- Latitude.
- Immunosuppression.
- Genetic predisposition.
- Family history.
- Skin type.³

DIAGNOSIS

CLINICAL FEATURES

Common clinical features of the three most common morphologic types are listed below.

Nodular BCC

- Raised pearly white, smooth translucent surface with telangiectasias.
- Smooth surface with loss of the normal pore pattern (**Figures 170-1 to 170-4**).
- May be moderately to deeply pigmented (**Figures 170-10 to 170-12**).
- May ulcerate (**Figures 170-13 to 170-16**) and can leave a bloody crust.

Superficial BCC

- Red or pink patches to plaques often with mild scale and a thready border (slightly raised and pearly) (**Figure 170-5**).
- Found more commonly on the trunk and upper extremities than the face.

Sclerosing (morpheaform)

- Ivory or colorless, flat or atrophic, indurated, may resemble scars, are easily overlooked (**Figures 170-7 and 170-8**).
- Called morpheaform because of their resemblance to localized scleroderma (morphea).
- The border is not well demarcated and the tumor can spread far beyond what is clinically visible (**Figure 170-17**).
- These BCCs are the most dangerous and have the worst prognosis.

TYPICAL DISTRIBUTION

Ninety percent appear on face, ears, and head, with some found on the trunk and upper extremities (especially the superficial type).¹

Recently lesions on the ears have been associated with a more aggressive behavior (**Figure 170-18**).⁴

DERMOSCOPY

Dermoscopic characteristics of BCCs (**Figures 170-19 and 170-20**) include:

- Large blue-gray ovoid nests.

FIGURE 170-7 Sclerosing basal cell carcinoma on the forehead of a man resembling a scar. Note the white color with shiny atrophic skin. (Courtesy of the Skin Cancer Foundation. For more information www.skincancer.org.)

FIGURE 170-8 Advanced sclerosing basal cell carcinoma on the cheek of a man, causing ectropion (the eyelid is being pulled down by the sclerotic skin changes). (With permission from Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 170-11 Darkly pigmented large basal cell carcinoma with raised borders and some ulceration in a 53-year-old Hispanic man. A biopsy was performed to rule out melanoma before this was excised. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-10 Large pigmented nodular basal cell carcinoma on the face with ulceration mimicking melanoma. (Courtesy Jonathan B. Karnes, MD.)

FIGURE 170-12 Darkly pigmented basal cell carcinoma with pearly borders and some ulceration in a 73-year-old Hispanic woman. A biopsy was performed to rule out melanoma before this was excised. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-13 Ulcerated basal cell carcinoma on the scalp of a 35-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-16 A. Very large ulcerating basal cell carcinoma on the neck of a 65-year-old white man, which has been growing there for 6 years. It was excised in the operating room with a large flap from his chest used to close the big defect. B. The same man showing recurrence within the scar a few years later. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-14 Basal cell carcinoma in the nasal alar groove. There is a high risk of recurrence at this site so Mohs surgery is indicated for removal. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-15 Large advanced basal cell carcinoma with ulcerations and bloody crusting infiltrating the upper lip. The patient was referred for Mohs surgery. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-17 A. Sclerosing basal cell carcinoma in an elderly man. The size of the basal cell carcinoma did not appear large by clinical examination. B. Mohs surgery of the same sclerosing basal cell carcinoma. This took four excisions to get clean margins. Usual 4- to 5-mm margins with an elliptical excision would not have removed the full tumor. C. Repair by Mohs surgery to close the large defect. The cure rate should be close to 99%. (Courtesy of Ryan O'Quinn, MD.)

FIGURE 170-18 Ulcerated nodular basal cell carcinoma of the ear in a 67-year-old man. These may have more aggressive behavior. (Courtesy of Richard P. Usatine, MD.)

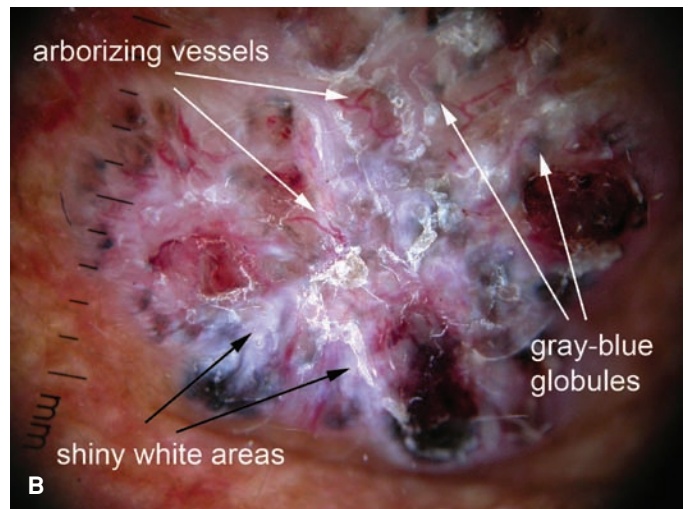

FIGURE 170-19 A. Large nodular basal cell carcinoma on the cheek of a 52-year-old man. There is a loss of normal pore pattern, pearly appearance, telangiectasias, and some areas of dark pigmentation. B. Dermoscopy of the nodular basal cell carcinoma. There are visible arborizing "tree-like" telangiectasias, ulcerations, shiny white areas, and gray-blue globules all consistent with a basal cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

- Multiple blue-gray globules.
- Leaf-like areas, also called clods, that look like maple leaves.
- Spoke-wheel areas.
- Arborizing “tree-like” telangiectasia.
- Ulceration.
- Shiny white areas/stellate streaks (see Appendix C: Dermoscopy for further information).

BIOPSY

- A shave biopsy is adequate to diagnose a nodular BCC or a thick superficial BCC.
- A scoop shave or punch biopsy is preferred for a sclerosing BCC or a very flat superficial BCC.
- In many instances, excision at the time of definitive treatment reveals a different morphologic type in deeper tissue.⁵

DIFFERENTIAL DIAGNOSIS

Nodular BCC

- Intradermal (dermal) nevi may look very similar to nodular BCCs with telangiectasias and smooth pearly borders (**Figure 170-21**). A history of stable size and lack of ulceration may be helpful in distinguishing them from a nodular BCC. A simple shave biopsy is diagnostic and produces a good cosmetic result. Excisional biopsy is usually unnecessary and can be deforming. It is remarkable how similar **Figure 170-21** appears to **Figure 170-1** (both biopsies proven to be as labeled) (see Chapter 162, Benign Nevi).
- Sebaceous hyperplasia is a benign adnexal tumor common on the face in older adults and usually occurs with more than one lesion present (**Figure 170-22**). This benign overgrowth of the sebaceous glands produces small waxy yellow to pink papules with telangiectasias. Dermoscopy may show vessels that radiate out from the center like spokes on a wheel (see Chapter 159, Sebaceous Hyperplasia).
- Fibrous papule of the face is a benign condition with small papules that can be firm and pearly.
- Trichoepithelioma/trichoblastoma/trichilemmoma are benign tumors on the face that can appear around the nose. They may be pearly but usually do not have telangiectasias. These are best diagnosed with a shave biopsy, but trichoepitheliomas can even mimic a BCC on histology.
- Keratoacanthoma is a type of squamous cell carcinoma that is raised, nodular, and may be pearly with telangiectasias. A central keratin-filled crater may help to distinguish this from a BCC (see Chapter 167, Keratoacanthoma).

Superficial BCC

- Actinic keratoses are precancers that are flat, pink, and scaly. They lack the pearly and thready border of the superficial BCC (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Bowen disease is a squamous cell carcinoma in situ that appears like a larger thicker actinic keratosis with more distinct well-demarcated borders. It also lacks the pearly and thready border of the superficial BCC (see Chapter 166, Actinic Keratosis and Bowen Disease).

FIGURE 170-20 Dermoscopy of two different basal cell carcinomas. Characteristic findings of basal cell carcinomas include arborized vessels, blue-gray ovoid nests, spoke wheel structures, and leaf-like structures. **A.** (Courtesy of Ashfaq Marghoob, MD.) **B.** Note the leaf-like structures on the periphery of this BCC. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-21 Pearly dome-shaped intradermal nevus near the nose with telangiectasias closely resembling a basal cell carcinoma. A shave biopsy proved that this was an intradermal nevus. (Courtesy of Richard P. Usatine, MD.)

- Nummular eczema can usually be distinguished by its multiple coin-like shapes, transient nature, and rapid response to topical steroids. These lesions are extremely pruritic and most patients will have other signs and symptoms of atopic disease (see Chapter 145, Atopic Dermatitis).
- Discoid lupus erythematosus is a cutaneous manifestation of autoimmune disease and often presents with skin color change, scaling, and hair follicle destruction. These have characteristic predilection for the ears, scalp, and face, but may be found on the trunk and extremities.
- Benign lichenoid keratosis is a variably scaly flat or slightly raised benign reactive neoplasm on sun-damaged skin. It is often on the trunk or extremities and can have blue-gray globules on dermoscopy and some pearly color.

Sclerosing (morpheaform) BCC

- Scars may look like a sclerosing BCC. Ask about previous surgeries or trauma to the area. If the so-called scar is flat, shiny, and enlarging, a biopsy still may be needed to rule out a sclerosing BCC.

MANAGEMENT

- Mohs micrographic surgery (3 studies, $n = 2660$) is the gold standard but is not needed for all BCCs. Recurrence rate is 0.8% to 1.1% (**Figure 170-17B**). Mohs micrographic surgery (pioneered by Dr. Frederick Mohs) entails surgical removal of tumors with immediate histologic processing in sequential horizontal layers preserving a continuous peripheral margin that is mapped to the clinical lesion. Concentric surgical margins are taken until all margins are clear (**Figure 170-17**). This is the treatment of choice for BCCs with poorly defined clinical margins or in areas of significant cosmetic or functional importance such as the face.⁶ **SOR A**
- Surgical excision (3 studies, $n = 1303$): Recurrence rate was 2% to 8%. Mean cumulative 5-year rate¹ (all 3 studies) was 5.3%. Recommended margins are 4 to 5 mm. **SOR A**
- Cryosurgery (4 studies, $n = 796$): Recurrence rate was 3.0% to 4.3%. Cumulative 5-year rate (3 studies) ranged from 0% to 16.5%.⁶ **SOR A** Recommended freeze times are 30 to 60 seconds with a 5-mm halo. This can be divided up into two 30-second freezes with a thaw in between. For such long freeze times, most patients will prefer a local anesthetic (**Figure 170-23**). **SOR C**
- Curettage and desiccation (6 studies, $n = 4212$): Recurrence rate ranged from 4.3% to 18.1%; cumulative 5-year rate ranged from 5.7% to 18.8%. Three cycles of curettage and desiccation can produce higher cure rates than one cycle (**Figure 170-24**).⁶ **SOR A**
- Imiquimod is FDA approved for the treatment of superficial BCCs less than 2 cm in diameter.⁷ **SOR B** Confirm diagnosis with biopsy and use when surgical methods are contraindicated. A recent study combining cryotherapy with imiquimod improved decreased the recurrence rate.⁸
- Vismodegib is an FDA-approved targeted chemotherapy for the treatment of metastatic or nonresectable BCCs that cannot be treated with radiation. It targets the smoothed pathway, which is damaged in basal cell nevus syndrome and altered in most BCCs.⁹ **SOR B**

FIGURE 170-22 Extensive sebaceous hyperplasia on the cheek of a 52-year-old woman. The largest one has visible telangiectasias and could be mistaken for a basal cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 170-23 Cryosurgery was a favored treatment modality in a 94-year-old female patient with Alzheimer's dementia with a basal cell carcinoma on the cheek. The family appreciated how easy this was to complete and how well it healed. (Courtesy of Richard P. Usatine, MD.)

PREVENTION AND SCREENING

- All skin cancer prevention starts with sun protection.
- Unfortunately there is no proof that sunscreen use prevents BCC.¹⁰
- Sun protection should include sun avoidance, especially during peak hours of UV transmission, and protective clothing.
- United States Preventive Services Task Force has not found sufficient evidence to recommend regular screening for any skin cancer in the general population.¹¹
- Most experts believe that persons at high risk for BCC (including previous personal history of BCC, high risk family history, and high risk skin types with significant sun exposure) should be screened regularly for skin cancer by a physician trained in such screening.
- Evidence for the value of self-screening is lacking but persons at high risk for skin cancer should also be encouraged to observe their own skin and to come in for evaluation if they see any suspicious changes or growths.

PROGNOSIS

The prognosis for basal cell carcinoma is generally excellent with high cure rates with surgery and destructive modalities. Large lesions on the face or lesions that have spread to sites deep to the skin have a poorer prognosis.

FOLLOW-UP

Patients should be seen at least yearly after the diagnosis and treatment of a BCC. The 3-year risk of BCC recurrence after having a single BCC is 44%.¹²

PATIENT EDUCATION

Patients should practice skin cancer prevention by sun-protective behaviors such as avoiding peak sun, covering up, and using sunscreen.

171 SQUAMOUS CELL CARCINOMA

Jonathan B. Karnes, MD
Richard P. Usatine, MD

PATIENT STORY

A 66-year-old farmer presents with new growths on his scalp (**Figure 171-1**). The patient admits to lots of sun exposure and has already had one squamous cell carcinoma (SCC) excised from the scalp 5 years ago. On close inspection there are many suspicious areas for SCC (**Figure 171-1**). **Figure 171-2** demonstrates a shave biopsy of a SCC on a scalp using a dermablade. The pathology demonstrated that 2 of 3 biopsy sites were positive for SCC (E and G were SCC and F was read as actinic keratoses). The patient was referred for Mohs surgery. The Mohs surgeon recommended field treatment with 5-fluoruracil for 4 weeks before surgery to minimize the amount of cutting that would be needed to clear the SCC from this diffusely sun-damaged scalp.

INTRODUCTION

Cutaneous SCC is the second most common cancer in humans and arises most often as a result of cumulative sun damage. Although the mortality is declining, incidence is increasing in all populations making this cancer a common and significant burden on patients.

EPIDEMIOLOGY

- Mortality from SCC has been observed as 0.29 per 100,000 population.¹
- Metastasis from SCC occurs in 2% to 9.9% of cases.²
- The incidence is increasing in all age groups and populations at a rate of 3% to 10%.²
- In the United States, approximately 2500 people die from SCC every year.³
- SCC is the second most common skin cancer and accounts for up to 25% of nonmelanoma skin cancers.⁴
- More than 250,000 new cases of invasive SCC are diagnosed annually in the United States.⁴

PATHOPHYSIOLOGY

SCC is a malignant tumor of keratinocytes. Most SCCs arise from precursor lesions called actinic keratoses. SCCs usually spread by local extension but are capable of regional lymph node metastasis and distant metastasis. Human papillomavirus (HPV)-related lesions may be found on the penis, labia, and perianal mucosa, or in the periungual region or elsewhere associated with immunosuppression.⁵

FIGURE 171-1 Multiple squamous cell carcinomas on the scalp of a farmer with a lot of sun exposure. The pathology demonstrated that 2 of 3 biopsy sites were positive for squamous cell carcinoma (E and G were squamous cell carcinomas and F was read as actinic keratosis). (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-2 Shave biopsy of a squamous cell carcinoma on the scalp. (Courtesy of Richard P. Usatine, MD.)

SCCs that metastasize most often start on mucosal surfaces and sites of chronic inflammation.

RISK FACTORS

- Long-term cumulative UV exposure is the greatest risk factor.
- Childhood sunburns.
- Occupational exposure.
- Other UV exposure including PUVA therapy and tanning beds.
- Smoking.
- HPV exposure.
- Exposure to ionizing radiation.
- Arsenic exposure.
- Fair skin.
- Age older than 60 years.
- Male gender.
- Living at lower latitude and higher altitude.
- Nonhealing ulcers.
- Chronic or severe immunosuppression, including posttransplant immunosuppression, HIV, and long-term steroid use.
- Genetic syndromes, including Muir Torre, xeroderma pigmentosum, dystrophic epidermolysis bullosa, epidermodysplasia verruciformis, and oculocutaneous albinism.⁴

DIAGNOSIS

- The only sure method of making the diagnosis is a biopsy. Biopsy suspicious lesions (thickened, tender, indurated, ulcerated, or crusting) especially in sun-exposed areas.

CLINICAL FEATURES

SCC often presents as areas of persistent ulceration, crusting, hyperkeratosis, and erythema, especially on sun-damaged skin.

Less common types of SCC:

- Marjolin ulcer—SCC of the extremities found in chronic skin ulcers or burn scars. This is a more common risk in darker pigmented individuals (**Figure 171-3**).
- Erythroplasia of Queyrat—SCC in situ on the penis or vulva related to HPV infection (**Figure 171-4**). This can progress to invasive SCC of the penis (**Figure 171-5**).

TYPICAL DISTRIBUTION

SCC is found in all sun-exposed areas and on mucous membranes. The most common sites are:

- Face (**Figures 171-6 and 171-7**).
- Lower lip (**Figures 171-8 and 171-9**).
- Ears (**Figure 171-10**).
- Scalp (**Figures 171-1 and 171-11**).
- Extremities—arm—(**Figures 171-12 and 171-13**).

FIGURE 171-3 Marjolin ulcer (squamous cell carcinoma) arising in a burn that occurred years before on the face. (Courtesy of Richard P Usatine, MD.)

FIGURE 171-4 Erythroplasia of Queyrat (squamous cell carcinoma in situ) under the foreskin of an uncircumcised man. This is related to human papillomavirus infection as is cervical cancer. (Courtesy of John Pfenninger, MD.)

FIGURE 171-5 Squamous cell carcinoma of the glans penis. (Courtesy of Jeff Meffert, MD.)

- Hands (**Figure 171-14**).
- Fingers (**Figure 171-15**).
- Mucous membranes (**Figure 171-16**) (see Chapter 43, Oral Cancer).

BIOPSY

- Deep shave biopsy is adequate to make the diagnosis of most SCCs.
- Punch biopsy or incisional biopsy is an alternative for lesions that are pigmented or appear to be deeper.

FACTORS AFFECTING METASTATIC POTENTIAL OF CUTANEOUS SQUAMOUS CELL CARCINOMA⁶

The following factors are taken from “Multiprofessional guidelines for the management of the patient with primary cutaneous squamous cell carcinoma.”⁶

SITE.

Tumor location influences prognosis: sites are listed in order of increasing metastatic potential.²

1. SCC arising at sun-exposed sites excluding lip and ear.
2. SCC of the lip (**Figures 171-8** and **171-9**).
3. SCC of the ear (**Figure 171-10**).
4. Tumors arising in non–sun-exposed sites (e.g., perineum, sacrum, sole of foot) (**Figures 171-4**, **171-5**, and **171-16**).
5. SCC arising in areas of radiation or thermal injury, chronic draining sinuses, chronic ulcers, chronic inflammation, or Bowen disease, such as the SCC arising in a burn site (**Figure 171-3**).

SIZE: DIAMETER.

Tumors larger than 2 cm in diameter are twice as likely to recur locally (15.2% vs. 7.4%), and 3 times as likely to metastasize (30.3% vs. 9.1%) as smaller tumors (**Figure 171-17**).

SIZE: DEPTH.

Tumors greater than 4 mm in depth (excluding surface layers of keratin) or extending down to the subcutaneous tissue (Clark level V) are more likely to recur and metastasize (metastatic rate 45.7%) compared with thinner tumors. Recurrence and metastases are less likely in tumors confined to the upper half of the dermis and less than 4 mm in depth (metastatic rate 6.7%).

HISTOLOGIC DIFFERENTIATION.

Poorly differentiated tumors have a poorer prognosis, with more than double the local recurrence rate and triple the metastatic rate of better differentiated SCC. Tumors with perineural involvement are more likely to recur and to metastasize.

HOST IMMUNOSUPPRESSION.

Tumors arising in patients who are immunosuppressed have a poorer prognosis. Host cellular immune response may be important both in determining the local invasiveness of SCC and the host's response to metastases. **Figures 171-16**, **171-17**, and **171-18** are SCCs in patients who are HIV-positive.

PREVIOUS TREATMENT AND TREATMENT MODALITY.

The risk of local recurrence depends upon the treatment modality. Locally recurrent disease itself is a risk factor for metastatic disease.

FIGURE 171-6 A. Squamous cell carcinoma on the nose of an 88-year-old woman. B. Subtle small squamous cell carcinoma on the nasal alae. Note that any crusting lesion on the face may be a squamous cell carcinoma no matter how small it is. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-7 A. Large cystic appearing squamous cell carcinoma on the face. Although this could have been a basal cell carcinoma, it definitely required a biopsy and excision. B. Small subtle invasive squamous cell carcinoma on the face that could have been overlooked or treated as an actinic keratosis. Any scaling lesion on the face that persists should be biopsied. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-8 Squamous cell carcinoma on the lower lip growing rapidly in a patient that was taking an immunosuppressive medication after a renal transplant. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-12 Large squamous cell carcinoma on the leg of a homeless man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-13 3 Large ulcerating squamous cell carcinoma on arm. (Courtesy of Jonathan B. Karnes, MD.)

FIGURE 171-11 Squamous cell carcinoma on the shaved scalp of a 35-year-old man, which was formerly mistaken for a wart. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-14 Squamous cell carcinoma in situ on the thenar eminence of the hand. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-15 Two different appearing cases of squamous cell carcinoma on the finger. **A.** It took 2 shave biopsies to establish the correct diagnosis in this case. **B.** Squamous cell carcinoma in situ with human papillomavirus changes and pigment incontinence in a 35-year-old woman. The irregular hyperpigmented lesion on the proximal nailfold was originally suspicious for melanoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-16 Perianal invasive squamous cell carcinoma in an immunodeficient man who had engaged in anal intercourse and was infected with human papillomavirus. The ulcerations were suspicious for invasive squamous cell carcinoma and not typical of condyloma acuminata. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-17 Large squamous cell carcinoma on the arm of an immunodeficient virus-positive 51-year-old man. It grew to this size in 1 year and took 2 biopsies to get a definitive diagnosis. Differential diagnosis includes mycosis fungoides. (Courtesy of Richard P. Usatine, MD.)

FIGURE 171-18 Squamous cell carcinoma invading the internal nasal structures in an immunodeficient virus-positive man who was afraid of having a biopsy done earlier. Patient referred to ear, nose, and throat specialist. (Courtesy of Richard P. Usatine, MD.)

Local recurrence rates are considerably less with Mohs micrographic surgery than with any other treatment modality.

DIFFERENTIAL DIAGNOSIS

- Actinic keratoses are precancers on sun-exposed areas, which can progress to SCC (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Bowen disease is SCC in situ before it invades the basement membrane (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Keratoacanthoma is a subtype of SCC that may resolve spontaneously, but is generally treated as a low risk SCC. **Figure 171-19** shows an invasive SCC resembling a lower-risk keratoacanthoma subtype (see Chapter 167, Keratoacanthoma).
- Basal cell carcinoma (BCC) cannot always be distinguished from SCC by clinical appearance alone. **Figure 171-17A** could be a BCC by appearance but was proven to be SCC by biopsy (see Chapter 170, Basal Cell Carcinoma).
- Merkel cell carcinoma (neuroendocrine carcinoma of the skin) is a rare aggressive malignancy. It is most commonly seen on the face of white elderly persons. It can resemble a SCC and the diagnosis is made on biopsy (**Figure 171-20**).
- Nummular eczema can usually be distinguished by the multiple coin-like shapes, transient nature, and pruritus (Chapter 145, Atopic Dermatitis).

MANAGEMENT

The following recommendations are derived from the “Multiprofessional guidelines for the management of the patient with primary cutaneous squamous cell carcinoma.” **Table 171-1** for a summary of treatment options.

Surgical resection for definitive treatment should include margins as given below:

- 4-mm margin—Should be adequate for well-defined, low-risk tumors less than 2 cm in diameter, such margins are expected to remove the primary tumor mass completely in 95% of cases.⁵
SOR A
- 6-mm margin—Recommended for larger tumors, high-risk tumors, tumors extending into the subcutaneous tissue and those in high-risk locations (ear, lip, scalp, eyelids, nose).⁵

MOHS MICROGRAPHIC SURGERY

Frederick Mohs pioneered a technique for excising cutaneous tumors with immediate analysis of a continuous margin mapped to the clinical site. Mohs surgery offers superior cure rates compared with standard excision or destructive techniques, spares uninvolved tissue, and allows for reconstruction at the time of excision.

Mohs surgery may be considered for any continuous tumor, but is specifically indicated for lesions larger than 2 cm, lesions with ill-defined clinical borders, lesions with aggressive histologic subtypes, recurrent lesions, and lesions on or near the eye, nose, ear, mouth,

FIGURE 171-19 Squamous cell carcinoma on the shoulder of an human immunodeficiency virus-positive man. Note that the pearly borders and telangiectasias resemble a basal cell carcinoma and the central crater suggests that this could be a keratoacanthoma. (Courtesy of Richard P. Usatine, MD.)

TABLE 171-1 Summary of Treatment Options for Primary Cutaneous Squamous Cell Carcinoma

Treatment	Indications	Contraindications	Notes
Surgical excision	All resectable tumors	Where surgical morbidity is likely to be unreasonably high	Generally treatment of choice for SCC High-risk tumors need wide margins or histologic margin control
Mohs' micrographic surgery/excision with histologic control	High-risk tumors, recurrent tumors	Where surgical morbidity is likely to be unreasonably high	Treatment of choice for high-risk tumors
Radiotherapy	Nonresectable tumors	Where margins are ill-defined	
Curettage and cautery	Small, well-defined, low-risk tumors	High-risk tumors	Curettage may be helpful prior to surgical excision
Cryotherapy	Small, well-defined, low-risk tumors	High-risk tumors, recurrent tumors	Only suitable for experienced practitioners

Reprinted from Motley R, Kersey P, Lawrence C. Multiprofessional guidelines for the management of the patient with primary cutaneous squamous cell carcinoma. *BrJ Plast Surg.* 2003;56:85-91.

hair-bearing scalp, or chronic ulcers. Patients with chronic immunosuppression or genetic tumor syndromes may also benefit from Mohs surgery compared to standard excision.⁴

CURETTAGE AND ELECTRODESICCATION

Excellent cure rates have been reported in several series, and experience suggests that small (<1 cm), well-differentiated, primary, slow-growing tumors arising on sun-exposed sites can be removed by experienced physicians with electrodesiccation and curettage (EDC).⁵

The experienced clinician undertaking EDC can detect tumor tissue by its soft consistency, which may be of benefit in identifying invisible tumor extension and ensuring adequate treatment. Electrodesiccation is applied to the curetted wound and the curettage-cautery cycle then repeated twice. **SOR C**

CRYOSURGERY

Good short-term cure rates have been reported for small, histologically confirmed SCC treated by cryosurgery in experienced hands. Prior biopsy is necessary to establish the diagnosis histologically. There is great variability in the use of liquid nitrogen for cryotherapy. Start by drawing a 4- to 6-mm margin around the SCC and then use a total freeze time of 60 seconds. This can be divided up into two 30-second freezes with a thaw in between. Most patients prefer local anesthetic because these long freeze times are quite painful. **SOR C**

Cryosurgery and curettage and electrodesiccation are not appropriate for locally recurrent disease.

RADIOTHERAPY

Radiation therapy alone offers short- and long-term cure rates for SCC that are comparable with other treatments. It is recommended for lesions arising on the lip, nasal vestibule (and sometimes the outside of the nose), and ear. Certain very advanced tumors, where surgical morbidity would be unacceptably high, may also be best treated by radiotherapy. **SOR C**

ELECTIVE PROPHYLACTIC LYMPH NODE DISSECTION

Elective prophylactic lymph node dissection has been proposed for SCC on the lip that is greater than 6 mm in depth and for cutaneous SCC that is greater than 8 mm in depth, but evidence for this is weak. **SOR C**

PREVENTION AND SCREENING

- All skin cancer prevention starts with sun protection.
- There is good evidence from multiple randomized controlled trials (RCTs) that daily sunscreen use decreases the risk of developing sun-related SCCs.^{7,8} **SOR A** In the longest RCT, sunscreen was applied regularly to the head, neck, hands, and forearms for 4.5 years with a decrease in SCC during the study period.⁷ After cessation of the trial, the participants were followed for another 8 years and SCC tumor rates were significantly decreased, by almost 40%, during the entire follow-up period.⁸
- Sun protection should include sun avoidance, especially during peak hours of UV transmission, protective clothing, and sunscreen use.
- Indoor tanning is not safe and should be avoided.
- United States Preventive Services Task Force has not found sufficient evidence to recommend regular screening for any skin cancer in the general population.⁹
- Most experts believe that persons at high risk for SCC (including previous personal history of any skin cancer, high-risk family history and high-risk skin types with significant sun exposure, on immunosuppression after an organ transplant) should be screened regularly for skin cancer by a physician trained in such screening.
- Evidence for the value of self-screening is lacking but persons at high risk for skin cancer should also be encouraged to observe their own skin and to come in for evaluation if they see any suspicious changes or growths.

PROGNOSIS

Prognosis is excellent for small, thin lesions less than 2 mm thick that are removed with clear margins in immunocompetent patients. In these patients, the risk of metastasis is near zero. The risk of metastasis increases markedly with thicker lesions and lesions with thicknesses greater than 6 mm metastasize to the regional nodes 16% of the time.¹⁰

FOLLOW-UP

Patients should be seen at least yearly for skin examinations after the diagnosis and treatment of a SCC. The 3-year risk of recurrence of a new SCC after having a single SCC is 18%.¹¹

PATIENT EDUCATION

Includes use of a hat and sunscreen on a regular basis with frequent follow-up for early recognition of new skin cancers.

172 MELANOMA

Jonathan B. Karnes, MD
Richard P. Usatine, MD

PATIENT STORIES

A 40-year-old woman noticed a new dark spot on her neck (**Figure 172-1**). On examination the spot was 8 mm in its longest diameter, was asymmetrical with irregular borders, and had variation in color. A scoop shave biopsy demonstrated melanoma in situ. The spot was excised with 0.5 cm margins and no residual tumor was found in the excised ellipse. She has a near 100% chance of complete cure.

The wife of a 73-year-old man noticed that a “mole” on his back was enlarging and bleeding. (**Figure 172-2**). It had been there for years. Even though a year earlier a doctor had told him not to worry about it, his wife sent him to have it rechecked. **Figure 172-2B** shows a close-up of the pigmented lesion showing ulceration and bleeding. An elliptical excision was performed and the tissue appeared to be a nodular melanoma with dark pigment into the subcutaneous fat (**Figure 172-2C**). Histology revealed a nodular melanoma with a Breslow depth of 22 mm. The patient was referred to surgical and medical oncology. He underwent wide excision with 2-cm margins and a sentinel lymph node biopsy. The sentinel node was positive and further nodal dissection showed a total of another 4 axillary lymph nodes positive (1 on right and 3 on left). The lymph nodes on the left were black and enlarged. No distant metastases were found. Because more than 2 regional nodes were macroscopically positive, he was stage IIIC. He received radiation treatment to the original site and both axillae. Despite advances in targeted chemotherapy and immunotherapy, his prognosis was poor.

INTRODUCTION

Melanoma is the third most common skin cancer and the most deadly. The incidence of melanoma and the mortality from it are rising. Most lesions are found by clinicians on routine examination. When discovered early, surgical treatment is almost always curative. However, deeper lesions are prone to metastasize and have a much poorer prognosis. New therapies directed at the known gene changes in melanoma are beginning to show some promise, but widespread benefits of this research are still far off.

EPIDEMIOLOGY

- In 2012, an estimated 76,250 individuals will be diagnosed with melanoma of the skin and 9180 individuals will die from metastatic disease—or about 1 every hour.¹
- Melanoma incidence has increased in every age group and in every thickness over the course of 1992 to 2006 among non-Hispanic whites, with death rates increasing in those older than age 65 years.²

FIGURE 172-1 Melanoma in situ on the neck of a 40-year-old woman. Note the central regression. (Courtesy of Richard P. Usatine, MD.)

- Incidence continues to increase worldwide at approximately 4% to 8% per year.³
- In the United States, the death rate for melanoma is decreasing among persons younger than age 65 years.²
- Deaths from thin melanomas account for more than 30% of total deaths.
- The lifetime risk of developing melanoma is 1 in 55 for men and 1 in 36 for women.¹

RISK FACTORS

Risk factors can be broadly thought of as genetic risks, environmental risks, and phenotypic risks arising from a combination of genetic and environmental risks. For example, a fair-skinned child (genetic risk) who gets a sunburn (environmental) is much more likely to develop freckles (phenotypic) and melanoma.

ENVIRONMENTAL RISKS

- Exposure to sunlight.
 - History of sunburn doubles the risk of melanoma and is worse at a young age.
- Living closer to the equator.
- Indoor tanning.
- History of immunosuppression.
- Higher socioeconomic status (likely associated with more frequent opportunity for sunburns).

GENETIC RISKS

- Fair skin, blue or green eyes, red or blonde hair.
- Male sex.
- Melanoma in a first-degree relative.
- History of xeroderma pigmentosa or familial atypical mole melanoma syndrome.

PHENOTYPIC RISKS

- Many nevi.
- Multiple dysplastic nevi.
- Increased age.
- Personal history of any skin cancer.

DIAGNOSIS

CLINICAL FEATURES

Remember the *ABCDE* guidelines for diagnosing melanoma (**Figure 172-3**).⁴

A = Asymmetry. Most early melanomas are asymmetrical: a line through the middle will not create matching halves. Benign nevi are usually round and symmetrical.

B = Border. The borders of early melanomas are often uneven and may have scalloped or notched edges. Benign nevi have smoother, more even borders.

FIGURE 172-2 A. A 73-year-old man presents with bleeding “mole” on his back. Elliptical excision demonstrates this to be a nodular melanoma of 22-mm depth. B. Closeup of the nodular melanoma showing it to be thick with ulcerations and bleeding. C. Nodular melanoma after initial resection showing dark pigment into the subcutaneous fat. The Breslow depth is 22 mm with Clark level V. (Courtesy of Richard P. Usatine, MD.)

C = Color variation. Benign nevi are usually a single shade of brown. Melanomas are often in varied shades of brown, tan, or black, but may also exhibit red, white, or blue.

D = Diameter greater than or equal to 6 mm. Early melanomas tend to grow larger than most nevi. (Note: Congenital nevi are often large.)

E = Evolving. Any evolving or enlarging nevus should make you suspect melanoma. Evolving could be in size, shape, symptoms (itching, tenderness), surface (especially bleeding), and shades of color.

- A prospective controlled study compared 460 cases of melanoma with 680 cases of benign pigmented tumors and found significant differences for all individual ABCDE criteria ($p < 0.001$) between melanomas and benign nevi.⁴
- Sensitivity of each criterion: A 57%, B 57%, C 65%, D 90%, E 84%; specificity of each criterion: A 72%, B 71%, C 59%, D 63%, E 90%.⁴
- Sensitivity of ABCDE criteria varies depending upon the number of criteria needed: using 2 criteria it was 89.3%; with 3 criteria, it was 65.5%. Specificity was 65.3% using 2 criteria and 81% using 3.⁴
- The number of criteria present was different between benign nevi (1.24 ± 1.26) and melanomas (3.53 ± 1.53 ; $p < 0.001$). Unfortunately, no significant difference was found between melanomas and atypical nevi.⁴

There are 4 major categories of melanomas. With the exception of nodular melanoma, the growth patterns of the 3 other subtypes are characterized by a radial growth phase prior to dermal invasion. At the present time, the thickness of the lesion histologically regardless of the morphologic type is used to stage the tumor and assess prognosis. In the future, molecular analysis may allow more accurate risk stratification.⁵ Here are the major categories of melanomas:

1. *Superficial spreading melanoma* is the most common type, representing 70% of all melanoma (**Figures 172-3 to 172-6**). This melanoma has the radial growth pattern before dermal invasion occurs. The first sign is the appearance of a flat macule or slightly raised discolored plaque that has irregular borders and is somewhat geometrical in form. The color varies, with areas of tan, brown, black, red, blue, or white. These lesions can arise in an older nevus. The melanoma can be seen almost anywhere on the body, but is most likely to occur on the trunk in men, the legs in women, and the upper back in both. Most melanomas found in the young are of the superficial spreading type.⁵
2. *Nodular melanoma* occurs in 15% to 30% of cases (**Figures 172-2, 172-7 to 172-9**).⁵ It is usually invasive at the time it is first diagnosed, and the malignancy is recognized when it becomes a bump. The color is most often black, but occasionally is blue, gray, white, brown, tan, red, or nonpigmented. The nodule in **Figure 172-9** is multicolored.
3. *Lentigo maligna melanoma* occurs in 4% to 15% of cutaneous melanoma.⁴ It is similar to the superficial spreading type and appears as a flat or mildly elevated mottled tan, brown, or dark brown discoloration. This type of melanoma is found most often in the elderly and arises on chronically sun-exposed, damaged skin on the face, ears, arms, and upper trunk. These account for most melanomas on the face. The average age of onset is 65 years and it grows slowly over 5 to 20 years. The precursor lesion, lentigo maligna, goes on to melanoma in approximately 5% of cases. The in situ precursor lesion is usually larger than 3 cm in diameter and has existed for a minimum of 10 to 15 years (**Figures 172-10 and 172-11**) (see Chapter 168, Lentigo Maligna).⁵

FIGURE 172-11 Lentigo malignant melanoma presenting as a large pigmented area on the face of an elderly man. (Courtesy of the Skin Cancer Foundation. For more information www.skincancer.org)

4. *Acral lentiginous melanoma* is the least common subtype of melanoma (2% to 8%) cases in white people; however, it is the most frequent subtype found in African Americans (70%) and is also a frequent subtype in Asians (45%).⁵ It may occur under the nail plate or on the soles or palms (**Figures 172-12 to 172-16**). This subtype often carries a worse prognosis because of delays in diagnosis. Subungual melanoma may manifest as diffuse nail discoloration or a longitudinal pigmented band within the nail plate. When subungual pigment spreads to the proximal or lateral nail fold, it is referred to as the Hutchinson sign, and is highly suggestive of acral lentiginous melanoma (**Figure 172-14**) (see Chapter 191, Pigmented Nail Disorders).

Less common types of melanomas include:

- *Amelanotic melanoma* (<5% of melanomas) is nonpigmented and appears pink or flesh-colored, often mimicking basal cell or squamous cell carcinoma or a ruptured hair follicle. Any of the 4 principal subtypes may present as an amelanotic variant, but nodular melanomas are highly represented. These may be intrinsically more aggressive and often present with a thicker Breslow depth than similarly pigmented melanomas (**Figures 172-17, 172-18 and 172-19**).⁶
- Other rare melanoma variants include (a) nevoid melanomas, (b) malignant blue nevus, (c) desmoplastic/spindled/neurotropic melanoma, (d) clear cell sarcoma (in fact a melanoma), (e) animal-type melanoma, (f) ocular melanoma, and (g) mucosal (lentiginous) melanoma.⁵

TYPICAL DISTRIBUTION

Melanoma occurs most commonly on the trunk in white males and the lower legs and back in white females, but may occur in any location where melanocytes exist. The most common site in African Americans, Hispanics, and Asians is the plantar foot, followed by the subungual, palmar, and mucosal sites.

DERMOSCOPY

Dermoscopy can be used to determine if a pigmented lesion has features suspicious for a melanoma, and it can also help determine when a biopsy is needed.⁷ In a prospective study of 401 lesions evaluated for melanoma by experts in dermoscopy, the sensitivity of 66.6% with ABCDE criteria improved to 80%, and specificity rose from 79.3% to 89.1% (**Figure 172-20**).⁷

In a study of dermoscopy done by 60 physicians (35 general practitioners, 10 dermatologists, and 16 dermatology trainees) on unaided photos of 40 lesions using the ABCD rule, the Menzies method, a 7-point checklist, and pattern analysis, the sensitivity rose over the unaided eye.⁸ The physicians were instructed in each of the dermoscopy methods using a CD-ROM. The unaided eye using a standard photo of the lesion was 61% sensitive and 85% specific with a 73% diagnostic accuracy. The dermoscopic photo increased sensitivity (68% for pattern analysis, 77% for the ABCD rule, 81% for the 7-point checklist, and 85% for the Menzies method). The specificity did not improve. Sensitivity is more important than specificity to avoid missing melanoma. Although the number of biopsies could increase with some drop in specificity, the biopsy itself is the most specific test to differentiate melanoma from benign pigmented lesions.⁸

FIGURE 172-16 Acral lentiginous melanoma on the bottom of the foot where it went undetected for years. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 172-19 A. Amelanotic melanoma on the arm of a young woman prior to elliptical excision. The diagnosis was unexpected and shows the importance of excising suspicious lesions even when they are not pigmented. (Courtesy of E.J. Mayeaux, Jr., MD.) B. Amelanotic melanoma with a dermoscopy insert in upper corner. The use of the dermatoscope and the recognition of the abnormal vascular pattern lead to a high suspicion for amelanotic melanoma that was confirmed on excision. (Courtesy of Ashfaq Marghoob, MD.)

FIGURE 172-20 A. A melanoma on the leg that could be missed because of its small size (7-mm long). B. Closeup of that melanoma showing the asymmetry, irregular borders and a variation in color. C. Dermoscopy of a melanoma showing a blue-white veil, radial streaks, pigment network, structureless areas and regression structures with peppering. This early superficial-spreading melanoma was proven to be 0.55 mm at the time of excision. (Courtesy of Ashfaq Marghoob, MD.)

Accepted dermoscopic local features of melanoma include:

- Atypical network (includes branched-streaks).
- Streaks: pseudopods and radial streaming.
- Atypical dots and globules.
- Negative pigment network.
- Blotch (off center).
- Blue-white veil/peppering over macular areas (regression).
- Blue-white veil over raised areas.
- Vascular structures.
- Peripheral tan/brown structureless areas.

Figure 172-20 demonstrates a number of these features. See Appendix 3: Dermoscopy.

BIOPSY

A full-thickness skin biopsy remains the gold standard for diagnosing melanoma. Complete excisional biopsy with close margins (1 to 3 mm) is ideal for histologic diagnosis and tumor staging (**Box 172-1**). Although there is evidence that an incisional biopsy of a portion of a melanoma does not worsen the prognosis, this should only be performed when a lesion is too large to excise in the office. When the clinical impression differs markedly from the pathology report, discuss with the pathologist and share clinical photos if you haven't done so already. You may need to have the pathologist prepare "deeper sections" or "step sections"—meaning more slices from the same loaf of bread. Additionally, if the diagnosis of melanoma was expected and the result of an incisional biopsy does not meet the expectation, go forward with a complete excision or refer to a surgeon who can.

Despite strong opinions about biopsy technique, there is evidence that a saucerization (scoop or deep shave biopsy) leads to an accurate diagnosis and staging 97% of the time (**Figure 172-21**).⁹ Still, a shallow shave biopsy may miss important staging information and may cause "upstaging" and unnecessary lymph node biopsy. However, for very large lesions, such as a suspected lentigo maligna, a broad scoop shave (saucerization) can often provide better tissue to the pathologist than a single or several punch biopsies (**Figure 172-10**).¹⁰

The impact of partial biopsy on histopathologic diagnosis of cutaneous melanoma has been studied extensively by Ng et al in Australia. They found increased odds of histopathologic misdiagnosis were associated with punch biopsy of part of the melanoma (odds ratio [OR] 16.6) and shallow shave biopsy (OR 2.6) compared with excisional biopsy (including saucerization). Punch biopsy of part of the melanoma was also associated with increased odds of misdiagnosis with an adverse outcome (OR 20).¹¹

DIFFERENTIAL DIAGNOSIS

Nevi of all types can mimic melanoma. Congenital nevi can be especially large and asymmetrical. Therefore, it is important to ask the patient if the pigmented area has been there from birth. Because some melanomas arise in congenital nevi, a changing congenital nevus needs to be biopsied to rule out melanoma.

- Dysplastic nevi, also called atypical moles, can mimic melanoma. When an atypical nevus is suspicious for melanoma, perform a full-thickness biopsy or a broad scoop shave for histology. Only the

BOX 172-1 The National Comprehensive Cancer Network (NCCN) Melanoma Guidelines on the Principles of Biopsy State¹²

- Excisional biopsy (elliptical, punch [when whole lesion is small], or saucerization) with 1- to 3-mm margins is preferred. Avoid wider margins to permit accurate subsequent lymphatic mapping.
- The orientation of the biopsy should be planned with definitive wide excision in mind.
- Full-thickness incisional or punch biopsy of clinically thickest portion of the lesion is acceptable in certain anatomic areas (e.g., palm/sole, digit, face and ear) or for very large lesions.
- Shave biopsy (not saucerization or deep shave) may compromise pathologic diagnosis and complete assessment of Breslow thickness, but is acceptable when the index of suspicion is low.
- For lentigo maligna melanoma in situ, broad shave biopsy may help to optimize diagnosis.¹²

FIGURE 172-21 Saucerization (scoop or deep shave) of the entire pigmented lesion suspected to be a superficial spreading melanoma was performed successfully with a dermatome. Breslow's thickness was 0.6 mm and the patient then underwent a full surgical excision with 1-cm margins. (Courtesy of Richard P. Usatine, MD.)

less-suspicious dysplastic nevi should be followed with photography or serial exams (see Chapter 165, Dysplastic Nevus).

- Seborrheic keratoses (SKs) usually look like they are stuck-on with surface cracks and a verrucous (wart-like) appearance. These are benign and not precancerous. SKs can be darkly pigmented, asymmetrical with irregular borders and have varied colors. Perform a biopsy if the diagnosis is uncertain. Be careful to not mistake a lesion for a SK (**Figure 172-4**) (see Chapter 158, Seborrheic Keratosis).
- Solar lentigines often appear as light brown macules on the face and the dorsum of the hands. Many patients call them liver spots, but they have nothing to do with the liver. A large isolated solar lentigo on the face can mimic lentigo maligna melanoma. In this case, perform a broad scoop shave of the most suspicious area or the whole lesion.
- Dermatofibromas are fibrotic nodules that occur most frequently on the legs and arms. They can be any color from skin color to black and often have a brown halo surrounding them. A pinch test will produce a dimpling of the skin in most cases (see Chapter 160, Dermatofibroma).
- Pyogenic granulomas can resemble an amelanotic melanoma so always send the lesion to the pathologist to make sure that the clinical diagnosis is correct (**Figure 172-22**) (see Chapter 161, Pyogenic Granuloma).
- Pigmented basal cell carcinomas (BCCs) may resemble a melanoma. However, the pigment in the BCC is often scattered throughout the lesion, and it has other features of a BCC, such as a pearly appearance with a rolled border (**Figures 172-23** and **172-24**) (see Chapter 170, Basal Cell Carcinoma). Dermoscopy can be very helpful as a pigmented BCC has a number of specific dermoscopic structures to look for.

MANAGEMENT

- Cutaneous melanoma is surgically treated with complete full skin-depth excision using margins determined by the Breslow depth. This depth is a measure of tumor thickness from the granular layer of the epidermis to the point of deepest invasion using an ocular micrometer.
- Current recommendations for excision margins range from 5 mm for in situ lesions to 1 to 2 cm for invasive lesions. A recent study showed significant benefit with a 9-mm margin on Mohs excision of melanoma in situ compared with 6-mm margins at a referral center.¹³ **Table 172-1** for a comparison of world recommendations.¹⁴ **SOR A**
- Mohs micrographic surgery, performed by specially trained physicians, may prove useful in completely removing subclinical tumor extension in certain subtypes of melanoma in situ, such as lentigo maligna, desmoplastic melanoma, and acral lentiginous melanoma in situ.¹⁵
- Sentinel lymph node biopsies are recommended for tumors of greater than or equal to 1 mm in depth and should be considered for thinner lesions with ulceration or more than 1 mitoses per mm². In the most recent guidelines, mitoses per mm² has replaced Clark levels to distinguish T1a from T1b tumors.¹⁶

FIGURE 172-22 Thick ulcerated nodular melanoma on the back of a young woman that could be mistaken for a pyogenic granuloma or basal cell carcinoma. Most importantly, a full depth biopsy was performed. The melanoma depth was greater than 1 mm and the patient was sent for a complete excision with a sentinel node biopsy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 172-23 A pigmented basal cell carcinoma on the lower eyelid that has rolled pearly borders even though the color is black. A shave biopsy allowed a diagnosis of a basal cell carcinoma to be made. (Courtesy of Richard P. Usatine, MD.)

- Patients with advanced melanoma should be referred to medical oncology and may receive combination therapy with multiple chemotherapeutic agents and immunotherapy. Many trials are ongoing and 3 new drugs, including interferon 2 α , vemurafenib, and ipilimumab, have been approved for use in advanced melanoma. Consideration should be given to consulting palliative care.
- Recently 2 new chemotherapeutic agents have been FDA approved for the treatment of metastatic melanoma (**Figure 172-25**). One, vemurafenib is a monoclonal antibody targeting the BRAF mutation expressed on many melanomas. Ipilimumab prevents dampening of the immune system by blocking a regulatory molecule CTLA-4. Both of these medications used in combination with dacarbazine have shown a small but significant increase in progression-free survival.¹⁷

PREVENTION AND SCREENING

- Melanoma prevention starts with sun protection.
- Until recently there is no proof that sunscreen helped to prevent melanoma. A recent study provides some evidence that sunscreen use does decrease the risk of invasive melanomas in adults.¹⁸
- Sun protection should include sun avoidance, protective clothing, and sunscreen.
- Indoor tanning is not safe and should be avoided.
- United States Preventive Services Task Force has not found sufficient evidence to recommend regular screening for melanoma or skin cancer in the general population.¹⁹
- Most experts believe that persons at high risk for melanoma (including previous personal history of melanoma, high-risk family history and high-risk skin types with significant sun exposure) should be screened regularly for melanoma by a physician trained in such screening.
- Evidence for the value of self-screening is lacking but persons at high risk for melanoma should also be encouraged to observe their own skin and to come in for evaluation if they see any suspicious changes or growths.

FIGURE 172-24 A. A pigmented basal cell carcinoma on the scalp mimicking a melanoma. B. Dermoscopy shows the typical maple leaf patterns of a pigmented basal cell carcinoma. A shave biopsy easily allowed for a diagnosis of a basal cell carcinoma to be made. (Courtesy of Richard P. Usatine, MD.)

TABLE 172-1 Currently Recommended Excision Margins for Primary Melanoma

Tumor Thickness	Excision Margin			
	UK MSG	WHO	Australian	Dutch MSG
In situ	2–5 mm	5 mm	5 mm	2 mm
<1 mm	1 cm	1 cm	1 cm	1 cm
1–2 mm	1–2 cm	1 cm*	1 cm	1 cm
2.1–4 mm	2–3 cm (2 cm preferred)	2 cm	1 cm	2 cm
>4 mm	2–3 cm	2 cm	2 cm	2 cm

*For melanomas thicker than 1.5 mm, recommended excision margin is 2 cm.

PROGNOSIS

Prognosis depends upon tumor depth, mitotic rate, the presence of ulceration, positive lymph nodes, and metastases. In stage 0 disease surgical excision is almost always curative. Ten-year survival in patients by tumor thickness is almost 100% for in situ lesions, 92% for lesions less than 1 mm thick, 80% for lesions between 1 and 2 mm thick, 63% for lesions 2 to 4 mm thick, and 50% for lesions thicker than 4 mm. When accounting for nodal and distant metastasis, stage III disease carries a 39% to 70% 5-year survival depending on the number of nodal metastases, and stage IV disease carries a 32% to 62% 1-year survival rate.¹⁶

FOLLOW-UP

The need for follow-up is largely determined by the stage of the disease. The 2010 American Joint Committee on Cancer staging system is provided in **Table 172-2**. The prognosis is worsened by increasing depth, mitotic rate, presence of ulceration, positive lymph nodes, and metastases.

The follow-up for stages 0 and 1 cutaneous melanoma includes regular skin examinations by a physician trained in skin cancer screening. Total body photography may be of benefit in monitoring patients with multiple nevi. The rate of subsequent cutaneous melanomas among persons with a history of melanoma was found to be more than 10 times the rate of a first cutaneous melanoma and the highest incidence of recurrence was in the first 3 to 5 years after initial diagnosis.^{20,21}

PATIENT EDUCATION

Advise patients who have had melanoma to avoid future sun exposure and monitor their skin for new and changing moles. Recommend a complete skin examination yearly by a physician trained to detect early melanoma.

*Clinical staging includes microstaging of the primary melanoma and clinical/radiologic evaluation for metastases. By convention, it should be used after complete excision of the primary melanoma with clinical assessment for regional and distant metastases.

†Pathologic staging includes microstaging of the primary melanoma and pathologic information about the regional lymph nodes after partial (ie, sentinel node biopsy) or complete lymphadenectomy. Pathologic stage 0 or stage IA patients are the exception; they do not require pathologic evaluation of their lymph nodes.

SECTION 13 INFILTRATIVE IMMUNOLOGIC

173 GRANULOMA
ANNULARE

Melissa A. Muszynski, MD
Richard P. Usatine, MD

PATIENT STORY

A 39-year-old woman presents with raised rings on her right hand only. Not knowing the correct diagnosis, another physician prescribed topical steroids and antifungal medicines with no benefit. The diagnosis of granuloma annulare (GA) was made by the typical clinical appearance and the patient was offered intralesional steroids. Triamcinolone acetonide was injected as seen in **Figure 173-1, A**. The patient noted improvement over the subsequent weeks, but within a month new lesions began to appear on her other hand (**Figure 173-1, B**). Additional injections were provided and 1 month later the patient had regression of the treated lesions but had new lesions on the right arm (**Figure 173-2, A**). At the next visit, the patient had new lesions on her feet as well (**Figure 173-2, B**). The diagnosis of disseminated GA was made and systemic treatment was started.

INTRODUCTION

GA is a common dermatologic condition that presents as small, light-red, dermal papules coalescing into annular plaques without scale. As in the above vignette, it is often mistaken as nummular eczema or tinea corporis. Distribution, pattern, and lack of scale are important diagnostic clues.

EPIDEMIOLOGY

- GA affects twice as many women as men.¹
- The four presentations of GA are localized, disseminated/generalized, perforating, and subcutaneous.
- Of the four variations, the localized form is seen most often.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Benign cutaneous, inflammatory disorder of unknown origin.¹
- Disease may be self-limiting, but may persist for many years.
- Reported associations include diabetes mellitus, viral infections (including HIV), *Borrelia* and streptococcal infections, insect bites, lymphoma, tuberculosis, and trauma.^{2,3}
- One proposed mechanism for GA is a delayed-type hypersensitivity reaction as a result of T-helper-type cell (Th)-1 lymphocytic

FIGURE 173-1 A. GA in a 42-year-old woman. Intralesional steroids were administered on the first visit with resolution of the injected lesions. B. Same patient months later with new annular lesions on the opposite hand. She requested additional injections. (Courtesy of Richard P. Usatine, MD.)

differentiation of macrophages. These macrophages become effector cells that express tumor necrosis factor (TNF)- α and matrix metalloproteinases. The activated macrophages are responsible for dermal collagen matrix degradation.⁴

- An association between high expression of *gii-1* oncogene and granulomatous lesions of the skin, including GA, has been established.⁵

RISK FACTORS

The only identifiable risk factor is being a woman. There are several associations, but nothing has been shown to be causative.

DIAGNOSIS

CLINICAL FEATURES

Annular lesions have raised borders that are skin-colored to erythematous (**Figures 173-1** and **173-2**). The rings may become hyperpigmented or violaceous (**Figure 173-2, B**). There is often a central depression within the ring. These lesions range from 2 mm to 5 cm. Although the classical appearance of GA is annular, the lesions may be arcuate instead of forming a complete ring (**Figure 173-3**). Most importantly, there should be no scaling as seen in tinea corporis (ringworm).

TYPICAL DISTRIBUTION

Each of the four types of GA has a different distribution. Localized and disseminated GA differ only in that disseminated lesions can spread to the trunk and neck and may be more pronounced in sun-exposed areas.⁶

- Localized—This is the most common form of GA affecting 75% of GA patients.¹ It typically presents as solitary lesions on the dorsal surfaces of extremities, especially of hands and feet (**Figure 173-4**).
- Disseminated or generalized—Adults are most affected by this form, which begins in the extremities and can spread to the trunk and neck (**Figures 173-5**).
- Perforating—Children and young adults present with 1 to hundreds of 1- to 4-mm annular papules that may coalesce to form a typical annular plaque. Although this form can appear anywhere on the body, it has an affinity for extremities, especially the hands and fingers.⁷ The papules may exude a thick and creamy or clear and viscous fluid.
- Subcutaneous—These lesions present as rapidly growing, nonpainful, subcutaneous or dermal nodules on the extremities, scalp, and forehead. Subcutaneous GA mainly affects children, with a mean age of 3.9 years (**Figure 173-6**).⁶ These lesions are often ill defined and less discrete.

LABORATORY STUDIES

Often a diagnosis of GA is made on clinical presentation alone, without the need for biopsy. Subcutaneous GA may be an exception, as the unusual appearance may be mistaken for a rheumatoid nodule. Histologic examination reveals an increase of mucin, which is a hallmark of GA. There is also a dense infiltrate of histiocytes in the mid-dermis and sparse perivascular lymphocytic infiltrate. The histiocytes are

FIGURE 173-2 A. Same patient as in **Figure 173-1** 1 month later with new crops of lesions on the arms and feet. She has disseminated GA. Note the central area of hypopigmentation secondary to a previous steroid intralesional steroid injection. B. Disseminated GA on the foot of the same patient. The rings are flatter and many are conjoined. (Courtesy of Richard P. Usatine, MD.)

FIGURE 173-3 GA on the elbow showing how the rings may not be complete. This patient is in her fifties and has had new crops of lesions over the past 10 years. (Courtesy of Richard P. Usatine, MD.)

either organized as palisading cells lining a collection of mucin or as a diffuse interstitial pattern. There are no signs of epidermal change.³

DIFFERENTIAL DIAGNOSIS

- Tinea corporis has a raised, scaling border and can present on any body surface. KOH preparation reveals hyphae with multiple branches (see Chapter 138, Tinea Corporis).
- Erythema annulare centrifugum has an affinity for thighs and legs. The diameter of these lesions can expand at a rate of 2 to 5 mm/day and may present with a trailing scale inside the advancing border.² Biopsy is helpful to differentiate this condition from GA (see Chapter 206, Erythema Annulare Centrifugum).
- Nummular eczema presents commonly on extremities, but is almost always associated with scaling plaques and intense itching (see Chapter 147, Hand Eczema).
- Pityriasis rosea often has oval lesions with a trailing collarette of scale. The lesions are minimally raised and have scale that is absent in GA (see Chapter 153, Pityriasis Rosea).
- Rheumatoid nodules may mimic appearance of subcutaneous GA. These nodules are often seen over the elbows, fingers, and other joints in a patient with joint pains and other clinical signs of arthritis (see Chapter 97, Rheumatoid Arthritis). Rheumatoid nodules have fibrin deposition on histologic examination, in contrast to mucin in GA.

MANAGEMENT

The evidence for various treatments is at best small series of cases that are not randomized controlled trials. This disease is asymptomatic, and treatments only improve cosmetic appearance. Many patients may want intervention as diffuse lesions can cause psychological distress. Although GA will eventually resolve, some treatments may cause pigment change or atrophy that might be permanent. Several of the treatments below have shown promise, but these treatments may appear to work when in fact the resolution was natural.

Localized GA:

- In a retrospective study of children with localized GA (mean age: 8.6 years), 39 of 42 presented with complete clearance within 2 years. The average duration was 1 year. Researchers of this study consider most treatments unnecessary because of the self-limiting nature of this variation.⁷ One treatment option is watchful waiting.⁸ **SOR B**
- Intralesional corticosteroids can be injected into GA lesions with resolution of the area injected (**Figure 173-1**). Inject directly into the ring itself with 3 to 5 mg/mL triamcinolone acetonide (Kenalog) using a 27-gauge needle. **SOR C** A large completed ring may take 4 injections to reach 360 degrees of the circle. The major complications include hypopigmentation (**Figure 173-2, A**) and skin atrophy at the injected sites.
- Cryotherapy was studied using nitrous oxide for 9 patients and liquid nitrogen for 22 patients. The results showed 80% clearing after a single freeze; however, 4 of 19 patients treated with liquid nitrogen developed atrophic scars when lesions were larger than

FIGURE 173-4 One single large irregular annular lesion of GA. This ring is also incomplete. (Courtesy of Richard P. Usatine, MD.)

FIGURE 173-5 Disseminated GA in a middle-aged woman with diabetes. (Courtesy of Richard P. Usatine, MD.)

4 cm. All patients developed blisters.⁹ Cryoatrophy may possibly be prevented by avoiding freeze thaw cycles greater than 10 seconds and not overlapping treatment areas.¹⁰ **SOR C**

- A 53-year-old Hispanic woman with GA on the dorsal surface of both hands agreed to treatment with cryotherapy on the right hand and intralesional steroids on the left hand (**Figure 173-7**). Cryotherapy was performed using a 9- to 10-second freeze time and a single freeze. The intralesional injections were performed with a 30-gauge needle and 5 mg/mL triamcinolone (10 mg/mL diluted 1:1 with 1% lidocaine). During the treatment the patient rated the pain from cryotherapy as 9 out of 10 and intralesional steroid 2 out of 10. **Figure 173-7** shows the initial lesions and final results after 1 month. The patient was happy with the results of intralesional steroid and disappointed with the results of the cryotherapy. The lesion treated with cryotherapy did not resolve and spotted areas of hyperpigmentation and hypopigmentation occurred. Upon questioning, the patient states that the lesion treated with cryotherapy was painful for many days whereas she had no residual pain from the lesion treated with intralesional steroid. The patient then asked for the two remaining lesions on her right hand to be injected with steroid. Although this is a single case example, we could find no published studies of a head-to-head comparison between these commonly used methods for local treatment of GA.

Generalized/disseminated GA:

- This variant is more difficult to treat, and often has a longer duration than localized GA. Many treatments have been claimed to be effective, but the studies touting these treatments have small sample sizes and were not randomized.
- In 2009, Marcus et al. reported the successful treatment of 6 patients with a combination of rifampin 600 mg, ofloxacin 400 mg, and minocycline 100 mg. All patients had complete clearance after 3 to 5 months of treatment.¹¹
- Successful treatment of 6 patients with GA was achieved with 100 mg of dapsone, once a day. Complete clearance in all patients took between 4 weeks and 3 months.¹² **SOR C**
- UVA1 phototherapy provided good or excellent results in 10 of 20 patients with disseminated GA. In patients with only a satisfactory treatment response, the disease reappeared soon after phototherapy was discontinued.¹³ **SOR C**
- In a study of 4 patients, topical 5% imiquimod cream was effective when used once daily for an average of 2 months. After discontinuing treatment, 3 patients went an average of 12 months without recurrence; the fourth patient had remission 10 days after treatment stopped, but after an additional 6 weeks of applying cream once daily, he was lesion-free for 18 months.¹⁴ **SOR C**
- Four patients were treated with twice-daily topical application of 0.1% tacrolimus ointment for 6 weeks; all reported improvement after 10 to 21 days. At treatment conclusion, two patients had complete clearance and the other two had marked improvement.¹⁵ **SOR C**
- Treatment with 0.5 to 1 mg/kg of isotretinoin daily has produced some positive results across multiple small studies; however, because of the potential for adverse effects, this option should be reserved for the most severe, nonresponsive cases in patients who are at low risk for the adverse effects of isotretinoin.¹⁶ **SOR C**

FIGURE 173-6 A. Subcutaneous GA in a 7-year-old girl showing one large ring on the dorsum of the finger with soft-tissue infiltration. B. Subcutaneous GA in a 7-year-old girl showing thickening of the involved finger along with the small annular patterns. Note the soft-tissue infiltration that has distorted the finger anatomy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 173-7 A. GA on the dorsum of the right hand of a 53-year-old Hispanic woman. B. Cryotherapy of the largest annular lesion. C. Intraslesional triamcinolone being injected with a 30-gauge needle of a different GA lesion on the left hand. D. One month later the lesion on the left hand treated with intraslesional steroid has flattened and begun to fade while the lesion on the right hand continues to be elevated and now has areas of hyperpigmentation and hypopigmentation secondary to the cryotherapy. At the time of therapy the patient stated the injection hurt less than the cryotherapy. (Courtesy of Richard P. Usatine, MD.)

- Three patients were treated with vitamin E 400 IU daily and zileuton 2400 mg daily. All responded within 3 months with complete clinical clearing.¹⁷ **SOR** **C**

Perforating, subcutaneous:

- Although we could find no specific data to inform the treatment of these less-common types of GA, treatments for both localized and disseminated GA could be applied based on clinical judgment along with patient's severity and preferences.

PROGNOSIS

In 50% of cases there is spontaneous resolution within 2 years; however, recurrence rate is as high as 40%.¹⁸ Patients with skin of color may have postinflammatory hyperpigmentation once the papules and plaques resolve.

FOLLOW-UP

Follow-up visits should be offered to patients who want active treatment.

PATIENT EDUCATION

It is important to reassure patients that this disease is self-limiting. Despite a displeasing appearance, the best treatment may be to let lesions resolve naturally. Numerous individual case studies and treatments have been attempted without consistent success. Treatments may produce side effects that are equally as unwanted, but more permanent, than the GA.

174 PYODERMA GANGRENOSUM

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 32-year-old man was diagnosed with Crohn disease 10 years prior to his visit for these nonhealing leg ulcers (**Figure 174-1**). The patient experienced minor trauma to his lower leg 1 year ago and these ulcers developed (pathergy). Multiple treatments have been tried with partial success, but the ulcers persist.

INTRODUCTION

Pyoderma gangrenosum (PG) is an uncommon ulcerative disease of the skin of unknown origin. It is a type of neutrophilic dermatosis.

EPIDEMIOLOGY

- PG occurs in approximately 1 person per 100,000 people each year.¹
- No racial predilection is apparent.
- A slight female predominance may exist.
- Predominately occurs in fourth and fifth decade, but all ages may be affected.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is poorly understood.
- Pathergy (initiation at the site of trauma or injury) is a common process and it is estimated that 30% of patients with PG experienced pathergy.¹
- Up to 50% of cases are idiopathic.²
- At least 50% of cases are associated with systemic diseases such as inflammatory bowel disease, hematologic malignancy, and arthritis.²
- It occurs in up to 5% of patients with ulcerative colitis and 2% of those with Crohn disease (**Figures 174-2 and 174-3**).^{3,4}
- Biopsies usually show a polymorphonuclear cell infiltrate with features of ulceration, infarction, and abscess formation.

RISK FACTORS^{2,5}

- Ulcerative colitis.
- Crohn disease.
- Polyarthritis (seronegative or seropositive).
- Hematologic diseases/disorders such as leukemia (predominantly myelocytic).

FIGURE 174-1 Classic pyoderma gangrenosum on the leg of a 32-year-old man with Crohn disease. This ulcer started with minor trauma (pathergy) and has been there for 1 year. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-2 Friable inflamed mucosa of the colon in Crohn disease. (Courtesy of Shashi Mittal, MD.)

- Monoclonal gammopathies (primarily immunoglobulin A).
- Psoriatic arthritis and rheumatoid arthritis (**Figure 174-4**).
- Hepatic diseases (hepatitis and primary biliary cirrhosis).
- Immunologic diseases (lupus erythematosus and Sjögren syndrome).

DIAGNOSIS

CLINICAL FEATURES

- Typically PG presents with deep painful ulcer with a well-defined border, which is usually violet or blue. The color has also been described as the color of gun metal. The ulcer edge is often undermined and the surrounding skin is erythematous and indurated. It usually starts as a pustule with an inflammatory base, an erythematous nodule, or a hemorrhagic bulla on a violaceous base. The central area then undergoes necrosis to form a single ulcer.⁵
- The lesions are painful and the pain can be severe.² Patients may have malaise, arthralgia, and myalgia.
- Two main variants of PG exist: classic and atypical.²
 - Classic PG is characterized by a deep ulceration with a violaceous border that overhangs the ulcer bed.² These lesions of PG most commonly occur on the legs (**Figures 174-1 and 174-3 to 174-5**).²
 - Atypical PG has a vesiculopustular wet component (**Figures 174-8 and 174-9**). This is usually only at the border, is erosive or superficially ulcerated, and most often occurs on the dorsal surface of the hands, the extensor parts of the forearms, or the face.²
- Other variants:
 - Peristomal PG may occur around stoma sites. This form is often mistaken for a wound infection or irritation from the appliance.⁶
 - Vulvar or penile PG occurs on the genitalia and must be differentiated from ulcerative sexually transmitted diseases (STDs) such as chancroid and syphilis.²
 - Intraoral PG is known as pyostomatitis vegetans. Occurs primarily in patients with inflammatory bowel disease.²

TYPICAL DISTRIBUTION

- Most commonly seen on the legs and hands, but can occur on any skin surface including the genitalia, and around a stoma. PG can be seen on the scalp, head, and neck (**Figures 174-10 and 174-11**).

LABORATORY TESTING

- Complete blood count (CBC), urinalysis (UA), and liver function tests (LFTs) should be obtained. Order a hepatitis profile to rule out hepatitis.² Systemic disease markers may be elevated if associated conditions exist, that is, erythrocyte sedimentation rate (ESR), antinuclear antibody (ANA), and rheumatoid factor. Obtain rapid plasma reagin (RPR), protein electrophoresis, and skin cultures as indicated. Consider culturing the ulcer/erosion for bacteria, fungi, atypical *Mycobacteria*, and viruses.²
- If GI symptoms exist, perform or refer for colonoscopy to look for inflammatory bowel disease.

FIGURE 174-3 Classic pyoderma gangrenosum on the leg of a 35-year-old woman with Crohn disease. This ulcer started with minor trauma (pathergy) and has been there for 2 years. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-4 Pyoderma gangrenosum on the leg of a 56-year-old woman with rheumatoid arthritis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-5 Pyoderma gangrenosum showing dusky red border with undermined edges. The surface appears purulent and necrotic. (Courtesy of Jack Resneck, Sr., MD.)

FIGURE 174-7 Partially healed pyoderma gangrenosum on the leg of a 29-year-old Hispanic woman. Note the areas of healed ulcerations and the dusky elevated borders. There remain 2 areas of active disease (arrows) with pain, erythema, swelling, and purulent discharge. The patient improved with dapsone. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-8 Atypical pyoderma gangrenosum with a vesiculopustular "juicy" component on the dorsal surface of the hand. Bulla were previously present before the ulcerations developed. (Courtesy of Eric Kraus, MD.)

BIOPSY

- Biopsy an active area of disease along with the border. A punch biopsy is preferred (4-mm punch is adequate). Although there are no specific pathologic signs of PG, the biopsy can be used to rule out other causes of ulcerative skin lesions.
- The pathologist may be able to confirm your clinical impression. Biopsy of the earliest lesions reveal a neutrophilic vascular reaction. Fully developed lesions exhibit dense neutrophilic infiltrate, and some lymphocytes and macrophages surrounding marked tissue necrosis. Ulceration, infarction of tissue, and abscess formation with fibrosing inflammation at the edge of the ulcer may be seen.⁷

DIFFERENTIAL DIAGNOSIS

- PG is sometimes a diagnosis of exclusion diagnosed with successful wound healing following immunosuppressant therapy.⁸ When misdiagnosed it is often confused for vascular occlusive or venous disease, vasculitis, cancer, primary infection, drug-induced or exogenous tissue injury, and other inflammatory disorders.⁹ Biopsy of a questionable lesion may be the only way to ultimately distinguish PG as the cause of ulcerative skin lesions.
- Ulcerative STDs, such as chancroid and syphilis, can resemble vulvar or penile PG. These STDs are more common than PG and should be diagnosed with appropriate tests, including RPR and bacterial culture for *Haemophilus ducreyi*. If these tests are negative, then PG should be considered. RPR should also be repeated in 2 weeks if it is initially negative at the start of a chancre—it takes some weeks to become positive and syphilis is easily treatable (see Chapter 216, Syphilis).
- Acute febrile neutrophilic dermatosis (Sweet syndrome) is a neutrophilic dermatosis like PG, but the patients are generally febrile with systemic symptoms (**Figure 174-12**). The diagnosis of Sweet syndrome is made when the patient fulfills 2 of 2 major criteria and 2 of 4 minor criteria. The 2 major criteria are (a) an abrupt onset of tender or painful erythematous plaques or nodules occasionally with vesicles, pustules, or bullae, and (b) predominantly neutrophilic infiltration in the dermis without leukocytoclastic vasculitis. Minor criteria include specific preceding or concurrent medical conditions, fever, abnormal lab values, including leukocytosis and an elevated sedimentation rate, and a rapid response to systemic steroids.
- Systemic vasculitis is perhaps the most difficult to differentiate, but history of minor trauma in the area preceding lesion formation (pathergy) and undermining of the violaceous border should lead one toward the diagnosis of PG.⁹
- Ecthyma is a type of impetigo in which ulcers form. Bacterial cultures will be positive and this disease should respond to cephalixin or other oral antibiotics (see Chapter 116, Impetigo).
- Spider bites from the black recluse spider can easily resemble PG when they ulcerate. The history of a spider bite can help differentiate this from PG.
- Sporotrichosis is a fungal infection that often starts from an injury while gardening with roses. It is usually on the arm or hand and can resemble PG. Use fungal culture to diagnose this when the history suggests this as the diagnosis. Oral antifungal medications can treat this (**Figure 174-13**).

FIGURE 174-9 Atypical pyoderma gangrenosum on the hands with violaceous borders that match the fingernail color. The lesions are “juicy” and resemble those seen in Sweet syndrome and have occurred at sites of minor trauma (pathergy). (Courtesy of Jeff Meffert, MD.)

FIGURE 174-10 Pyoderma gangrenosum on the scalp of a woman in Africa. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-11 Pyoderma gangrenosum on the face, neck, and chest of a child in Africa. The scarring has caused adhesions between the face, neck, and chest. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-13 Sporotrichosis (fungal infection) with the typical sporotrichoid spread up the arm from an inoculation of the hand. Note the ulcers that resemble pyoderma gangrenosum on the arm of this Panamanian child. (Courtesy of Richard P. Usatine, MD.)

FIGURE 174-12 Sweet syndrome is the eponym for acute febrile neutrophilic dermatosis. The lesion looks like pyoderma gangrenosum and occurs at sites of minor trauma (pathergy). However, this patient has a fever and is systemically ill. (Courtesy of John Gonzalez, MD.)

FIGURE 174-14 A large venous stasis ulcer on the lower leg not healing with intensive wound care and compression stockings. A punch biopsy on the edge was performed to make sure this was not pyoderma gangrenosum. (Courtesy of Richard P. Usatine, MD.)

- Squamous cell carcinoma with ulcerations may look like PG. Its diagnosis requires a biopsy. If the ulcer is on sun-exposed area, squamous cell carcinoma should be considered. A shave or punch biopsy can be used to diagnose this malignancy (see Chapter 171, Squamous Cell Carcinoma).
- Venous insufficiency ulcers are typically seen around the medial malleolus and the most severe of these ulcers resembles PG (Figure 174-14). The presence of signs and symptoms of venous insufficiency should help differentiate this from PG (see Chapter 52, Venous Stasis).
- Mycosis fungoides is a cutaneous T-cell lymphoma that can ulcerate and resemble PG. Use tissue biopsy to differentiate these two conditions (see Chapter 176, Mycosis Fungoides).

MANAGEMENT

NONPHARMACOLOGIC

- At each visit, measure and document the lesion's depth, length, and width to track treatment progression.¹⁰
- Surgical debridement is contraindicated as pathergy occurs in 25% to 50% of cases and surgery will make the lesions worse. **SOR B**

MEDICATIONS

- Patients frequently are in pain from the lesions, so treatment is aimed at pain relief as well as healing the skin lesions.
- Therapy directed at the underlying inflammatory bowel disease (IBD), when present, usually results in healing, although treatment with steroids is often necessary.¹⁰ **SOR B**
- Topical medications are first-line therapy in cases of localized PG that are not severe. Start with potent corticosteroid ointments or tacrolimus ointment.^{10,11} **SOR B**
- Small ulcers can be managed with topical steroid creams, silver sulfadiazine, or potassium iodide solution. **SOR C**
- Intralesional injections with corticosteroids are also an option.^{10,11} **SOR B**
- Systemic treatment with oral corticosteroids, such as methylprednisolone (1 g/day IV for 3 days) or prednisone (0.5 to 1 mg/kg per day) or oral cyclosporine (e.g., 5 mg/kg per day) alone or together appears to be effective (in the absence of controlled trials) in many cases and should be considered first-line therapy.^{6,11} **SOR B** Response is usually rapid, with stabilization of the PG within 24 hours.¹²
- In steroid-refractory PG associated with IBD, infliximab was effective in case series and a small placebo-controlled trial.^{13,14} **SOR B** Other biologic therapies reported include alefacept, etanercept, efalizumab, and adalimumab.¹⁰ **SOR C**
- To date, case reports have been published that show therapeutic efficacy of dapsone (100 mg/day), azathioprine (50 to 150 mg/day), 6-mercaptopurine, mycophenolate mofetil (1 to 2 g twice daily), cyclophosphamide (2 to 3 mg/kg per day), and tacrolimus (0.1 mg/kg per day).^{11,15} **SOR C**

REFERRAL

In many cases, referral to a dermatologist is needed.

PROGNOSIS

- The prognosis of PG is generally good, but residual scarring is common (Figure 174-11) and recurrences may occur.
- Although many patients improve with initial immunosuppressive therapy, patients may follow a refractory course and require multiple therapies.

FOLLOW-UP

- All patients suspected of having PG need close and frequent follow-up to obtain a definitive diagnosis and treat this challenging condition.

PATIENT EDUCATION

- PG is a rare ulcerative skin condition that is poorly understood.
- A skin biopsy is needed to rule out other diagnoses.
- Most treatments are empirical and based on small studies.
- The risks and benefits of steroids and/or other immunosuppressive medications need to be explained.
- Surgical treatments are contraindicated.

175 SARCOIDOSIS

Yoon-Soo Cindy Bae-Harboe, MD
Khashayar Sarabi, MD
Amor Khachemoune, MD

PATIENT STORY

A 42-year-old man presents with “multiple bumps” that had been growing on his scalp, the back of the neck, and on preexisting scars (**Figure 175-1**). These lesions started developing slowly over a period of 1 year. The differential diagnosis of these lesions included cutaneous sarcoidosis, acne keloidalis nuchae, and pseudofolliculitis barbae. A punch biopsy was performed and the diagnosis of sarcoidosis was made.

INTRODUCTION

Sarcoidosis is a multisystem granulomatous disease most commonly involving the skin, lungs, lymph nodes, liver, and eyes. Patients of African descent are more commonly affected compared to white patients. Diagnosing cutaneous sarcoidosis is critical as 30% of these patients have been found to have systemic involvement. Diverse presentations of cutaneous sarcoidosis have been reported in addition to variants of specific sarcoidosis syndromes.

SYNONYMS

- Lupus pernio (cutaneous sarcoidosis).
- Darier-Roussy disease (subcutaneous sarcoidosis).
- Löfgren syndrome (erythema nodosum, hilar adenopathy, fever, arthritis).
- Heerfordt syndrome (parotid gland enlargement, uveitis, fever, cranial nerve palsy).

EPIDEMIOLOGY

- Cutaneous manifestations occur in approximately 25% of systemic sarcoidosis patients.
- The ratio between patients with only cutaneous sarcoid versus multisystem involvement is 1:3.
- Specific cutaneous involvement is seen most commonly in older, female patients of African descent (**Figures 175-2** and **175-3**).
- Common types are maculopapular, lupus pernio, cutaneous, or subcutaneous nodules, and infiltrative scars.
- Erythema nodosum (EN) occurs in 3% to 34% of patients with sarcoidosis and is the most common associated skin finding (see Chapter 178, Erythema Nodosum).
- Sarcoidosis-related EN is more prevalent in whites, especially Scandinavians. Irish and Puerto Rican females are also affected more often.

FIGURE 175-1 Papular and annular lesions of sarcoid on the scalp and neck of a 42-year-old black man. (Courtesy of Amor Khachemoune, MD.)

FIGURE 175-2 Lupus pernio in a 45-year-old black woman with sarcoid involving the nasal rim. (Courtesy of Richard P. Usatine, MD.)

- EN occurs between the second and fourth decades of life, more commonly in women.
- Nonspecific lesions of sarcoidosis reported, besides EN, include erythema multiforme, calcinosis cutis, prurigo, and lymphedema. Nail changes can include clubbing, onycholysis, subungual keratosis, and dystrophy, with or without underlying changes in the bone (cysts).

ETIOLOGY AND PATHOPHYSIOLOGY

- Sarcoidosis is a granulomatous disease with involvement of multiple organ systems with an unknown etiology.
- The typical findings in sarcoid lesions are characterized by the presence of circumscribed granulomas of epithelioid cells with little or no caseating necrosis, although fibrinoid necrosis is not uncommon.
- Granulomas are usually in the superficial dermis but may involve the thickness of dermis and extend to the subcutaneous tissue. These granulomas are referred to as “naked” because they only have a sparse lymphocytic infiltrate at their margins.

RISK FACTORS

- Positive family history.
- African descent.

DIAGNOSIS

CLINICAL FORMS OF DISEASE

Cutaneous involvement is either *specific* or *nonspecific*.

- Specific:
 - Typical noncaseating granulomas, no evidence of infection, foreign body, or other causes.
 - May be disfiguring, but almost always nontender and rarely ulcerate.
 - Maculopapular type is most common, red-brown or purplish, usually smaller than 1 cm, and found mostly on face, neck, upper back, and limbs (**Figure 175-4**).
 - Lupus pernio type are most distinctive lesions and present as purplish lesions resembling frostbites with shiny skin covering them, typically affecting nose, cheeks, ears, and lips and distal extremities (**Figures 175-2, 175-3, and 175-5**).
 - Lupus pernio may occur as a syndrome involving upper respiratory tract with pulmonary fibrosis, or be associated with chronic uveitis and bone cysts.
 - Annular or circinate type appear ribbon-like, with mild scaling and yellowish red in color, with centrifugal progression and central healing and depigmentation (**Figure 175-1**).
 - Plaque sarcoidosis is typically chronic, occurring over the forehead, extremities, and shoulders, but may heal without scarring (**Figure 175-6**).
 - Nodular cutaneous and subcutaneous plaques that are skin-colored or violaceous without epidermal involvement are typically seen in advanced systemic sarcoidosis (**Figure 175-7**).

FIGURE 175-3 Lupus pernio with red to violaceous sarcoid papules and plaques on the nose and lips. (Courtesy of Amor Khachemoune, MD.)

FIGURE 175-4 Maculopapular sarcoidosis on the leg of a 46-year-old white woman. (Courtesy of Amor Khachemoune, MD.)

- Areas of old scars that are damaged by trauma, radiation, surgery, or tattoo may also be infiltrated with sarcoid granulomas (**Figures 175-8 and 175-9**). Lesions may be tender and appear indurated with red or purple discoloration.
- Nonspecific:
 - EN lesions usually are not disfiguring, but tender to touch, especially when they occur with fever, polyarthralgias, and sometimes arthritis and acute iritis.
 - EN appears abruptly with warm, tender, reddish nodules on the lower extremities, most commonly the anterior tibial surfaces, ankles, and knees.
 - EN nodules are 1 to 5 cm, usually bilateral, and evolve through color stages: first bright red, then purplish, and lastly a bruise-like yellow or green appearance.
 - EN bouts occur with fatigue, fever, symmetrical polyarthritis, and skin eruptions that typically last 3 to 6 weeks with more than 80% of cases resolving within 2 years.⁴
 - EN is seen in the setting of Löfgren syndrome, appearing in conjunction with hilar lymphadenopathy (bilateral most often), and occasionally anterior uveitis and/or polyarthritis.
 - Löfgren syndrome is associated with right paratracheal lymph node involvement seen on x-ray.
 - Ulceration is typically not observed in EN, which heal without scarring.
 - Other nonspecific lesions of sarcoidosis include lymphedema, calcinosis cutis, prurigo, and erythema multiforme.
 - Nail changes seen in sarcoidosis include clubbing, onycholysis, and subungual keratosis.

FIGURE 175-5 Lupus pernio in a 48-year-old black man with sarcoid lesions on the nose and around the eyes. (Courtesy of Richard P. Usatine, MD.)

LABORATORY STUDIES

- Complete blood count (CBC) count with differential:
 - Leukopenia (5% to 10%) and/or thrombocytopenia may be seen.
 - Eosinophilia occurs in 24% of patients, and anemia occurs in 5% of patients.
 - Hypergammaglobulinemia (30% to 80%), positive rheumatoid factor, and decreased skin test reactivity.
 - Autoimmune hemolytic anemia and hypersplenism can occur in some patients, although rare.
 - Hypocapnia and hypoxemia may be present in certain patient populations, and may become worse with exercise.
- Serum calcium and 24-hour urine calcium levels:
 - Hypercalciuria has been found in 49% of patients in some studies, whereas 13% of patients had hypercalcemia.
 - Hypercalcemia occurs in sarcoidosis because of increased intestinal absorption of calcium that results from overproduction of a metabolite of vitamin D by pulmonary macrophages.
- Serum angiotensin-converting enzyme (ACE) level is elevated in 60% of patients:
 - Serum ACE levels are helpful in monitoring disease activity and treatment response. ACE is derived from epithelioid cells of the granulomas, therefore, it reflects granuloma load in the patient.
- Serum chemistries, such as alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, blood urea nitrogen (BUN), and creatinine levels. These levels may be elevated with hepatic and renal involvement.

FIGURE 175-6 Hypopigmented widespread cutaneous plaque sarcoidosis predominantly on the back of a black man. (Courtesy of Eric Kraus, MD.)

- Other—Elevated erythrocyte sedimentation rate, elevated antinuclear antibodies (30%), diabetes insipidus, and renal failure may be noted.

IMAGING STUDIES

- Chest x-ray (CXR):
 - Radiographic involvement is seen in almost 90% of patients. Chest radiography is used in staging the disease.
 - Stage I disease shows bilateral hilar lymphadenopathy (BHL). Stage II disease shows BHL plus pulmonary infiltrates. Stage III disease shows pulmonary infiltrates without BHL. Stage IV disease shows pulmonary fibrosis.
- CT of the thorax may demonstrate lymphadenopathy or granulomatous infiltration. Other findings may include small nodules with a bronchovascular and subpleural distribution, thickened interlobular septae, honeycombing, bronchiectasis, and alveolar consolidation.
- Pulmonary function tests—Evidence of both restrictive abnormalities and obstructive abnormalities may be found.

BIOPSY

- Punch biopsy is adequate to obtain a sample of skin that includes dermis.
- If EN nodules are deep, a biopsy should also include subcutaneous tissue.
- Biopsy specimens are sent for histologic examination, as well as stains and cultures to rule out infectious causes.

DIFFERENTIAL DIAGNOSIS

- Granulomatous skin disease (**Figure 175-10**).
 - Granuloma annulare (GA) is also a granulomatous skin disease, which appears in single or multiple rings in adults and children (see Chapter 173, Granuloma Annulare).
 - Rheumatoid nodules—These usually appear in the context of a diagnosed rheumatoid arthritis with joint disease present (see Chapter 97, Rheumatoid Arthritis).
 - Granulomatous mycosis fungoides—This is a type of cutaneous lymphoma with many clinical forms including granuloma formation (see Chapter 176, Mycosis Fungoides).
- Maculopapular type:
 - Lupus vulgaris—This is a type of cutaneous involvement with *Mycobacterium tuberculosis*.
 - Syringoma—These are small firm benign adnexal tumors usually appearing around the upper cheeks and lower eyelids.
 - Xanthelasma—These are the most common type of xanthomas. They are benign yellow macules, papules, or plaques often appearing on the eyelids. Approximately one half of the patients with xanthelasma have a lipid disorder (see Chapter 223, Hyperlipidemia).
 - Lichen planus—This is a very pruritic skin eruption with pink to violaceous papules and plaques. It may present in different body locations but the most common areas are the wrists and ankles (see Chapter 154, Lichen Planus).
 - Granulomatous rosacea—This is a variant of rosacea made of uniform papules involving the face.

FIGURE 175-7 Subcutaneous sarcoid (Darier-Roussy syndrome) in a patient with advanced systemic sarcoidosis. (Courtesy of Amor Khachemoune, MD.)

FIGURE 175-8 Sarcoidal plaque of the knee, which appeared after a trauma to the knee. (Courtesy of Amor Khachemoune, MD.)

FIGURE 175-9 Sarcoid on a heart-shaped homemade tattoo over the knee. (Courtesy of Amor Khachemoune, MD.)

- Acne keloidalis nuchae—This is commonly seen in dark-skinned patients. It presents with multiple perifollicular papules and nodules. The most common location is the back of the neck at the hairline (see Chapter 114, Pseudofolliculitis and Acne Keloidalis Nuchae).
- Pseudofolliculitis barbae—This is most commonly seen in patients with darker skin color, triggered by ingrown hair involving the beard area (see Chapter 114, Pseudofolliculitis and Acne Keloidalis Nuchae).
- Annular or circinate type of sarcoidosis (**Figure 175-11**):
- Granuloma annulare—Annular type (previously described above; see Chapter 173, Granuloma Annulare).
- Annular form of necrobiosis lipoidica—A granulomatous disease with areas of necrobiosis. This is usually seen on the pretibial areas of patients with diabetes. But not all patients have diabetes (see Chapter 222, Necrobiosis Lipoidica).
- These two entities may be differentiated histologically.
- Nodular cutaneous and subcutaneous type:
 - Morphea—Also known as localized scleroderma caused by excessive collagen deposition in the dermis or subcutaneous tissue leading to the formation of nodules (see Chapter 182, Scleroderma and Morphea).
 - Epidermal inclusion cyst—This is an encapsulated keratin-filled nodule of different sizes often found in the subcutaneous tissue. A central pore or punctum is often noted on examination of the overlying epidermis.
 - Lipoma—These are soft nodules of different sizes composed of mature fat cells and often found in the subcutaneous tissue.
 - Metastatic carcinoma—These nodular lesions often present in the context of a diagnosed primary carcinoma of other internal organs.
 - Foreign-body granuloma—This is usually localized to the area of introduction of the foreign body into the skin.

MANAGEMENT

- Cutaneous involvement of sarcoidosis is typically not life-threatening and, therefore, the major rationale for treatment is to prevent or minimize disfigurement. Cosmetic issues are particularly important on the face (**Figure 175-12 A**). Also, the lesions can be painful.
- Corticosteroids are the mainstay of treatment.¹⁻⁵ **SOR B**
- Limited cutaneous disease responds to very high-potency topical corticosteroids, or intralesional triamcinolone repeated monthly.^{3,4} **SOR B**
- Photochemotherapy (psoralen UVA) is successful in erythrodermic and hypopigmented lesions. **SOR C**
- Patients with lupus pernio may benefit from pulsed-dye or carbon dioxide laser treatments. **SOR C**
- Resistant lesions to topical therapy or large and diffuse lesions require prednisone.^{2,5} **SOR B**
- To prevent complications from long-term treatment by steroids, hydroxychloroquine or chloroquine are used as steroid-sparing agents.⁶ **SOR C**

FIGURE 175-10 Granulomatous plaques of biopsy proven sarcoidosis on the arm of a woman. She also has sarcoidosis of the lung. (Courtesy of Richard P. Usatine, MD.)

FIGURE 175-11 Violaceous sarcoidal papules coalescing into annular plaques on the back. (Courtesy of Richard P. Usatine, MD.)

- Other combinations that have been successful in chronic cutaneous disease and lung disease are methotrexate or azathioprine with low-dose prednisone.⁵ SOR C
- Agents such as cyclophosphamide and cyclosporin are also used but with caution because of severe drug toxicity.⁷ SOR C
- Infliximab, a tumor necrosis factor (TNF)- α monoclonal antibody has been found to be effective for severe cutaneous sarcoidosis with pulmonary involvement (**Figure 175-13**).⁸ SOR C

REFERRAL

- A multidisciplinary approach is imperative in patients with systemic sarcoidosis.
- Patients with eye symptoms should be referred to an ophthalmologist (**Figure 175-12 B**).
- Patients with lung involvement should be referred to a pulmonologist.
- Results from laboratory work-up may dictate appropriate referral.

PREVENTION AND SCREENING

As the cause remains to be elucidated, no preventative measures have been established.

Patients presenting with cutaneous sarcoidosis should be screened as clinically indicated.

PROGNOSIS

- Patients of African descent have more severe lung disease compared with white patients at presentation and an overall poorer long-term prognosis.⁹
- The presence of EN has been associated with a decreased frequency of respiratory involvement.⁹
- Lupus pernio, more commonly seen in patients of African descent, indicates a chronic disease course (**Figure 175-12** and **175-13**).⁹
- The prognostic value of cutaneous lesions alone remains unclear.⁹

FOLLOW-UP

Patients with cutaneous sarcoidosis should be worked up for systemic sarcoidosis. Regular follow-up is necessary.

PATIENT EDUCATION

Inform patients about the risk that systemic sarcoidosis can occur even if the skin is the only area currently involved.

176 CUTANEOUS T-CELL LYMPHOMA

Gina Chacon, MD
Anjeli Nayar, MD
Richard P. Usatine, MD

PATIENT STORY

A 52-year-old black woman presented with a 7-month history of a hypopigmented rash in a symmetric distribution on her upper thighs and arms (**Figures 176-1** and **176-2**). She had been from evacuated New Orleans following Hurricane Katrina. She had waded through polluted waters for hours before being rescued by a boat. Four days passed before she had access to a shower at which time she noticed a single erythematous spot the size of a silver dollar on her left thigh. Over the next several weeks, it faded to hypopigmented macules and plaques and eventually spread to both thighs and arms. The physical examination revealed no lymphadenopathy. A hematoxylin and eosin (H&E) stain of a full-thickness punch biopsy revealed “cerebriform” lymphocytes at the dermal–epidermal junction characteristic of mycosis fungoides (MF), a type of cutaneous T-cell lymphoma (CTCL). Her blood tests were essentially normal, and she was HIV-negative. The patient reported no improvement with topical high-potency generic steroid to affected areas and is currently receiving narrow-band UVB treatment twice weekly.

INTRODUCTION

CTCL clinically and biologically represent a heterogeneous group of non-Hodgkin lymphomas, with MF and Sézary syndrome being the most common subtypes.¹

EPIDEMIOLOGY

- The annual incidence of CTCL in the United States has increased from 2.8 per 1 million (1973 to 1977) to 9.6 per 1 million (1998 to 2002) according to data from Criscione and Weinstock.²
- CTCL is a rare disease, with 1000 new cases per year in the United States, comprising approximately 0.5% of all non-Hodgkin lymphoma cases.^{3,4}
- The two most common types of CTCL are MF (50% to 72%), which is generally indolent in behavior, and Sézary syndrome (1% to 3%), an aggressive leukemic form of the disease.²
- It is more common in African Americans than in whites, with an incidence ratio of 6:1.³
- It is more common in males, with a male-to-female ratio of 2:1.
- Median age at presentation is between 50 and 70 years,² although pediatric and young adult cases do occur.¹

FIGURE 176-1 The hypopigmented patches of mycosis fungoides on the thighs of a 52-year-old black woman. This is the patch stage of the disease. Although this mimicked vitiligo, the distribution and appearance warranted a biopsy that provided a definitive diagnosis of mycosis fungoides. (Courtesy of Richard P. Usatine, MD.)

FIGURE 176-2 Hypopigmented patches on the arm of the woman in **Figure 176-1** with mycosis fungoides. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- The exact etiology of CTCL is unknown, but environmental, infectious, and genetic causes have been suggested. CTCL is a malignant lymphoma of helper T cells that usually remain confined to skin and lymph nodes (LNs). MF is a specific type of CTCL named for the mushroom-like skin tumors seen in severe cases.³
- Human T-lymphocytic virus (HTLV) types 1 and 2, HIV-1, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and *Borrelia burgdorferi* have been suggested, but unproven, infectious causes of MF.^{4,5} Environmental exposure to Agent Orange may be responsible for some cases.³ There is one case report of possible conjugal transmission of MF between a heterosexual couple who developed advanced MF within 14 months of one another.⁵
- MF and Sézary syndrome (SS) are associated with specific human leukocyte antigen (HLA) types (Aw31, Aw32, B8, Bw38, and DR5).⁴ Genetic predisposition is also suggested by detection of HLA class II alleles DRB1*11 and DQB1*03 in association with sporadic and familial malignancy and familial clustering among Israeli Jews.^{4,6}
- Metastasis, to the liver, spleen, lungs, GI tract, bone marrow, and the central nervous system (CNS) may occur via T-cell spread through the lymphatic system.^{3,4}
- The reduction of T-cell receptor complexity contributes to immunosuppression in advanced MF and SS, and may manifest clinically as herpes simplex or zoster.⁷ Death is usually secondary to systemic infection, especially from *Staphylococcus aureus* and *Pseudomonas aeruginosa*.
- Host antitumor immunity also deteriorates, and patients have an increased risk for secondary malignancies, including higher-grade non-Hodgkin lymphoma, Hodgkin disease, secondary melanoma, and colon cancer in addition to cardiopulmonary complications.⁷

DIAGNOSIS

CLINICAL FEATURES

- The most common initial presentation involves patches or scaly plaques with a persistent rash that is often pruritic and usually erythematous (**Figures 176-1 to 176-4**).³ Patches may evolve to generalized, infiltrated plaques or to ulcerated, exophytic tumors (**Figures 176-5 and 176-6**).^{4,8}
- Hypo- or hyperpigmented lesions, petechiae, poikiloderma (skin atrophy with telangiectasia), and alopecia with or without mucinosis are other findings. The folliculotropic variant of MF presents with spotty alopecia (**Figure 176-7**).
- A “premycotic” phase may precede definitive diagnosis for months to decades, which involves nonspecific, slightly scaling skin lesions that intermittently appear and may eventually resolve with topical steroids.
- SS is characterized by generalized exfoliative erythroderma, lymphadenopathy, and atypical Sézary cells in the peripheral blood. Diffuse infiltration of malignant T cells in SS may exaggerate facial lines, creating a leonine facies.⁸

FIGURE 176-3 Reticulated mycosis fungoides (MF). This netlike pattern of mycosis fungoides is also called *parapsoriasis variegata*. (Courtesy of Heather Wickless, MD.)

FIGURE 176-4 Plaque stage of mycosis fungoides (MF) on the arm of a 57-year-old nurse. She has had mycosis fungoides for 8 years and has intermittently been on chemotherapy. Recently, her mycosis fungoides has worsened and she was started on nitrogen mustard. (Courtesy of E.J. Mayeaux, Jr., MD.)

- “Invisible MF” describes pruritus without visible lesions but the skin biopsy is positive for monoclonal T-cell infiltrates.⁴

TYPICAL DISTRIBUTION

- Lesions may affect any skin surface, but typically initially develop on non–sun-exposed areas, such as the trunk below the waistline, flanks, breasts, inner thighs and arms, and the periaxillary areas (**Figure 176-8**).⁹
- If there is follicular involvement, lesions may be found on the face or scalp (**Figures 176-9** and **176-10**).
- MF occasionally presents as a refractory dermatosis of the palms or soles.

BIOPSY AND LABORATORY STUDIES

- A full-thickness punch biopsy of the lesion is the most important diagnostic tool. If the initial biopsy is negative but the rash persists, the biopsy should be repeated.³ Topical treatments and systemic immunosuppressants should be discontinued 2 to 4 weeks before the biopsy.¹⁰
- If the LNs are palpable or lymphadenopathy is suspected, also known as “dermatopathic lymphadenitis,” biopsies should be performed (**Figure 176-11**).⁴
- A bone marrow biopsy should be performed if there is proven nodal or blood involvement.
- Histology—The skin biopsy may reveal Pautrier microabscesses or an inflammatory cell band-like infiltrate lining the basal layer or in the upper dermis (“mononuclear epidermotropism”). Malignant lymphocytes have hyperchromatic and convoluted or “cerebriform” nuclei. Capillary dermal fibrosis may also be observed.¹⁰
- Radiography—A chest radiograph and CT scan of the abdomen and pelvis are recommended for advanced stages IIB to IIIB, or if visceral disease is suspected.⁹ A combination of CT and positron emission tomography (PET) scans offers more sensitive detection of LN involvement than either imaging study alone.⁴
- Blood tests for infectious etiology—HIV test, HTLV type 1, EBV, CMV, as indicated by clinical history.
- Serology and blood tests—A complete blood cell count with differential, a buffy coat smear to screen for Sézary cells, lactic dehydrogenase and uric acid as markers for bulky or aggressive disease, and liver function tests to detect hepatic involvement should be measured. Progression of MF is associated with increased serum concentrations of immunoglobulin (Ig) E and IgA.⁴ Peripheral eosinophilia is an independent marker for poor prognosis and disease progression.^{4,11}
- Flow cytometry—This test may be used to detect malignant clones and to quantify CD8+ lymphocytes to assess immunocompetence.
- Immunophenotyping may be used to support histology results.
- Polymerase chain reaction (PCR) and Southern blot testing are recommended to detect T-cell rearrangements, if histology and immunophenotyping results are equivocal and to detect abnormal cells in LNs.⁴
- The International Society for Cutaneous Lymphoma proposed criteria for diagnosing early “classic” MF by incorporating clinical;

FIGURE 176-5 Tumor stage of mycosis fungoides (MF). (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 176-6 Tumor stage of mycosis fungoides (MF) with large leg ulcers. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

histopathologic; molecular biologic and immunopathologic features, including the presence of persistent or progressive patches or thin plaques in unexposed areas and/or poikiloderma; superficial lymphoid infiltrate, epidermotropism with spongiosis; lymphocytes with hyperchromatic and cerebriform nuclei; epidermal/dermal discordance between CD2, CD3, CD5, or CD7; and clonal T-cell receptor rearrangement.¹⁰ The International Society for Cutaneous Lymphoma also proposed criteria for diagnosing SS with leukemic blood involvement including an absolute Sézary cell count of greater than 1000/mm³, a CD4-to-CD8 ratio of 10 or greater, T-cell chromosomal abnormalities detected by Southern blot or PCR, increased circulation of T cells, and aberrant expression of pan T-cell markers as assessed by flow cytometry.⁸

DIFFERENTIAL DIAGNOSIS

- “Premycotic” period preceding diagnosis of MF may resemble parapsoriasis en plaque or nonspecific dermatitis.^{4,10}
- MF with erythroderma must be distinguished from generalized atopic dermatitis, contact dermatitis, photodermatitis, drug eruptions, erythrodermic psoriasis, and idiopathic hyper-eosinophilic syndrome (see Chapter 156, Erythroderma).^{4,8}
- Unilesional MF may resemble nummular eczema, lichen simplex chronicus, erythema chronicum migrans, tinea corporis, or digitate dermatosis (a variant of small plaque parapsoriasis).¹⁰
- Vitiligo typically involves discrete, hypopigmented macules on the hands and face that coalesce into larger areas.³ However, some MF may mimic vitiligo as seen in (Figures 176-1 and 176-2). The distribution of the hypopigmented macules in this case is atypical for vitiligo and this prompted a biopsy that led to the diagnosis of MF (see Chapter 198, Vitiligo).
- Idiopathic guttate hypomelanosis is a benign condition involving smaller hypopigmented macules than those seen in MF.³
- In patients with HIV, histopathology; resembling MF may represent a reactive inflammatory condition instead. Nonepidermotropic large T-cell cutaneous lymphoma and B-cell diffuse cutaneous lymphoma are more frequent complications than MF in these patients.¹²

MANAGEMENT

- The current treatments for CTCL can be divided into skin-directed therapy and systemic therapy. Of the skin-directed therapies, topical corticosteroids are widely used in all stages of CTCL in the hopes that they will help control the disease and palliate any cutaneous symptoms of itch.¹⁵ **SOR B**
- For stage I disease localized to the skin, symptomatic treatment with emollients, antipruritics (Doxepin cream 5%) and topical high-potency steroids (clobetasol cream) on an outpatient basis are recommended.⁹ **SOR C** Topical retinoids or topical chemotherapy (nitrogen mustard, bischloroethylnitrosourea, or carmustine) are treatment alternatives for localized disease and effective adjuvants in generalized disease.^{3,9,13,14} **SOR B**

FIGURE 176-7 A. Folliculotropic variant of mycosis fungoides (MF) with visible alopecia in the eyebrow region of this 38-year-old man. B. Note the absence of hair growth in parts of the beard where there is follicular involvement. (Courtesy of Richard P. Usatine, MD.)

- Bexarotene 1% topical gel may be used if disease persists despite treatment or if other medication is not tolerated. When used in combination with psoralen-enhanced UV light (PUVA), bexarotene decreases the total UVA dosage needed and if used as maintenance therapy increases the duration of remission.¹⁴ SOR C
- Alternatively, PUVA may also be used concurrently with interferon (IFN), 3 times weekly, or retinoids until skin lesions clear, then continued as maintenance therapy at a reduced frequency.¹⁴ SOR C
- For a plaque recalcitrant to PUVA and retinoid combination therapy, 1 case study showed that imiquimod 5% topical cream effectively cleared the lesion.⁷ SOR C
- UVA may also be enhanced with methoxsalen or Oxsoresalen instead of psoralen.⁹ SOR C
- Phototherapy is a safe, effective, and well-tolerated, first-line therapy in patients with early stage CTCL, with prolonged disease-free remissions being achieved. It suggests that narrowband UVB is at least as effective as PUVA for treatment of early stage MF.^{15,16} SOR C
- Narrowband UVB light has proven effective in early MF and prolonging remission, although an optimal maintenance protocol still needs to be established.¹⁷ SOR C
- The therapeutic effects of PUVA and UVB in immune-mediated skin diseases have been attributed to the direct apoptosis of lymphocytes, modification of cell surface receptors, and alteration in production of certain mediators.¹⁵
- Photodynamic therapy with 5-aminolevulinic acid (PDT-ALA) was found to effectively eradicate localized infiltrates better than topical steroids, but more studies are needed before it becomes standardized treatment.¹³ SOR C
- In general, photodynamic therapy works via direct cytotoxicity, vascular damage, and immune host response.^{8,18}
- Stage II disease involves the regional LNs and may be treated the same as for stage I. For stage IIB, the most recommended therapy is total-skin electron-beam therapy (EBT) followed by nitrogen mustard treatment for 6 or more months.¹⁴ SOR C For disease relapse after EBT, PUVA may be used in combination with IFN or a systemic retinoid.¹⁴ SOR C Other systemic therapies include fusion toxins, monoclonal antibody treatment, and single-agent chemotherapy.⁹ For recalcitrant tumors, there is no evidence that combination systemic chemotherapy regimens offer superior survival outcome than single agents.^{9,14} SOR C
- Stage III, or erythrodermic disease without extracutaneous disease or with limited LN involvement, should be treated with chemotherapy or photophoresis for 4 weeks.¹⁴ SOR C Extracorporeal photochemotherapy involves irradiation of white blood cells with PUVA after leukopheresis before reinfusing the blood cells intravenously.⁹ If the response is delayed, photophoresis may be combined with IFN or systemic retinoids.
- Stage IV extracutaneous disease should be treated with systemic chemotherapy. Although response rates are improved with combination chemotherapy, the response duration is less than 1 year. Regimens include cyclophosphamide, vincristine, and prednisone (CVP), CVP plus Adriamycin, CVP plus methotrexate, or

FIGURE 176-8 Mycosis fungoides (MF) causing hyperpigmented patches over the face, trunk, breasts, and upper extremities. (Courtesy of Richard P. Usatine, MD.)

FIGURE 176-9 Mycosis fungoides (MF) on the face with an ulcerated tumor under the nose. (Courtesy of Richard P. Usatine, MD.)

cyclophosphamide, vincristine, Adriamycin, and etoposide. Adjuvant treatments may include IFN, systemic retinoids, and photophoresis. Single-agent chemotherapy includes methotrexate, liposomal doxorubicin, gemcitabine, etoposide, cyclophosphamide, and purine analogs.¹⁴ **SOR**  The patient should be referred to a dermatologist, and to medical and radiation oncologists.³

PROGNOSIS AND FOLLOW-UP

- Patient age and stage are the most important clinical prognostic factors.¹⁹
- Patients have a normal life expectancy, if diagnosed early during stage IA in which the patch or plaque is limited to less than 10% of the skin surface area.³
- MF and SS are otherwise difficult to cure and have a prognosis of 3.2 years for stage IIB cutaneous tumors, 4 to 6 years for stage III generalized erythroderma, and less than 1.5 years for stage IVA and stage IVB with LN and visceral involvement, respectively.⁹
- The patient should be monitored for development of secondary malignancies.

POTENTIAL COMPLICATIONS

- Infection, particularly from indwelling intravenous catheters or from lymph node biopsy sites.
- High-output cardiac failure.
- Anemia of chronic disorders.
- Edema.
- Secondary malignancies (e.g., skin cancer, melanoma).

PATIENT EDUCATION

- Avoid sun exposure, stay in a cool environment, and keep skin lubricated.
- See your physician if any new skin symptoms and signs appear or the medication is not working.
- Avoid smoking and second-hand smoke.

SECTION 14 HYPERSENSITIVITY SYNDROMES

177 ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME, AND TOXIC EPIDERMAL NECROLYSISCarolyn Milana, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 14-year-old boy presents to the emergency department with a 1-day history of fever associated with lip swelling and peeling (**Figure 177-1 A**). Within 48 hours he developed involvement of his ocular (**Figure 177-1 B**) and urethral mucosa along with an erythematous papular rash on his trunk that spread to his extremities. In **Figure 177-1 C** target lesions can be seen on the back. He was diagnosed with Stevens-Johnson syndrome and admitted to the hospital.

INTRODUCTION

Erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) are skin disorders thought to be types of hypersensitivity reactions (undesirable reactions produced by a normal immune system in a presensitized host) that occur in response to medication, infection, or illness. Both SJS and TEN are severe cutaneous reactions thought to describe the same disorder, only differing in severity (TEN more severe); however, there is debate as to whether these three fall into a spectrum of disease that includes EM.

SYNONYMS

- EM has also been called EM minor.
- SJS has been called EM major in the past but it is now thought to be a distinct entity different from all types of EM.
- TEN is also known as Lyell syndrome.

EPIDEMIOLOGY

- The incidence of EM has been estimated to range from 1 in 1000 persons to 1 in 10,000 persons.¹ The true incidence of the disease is unknown.¹
- SJS and TEN are rare severe cutaneous reactions often caused by drugs. Reports of incidence vary from 1.2 to 6 per 1 million for SJS and from 0.4 to 1.2 per 1 million for TEN.²⁻⁴

FIGURE 177-1 Stevens-Johnson syndrome in a 14-year-old boy who received penicillin for pneumonia. **A.** Lips and mouth are involved. **B.** Eye involvement. (continued)

- EM most commonly occurs between the ages of 10 and 30 years, with 20% of cases occurring in children and adolescents.⁵
- With respect to EM, males are affected slightly more often than females.⁵

ETIOLOGY AND PATHOPHYSIOLOGY

Numerous factors have been identified as causative agents for EM:

- Herpes simplex virus (HSV) I and HSV II are the most common causative agents, having been implicated in at least 60% of the cases (**Figure 177-2**).^{6,7}
 - The virus has been found in circulating blood,⁸ as well as on skin biopsy of patients with EM minor.⁶
- For SJS and TEN, the majority of cases are drug induced.
- Drugs most commonly known to cause SJS and TEN are sulfonamide antibiotics, allopurinol, NSAIDs, amine antiepileptic drugs (phenytoin and carbamazepine), and lamotrigine.⁹
 - *Mycoplasma pneumoniae* has been identified as the most common infectious cause for SJS.⁷

Other less-common causative agents for EM, SJS, and TEN include:

- Infectious agents such as *Mycobacterium tuberculosis*, group A streptococci, hepatitis B, Epstein Barr virus, *Francisella tularensis*, *Yersinia*, enteroviruses, *Histoplasma*, *Coccidioides*.¹
- Neoplastic processes, such as leukemia and lymphoma.¹
- Antibiotics, such as penicillin, isoniazid, tetracyclines, cephalosporins, and quinolones.
- Anticonvulsants, such as phenobarbital and valproic acid.^{1,7}
- Other drugs, including captopril, etoposide, aspirin, and allopurinol.
- Immunizations, such as Calmette-Guérin bacillus, diphtheria-tetanus toxoid, hepatitis B, measles-mumps-rubella, and poliomyelitis.⁶
- Other agents or triggers, including radiation therapy, sunlight, pregnancy, connective tissue disease, and menstruation.¹

Although the pathogenesis of EM, SJS, and TEN remains unknown, recent studies show that it may be as a result of a host-specific cell-mediated immune response to an antigenic stimulus that activates cytotoxic T-cells and results in damage to keratinocytes.^{6,9}

- The epidermal detachment (skin peeling) seen in SJS and TEN appears to result from epidermal necrosis in the absence of substantial dermal inflammation.

RISK FACTORS

- Recent evidence shows individuals with certain human leukocyte antigen (HLA) alleles may be predisposed to developing SJS/TEN when taking certain drugs.²
- Certain diseases, such as HIV/AIDS (**Figure 177-3**), malignancy, or autoimmune disease, also predispose individuals to SJS/TEN.^{2,10}

FIGURE 177-1 (Continued) C. Target lesions on his back. (Courtesy of Dan Stulberg, MD.)

FIGURE 177-2 Erythema multiforme in a 43-year-old woman that recurs every time she breaks out with genital herpes. A. Target lesions on hand. B. Target lesions on elbow. (Courtesy of Richard P. Usatine, MD.)

FIGURE 177-3 Stevens-Johnson syndrome that evolved into toxic epidermal necrolysis in an human immunodeficiency virus-positive man with a CD4 of 6. He presented to the emergency department with fever and rash on face, eyes, and mouth. Chest x-ray suggested pneumonia, so he was started on azithromycin, ceftriaxone, and trimethoprim-sulfamethoxazole. He developed bulla on skin and a skin biopsy confirmed toxic epidermal necrolysis, possibly secondary to one of the antibiotics. He was transferred to a burn unit and given intravenous gammaglobulin 1 g/kg for 3 days. The patient survived. **A.** Oral lesions. **B.** Eye and facial involvement. **C.** Trunk and upper extremities involved so that greater than 30% of the skin was affected. (Courtesy of Robert T. Gilson, MD.)

DIAGNOSIS

CLINICAL FEATURES

In all of these conditions, there is a rapid onset of skin lesions. EM is a disease in which patients present with the following lesions:

- Classic lesions begin as red macules and expand centrifugally to become target-like papules or plaques with an erythematous outer border and central clearing (iris or bull's-eye lesions) (**Figures 177-4 to 177-7**). Target lesions, although characteristic, are not necessary to make the diagnosis. The center of the lesions should have some epidermal disruption, such as vesicles or erosions.
- Lesions can coalesce and form larger lesions up to 2 cm in diameter with centers that can become dusky purple or necrotic.
- Unlike urticarial lesions, the lesions of EM do not appear and fade; once they appear they remain fixed in place until healing occurs many days to weeks later.
- Patients are usually asymptomatic, although a burning sensation or pruritus may be present.
- Lesions typically resolve without any permanent sequelae within 2 weeks.
- Recurrent outbreaks are often associated with HSV infection (**Figure 177-2**).^{6,7}

In both SJS and TEN, patients may have blisters that develop on dusky or purpuric macules. SJS is diagnosed when less than 10% of the body surface area is involved, SJS/TEN overlap when 10% to 30% is involved, and TEN when greater than 30% is involved.

- Lesions may become more widespread and rapidly progress to form areas of central necrosis, bullae, and areas of denudation (**Figure 177-1**).
- Fever higher than 39°C (102.2°F) is often present.
- In addition to skin involvement, there is involvement of at least 2 mucosal surfaces, such as the eyes, oral cavity, upper airway, esophagus, GI tract, or the anogenital mucosa (**Figures 177-1 and 177-3**).
- New lesions occur in crops and may take 4 to 6 weeks to heal.
- Large areas of epidermal detachment occur (**Figures 177-8 to 177-10**).
- Severe pain can occur from mucosal ulcerations but skin tenderness is minimal.
- Skin erosions lead to increased insensible blood and fluid losses, as well as an increased risk of bacterial superinfection and sepsis.
- These patients are at high risk for ocular complications that may lead to blindness. Additional risks include bronchitis, pneumonitis, myocarditis, hepatitis, enterocolitis, polyarthritis, hematuria, and acute tubular necrosis.

TYPICAL DISTRIBUTION

- The distribution of the rash in EM can be widespread.
- The distal extremities, including the palms and soles, are most commonly involved.
- Extensor surfaces are favored.

FIGURE 177-7 Erythema multiforme on the dorsum of the hand showing targets with small, eroded centers. There should be some epidermal erosion to diagnose erythema multiforme. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 177-9 Toxic epidermal necrolysis with large areas of desquamation on the leg. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 177-8 Toxic epidermal necrolysis with desquamation of skin on the hand. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 177-10 Toxic epidermal necrolysis secondary to amoxicillin. A. Face with large areas of desquamation and loss of pigmentation. B. Skin detaching from leg in large sheets and bullae. (Courtesy of Richard P. Usatine, MD.)

- Oral lesions may be present, especially in SJS (**Figures 177-1 and 177-3**).
- Severe lesions with exfoliation and extensive mucosal lesions occur in SJS and TEN (**Figures 177-8 to 177-10**).

LABORATORY AND IMAGING

- There are no consistent laboratory findings with these conditions. The diagnosis is usually made based on clinical findings.
- Routine blood work may show leukocytosis, elevated liver transaminases, and an elevated erythrocyte sedimentation rate.
- In TEN, leukopenia may occur.

BIOPSY

- A cutaneous punch biopsy can be performed to confirm the diagnosis or to rule out other diseases.
- Histologic findings of EM will show a lymphocytic infiltrate at the dermal–epidermal junction. There is a characteristic vacuolization of the epidermal cells and necrotic keratinocytes within the epidermis.¹

DIFFERENTIAL DIAGNOSIS

- Bullous pemphigoid—Can be either subacute or acute with tense widespread blisters that can occur after persistent urticaria; mucosal involvement is rare. Significant pruritus can be present. As with EM, SJS, and TEN, bullous pemphigoid can occur after certain exposures such as UV radiation, or certain drugs (Chapter 184, Bullous Pemphigoid).
- Urticaria—A skin reaction characterized by red wheals that are usually pruritic. Unlike EM, individual lesions rarely last more than 24 hours (Chapter 150, Urticaria and Angioedema).
- Kawasaki disease—Fever persists at least 5 days and there must be at least four of the following features¹¹:
 - Changes in extremities—*Acute*: erythema of palms, soles; edema of hands and feet; or *subacute*: periungual peeling of fingers and toes in weeks 2 and 3.
 - Polymorphous exanthem.
 - Bilateral bulbar conjunctival injection without exudate.
 - Changes in lips and oral cavity—Erythema, lips cracking, strawberry tongue (see Chapter 34, Scarlet Fever and Strawberry Tongue), diffuse injection of oral and pharyngeal mucosae.
 - Cervical lymphadenopathy (>1.5 cm diameter), usually unilateral.
- Cutaneous vasculitis—Also caused by a hypersensitivity reaction, lesions are palpable papules or purpura. Blisters, hives, and necrotic ulcers can occur on the skin. Lesions are usually located on the legs, trunk, and buttocks (see Chapter 179, Vasculitis).
- Erythema annulare centrifugum—A hypersensitivity reaction caused by a variety of agents. Lesions look similar with erythematous papules of a few to several centimeters that enlarge and clear centrally and may be vesicular. Lesions tend to appear on the legs and thighs, but may occur on upper extremities, trunk, and face; palms and soles are spared (see Chapter 206, Erythema Annulare Centrifugum).

- Staphylococcal scalded skin syndrome—Rash may also follow a prodrome of malaise and fever but is macular, brightly erythematous, and initially involves the face, neck, axilla, and groin. Skin is markedly tender. Like SJS and TEN, large areas of the epidermis peel away. Unlike TEN, the site of the staphylococcal infection is usually extracutaneous (e.g., otitis media, pharyngitis) and not the skin lesions themselves (Chapter 116, Impetigo).

MANAGEMENT

EM:

- The treatment is mainly supportive. Symptomatic relief may be provided with topical emollients, systemic antihistamines, and acetaminophen. These do not, however, alter the course of the illness.
- The use of corticosteroids has not been well studied, but is thought to prolong the course or increase the frequency of recurrences in HSV-associated cases.⁷
- Prophylactic acyclovir has been used to control recurrent HSV-associated EM with some success.⁷

SJS and TEN:

- Treatment again, is mainly supportive and may require intensive care or placement in a burn unit. Early diagnosis is imperative so that triggering agents can be discontinued.
- Oral lesions can be managed with mouthwashes and glycerin swabs.
- Skin lesions should be cleansed with saline or Burow solution (aluminum acetate in water).
- IV fluids should be given to replace insensible losses.
- Daily examinations for secondary infections should occur and systemic antibiotics should be started as needed.
- Consultation with an ophthalmologist is important because of the high risk of ocular sequelae.
- Pharmacologic therapy is widely debated in the literature. Evidence suggests that intravenous immunoglobulin (IVIG) at doses of 2 to 3 g/kg can help shorten the course and improve outcome if started early in the course of the disease.¹²
- Systemic corticosteroids have been the mainstay of treatment for SJS/TEN. Recent evidence, however, suggests there may be an increase in morbidity and mortality when used for TEN.¹²
- Other agents that have been tried with limited success include thalidomide, tumor necrosis factor (TNF)- α inhibitors, cyclophosphamide, cyclosporine, and plasmapheresis.

PREVENTION

Screening populations known to carry HLA alleles prior to starting medications with higher risks for SJS/TEN has been suggested by some researchers.²

PROGNOSIS

- EM usually resolves spontaneously within 1 to 2 weeks.
- Recurrence of EM is common, especially when preceded by HSV infection.
- Prognosis is poorer for patients with SJS and TEN if they are older, have a large percentage of body surface area involved, or have intestinal or pulmonary involvement.
- Mortality for SJS/TEN can be predicted based on the severity of illness score for TEN.¹³ One point is given for each of the following: serum blood urea nitrogen greater than 10 mmol/L; serum bicarbonate less than 20 mmol/L; serum glucose greater than 14 mmol/L; age older than 40 years; malignancy present; heart rate greater than 120 beats per minute; percentage of body surface area involved greater than 10%. Scores of 0 to 1 are associated with a mortality rate of 3.2% whereas scores of 5 or higher are associated with a mortality rate of 90%.
- For patients with SJS, mortality rates have been reported of 5% to 10% and up to 30% for TEN.^{9,14}

FOLLOW-UP

- For uncomplicated cases, no specific follow-up is needed.
- For patients with EM major and any of the complications listed above, follow-up should be arranged with the appropriate specialist.

PATIENT EDUCATION

- If an offending drug is found to be the cause, it should be discontinued immediately.
- Patients with HSV-associated EM should be made aware of the risk of recurrence.

178 ERYTHEMA NODOSUM

E.J. Mayeaux, Jr., MD
Lucia Diaz, MD
Richard Paulis, MD

PATIENT STORY

A young woman presented to the office with several days of overall malaise, fever, and sore throat. At the time of presentation she noted some painful bumps on her lower legs, and denied trauma (**Figure 178-1**). No history of recent cough or change in bowel habits has been reported. The patient had no chronic medical problems, took no medications and had no known drug allergies. Her temperature was slightly elevated, but other vitals were normal. On examination, her oropharynx revealed tonsillar erythema and exudates. Bilateral lower extremities were spotted with slightly-raised, tender, erythematous nodules that varied in size from 2 to 6 cm. Rapid strep test was positive and she was diagnosed clinically with erythema nodosum (EN) secondary to group A β -hemolytic *Streptococcus*. She was treated with penicillin and NSAIDs, and was advised temporary bedrest. She experienced complete resolution of the EN within 4 weeks.

INTRODUCTION

EN is a common inflammatory panniculitis characterized by ill-defined, erythematous patches with underlying tender, subcutaneous nodules. It is a reactive process caused by chronic inflammatory states, infections, medications, malignancies, and unknown factors.

SYNONYMS

Lofgren syndrome (with hilar adenopathy).

EPIDEMIOLOGY

- Erythema nodosum occurs in approximately 1 to 5 per 100,000 persons.¹ It is the most frequent type of septal panniculitis (inflammation of the septa of fat lobules in the subcutaneous tissue).²
- EN tends to occur more often in women, with a male-to-female ratio of 1:4.5 in the adult population, generally during the second and fourth decades of life (**Figures 178-1** to **178-3**).³
- In 1 study, an overall incidence of 54 million people worldwide was cited in patients older than 14 years of age.⁴
- In the childhood form, the female predilection is not seen.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most EN is idiopathic (**Figures 178-3** and **178-4**). Although the exact percentage is unknown, 1 study estimated that 55% of

FIGURE 178-1 Erythema nodosum secondary to group A β -hemolytic *Streptococcus* in a young woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 178-2 EN in a middle-aged woman around the knee secondary to sarcoidosis. (Courtesy of Richard P. Usatine, MD.)

EN is idiopathic.⁵ This may be influenced by the fact that EN may precede the underlying illness. The distribution of etiologic causes may be seasonal.⁶ Identifiable causes can be infectious, reactive, pharmacologic, or neoplastic.

- Histologic examination is most useful in defining EN. Defining characteristics of EN are a septal panniculitis without presence of vasculitis. That this pattern develops in certain areas of skin may be linked to local variations in temperature and efficient blood drainage.
- Septal panniculitis begins with polymorphonuclear cells infiltrating the septa of fat lobules in the subcutaneous tissue. It is thought that this is in response to existing immune complex deposition in these areas.⁷ This inflammatory change consists of edema and hemorrhage which is responsible for the nodularity, warmth, and erythema.
- The infiltrate progresses from predominantly polymorphonuclear cells, to lymphocytes, and then histiocytes where fibrosis occurs around the lobules. There may be some necrosis though minimal as complete resolution without scarring is the typical course.
- The histopathologic hallmark of EN is the Miescher radial granuloma. This is a small, well-defined nodular aggregate of small histiocytes around a central stellate or banana-shaped cleft.

RISK FACTORS

- Group A β -hemolytic streptococcal pharyngitis has been linked to EN (**Figure 178-1**). A retrospective study of 129 cases of EN over several decades reports 28% had streptococcal infection.⁵
- Nonstreptococcal upper respiratory tract infections may also play a role.¹
- Historically, tuberculosis (TB) was a common underlying illness with EN, but TB is now a rare cause of EN in developed countries. There are reports of EN occurring in patients receiving the bacille Calmette-Guérin vaccination.⁸ In developed countries, sarcoidosis is more commonly found. One study estimates sarcoidosis as being the cause of 11% of EN cases (**Figure 178-2**).^{5,7}
- EN occurs in 3% of all patients with coccidiomycosis,⁹ and approximately 4% of patients with histoplasmosis.¹⁰
- EN is less frequently associated with other infectious agents, including *Yersinia gastroenteritis*, *Salmonella*, *Campylobacter*, toxoplasmosis, syphilis, amebiasis, giardiasis, brucellosis, leprosy, *Chlamydia*, *Mycoplasma*, *Brucella*, hepatitis B (infection and vaccine), Epstein-Barr virus, and *Bartonella*.^{4,11}
- When the EN rash occurs with hilar adenopathy, the entity is called Lofgren syndrome. Lofgren syndrome in TB represents primary infection. A more common cause of Lofgren syndrome is sarcoidosis.⁷
- The literature reports that EN is seen in patients with inflammatory bowel diseases. It is usually prominent around the time of GI flare-ups, but may occur before a flare. Most sources report a greater association between Crohn disease and EN than between ulcerative colitis and EN. Other chronic diseases associated with EN include Behçet disease and Sweet syndrome.¹¹
- Some debate exists over causality from pregnancy and oral contraceptives in the occurrence of EN.

FIGURE 178-3 EN in a middle-aged woman with no known cause. These lesions are bright red, warm, and painful. (Courtesy of Hanuš Rozsypal, MD.)

FIGURE 178-4 EN on the arms and legs of unknown cause in a young man. (Courtesy of Hanuš Rozsypal, MD.)

- Besides oral contraceptives, medications implicated as causing EN are antibiotics including sulfonamides, penicillins, and bromides. However, the antibiotics may have been prescribed for the underlying infection that had caused EN.¹¹
- Lymphomas, acute myelogenous leukemia, carcinoid tumor, and pancreatic carcinoma are associated with EN and should be considered in cases of persistent or recurrent EN.^{11,12}

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is usually clinical.
- The lesions of EN are deep-seated nodules that may be more easily palpated than visualized.
- Lesions are initially firm, round or oval, and are poorly demarcated.
- Lesions may be bright red, warm, and painful (**Figure 178-3**).
- Lesions number from 1 to more than 10.5 and vary in size from 1 to 15 cm.
- Over their course, the lesions begin to flatten and change to a purplish color before eventually taking on the yellowish hue of a bruise.
- A characteristic of EN is the complete resolution of lesions with no ulceration or scarring.
- EN is associated with systemic occurrence of fever, malaise, and polyarthralgia sometime near eruption.

TYPICAL DISTRIBUTION

- Lesions appear on the anterior/lateral aspect of both lower extremities (**Figures 178-1 to 178-3**).
- Although lesions may appear in other regions such as the arms, absence in the lower legs is unusual (**Figure 178-4**).¹
- Sarcoid, in particular, may present with lesions on the ankles and knees (**Figure 178-2**).
- Lesions may appear in dependent areas in bedridden patients.

LABORATORY TESTING

- Blood tests may help to identify the underlying cause. Typical tests include complete blood count, chemistries, liver function tests, and erythrocyte sedimentation rate. Erythrocyte sedimentation rate may be elevated.
- For suspected *Streptococcus* cases, rapid strep test or throat cultures are best during acute illness, whereas antistreptolysin O titers may be used in the convalescent phase.⁴
- In sarcoid, angiotensin-converting enzyme levels may be helpful but are not 100% sensitive.² A chest x-ray and/or skin biopsy of a suspected sarcoid lesion can help make this diagnosis (see Chapter 175, Sarcoidosis).

BIOPSY

- The diagnosis of EN is mostly made on physical examination. When the diagnosis is uncertain, a biopsy that includes subcutaneous fat is performed. This can be a deep punch biopsy or a deep incisional biopsy sent for standard histology. If a biopsy is needed,

this can be done by choosing a lesion not over a joint or vital structure and burying a 4-mm punch biopsy to the hilt.

DIFFERENTIAL DIAGNOSIS

- Cellulitis should be considered and not missed. These patients tend to be sicker and have more fever and systemic symptoms. EN tends to appear in multiple locations while cellulitis is usually in one localized area (see Chapter 120, Cellulitis).
- Nodular cutaneous and subcutaneous sarcoid is skin-colored or violaceous without epidermal involvement. The lack of surface involvement makes this resemble EN. Subcutaneous sarcoid may be seen in advanced systemic sarcoidosis that can also be the cause of EN. Skin biopsy is the best method to distinguish between these two conditions. Either way, treatment is directed toward the sarcoidosis (see Chapter 175, Sarcoidosis).
- Erythema induratum of Bazin is a lobular panniculitis that occurs on the posterior lower extremity of women with tendency of lesions to ulcerate with residual scarring.⁷ This condition is typically caused by TB and is more chronic in nature than EN.²
- Erythema nodosum leprosum may occur in patients with leprosy and probably represent an immune complex or hypersensitivity reaction (Figures 178-5 and 178-6). Erythema nodosum leprosum is typically seen as a type 2 reaction to standard leprosy therapy.¹³ It is more common in multibacillary lepromatous leprosy. Although the lesions often look like standard EN, the lesions may also ulcerate.
- An infectious panniculitis should also be considered in the differential, especially in immunocompromised patients. These lesions are often asymmetric and the patient may be febrile. If suspected, a punch biopsy of a lesion should be sent for tissue culture (bacteria, fungus, and *Mycobacteria*).

MANAGEMENT

- Look for and treat the underlying cause. There is limited evidence to guide treatment unless an underlying cause is found.

NONPHARMACOLOGIC

- Cool, wet compresses, elevation of the involved extremities, bedrest, gradient support stockings, or pressure bandages may help alleviate the pain.¹¹ SOR C

MEDICATIONS

- Treat the pain and discomfort of the nodules with NSAIDs and/or other analgesics.¹⁴ SOR C
- The value of oral prednisone is controversial and should be avoided unless it is being used to treat the underlying cause (such as sarcoidosis) and if underlying infection, risk of bacterial dissemination or sepsis, and malignancy have been excluded.¹ SOR C
- Oral potassium iodide, which is contraindicated in pregnancy, led to resolution of EN in several small studies.^{6,7} SOR B
- Colchicine, hydroxychloroquine, and dapsone have been used as well.^{2,7} SOR C

FIGURE 178-5 Erythema nodosum leprosum (ENL) in a Texas man who acquired multibacillary leprosy from handling and eating armadillos. His ENL started when he started the antibacterial treatment. A. Note the many subcutaneous nodules on his arms and legs. B. Close-up of the ENL lesions. (Courtesy of Richard P. Usatine, MD.)

- There are a few case reports of EN treated with penicillin, erythromycin, adalimumab, etanercept, infliximab, mycophenolate mofetil, cyclosporine, thalidomide, and extracorporeal monocyte granulocytapheresis.^{1,15,16} **SOR C**
- There is one case report of minocycline and tetracycline leading to EN improvement.¹⁷ **SOR C**

PREVENTION

- Good hand washing and general health measures may prevent respiratory infections that may predispose to EN.

PROGNOSIS

- EN is usually self-limited or resolves with treatment of the underlying disorder.
- Patients may continue to develop nodules for a few weeks.
- The course depends on the etiology, but usually lasts only 6 weeks.
- Lesions completely resolve with no ulceration or scarring.
- Recurrences occur in 33% to 41% of cases, usually when the etiology is unknown.¹⁶

FOLLOW-UP

- Follow-up is needed to complete the work-up for an underlying cause and to make sure that the patient is responding to symptomatic treatment.

PATIENT EDUCATION

Reassure the patient that there is complete resolution in most cases within 3 to 6 weeks. Inform the patient that some EN outbreaks may persist for up to 12 weeks, and some cases are recurrent.⁶

179 VASCULITIS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 21-year-old woman presented with a 3-day history of a painful purpuric rash on her lower extremities (**Figure 179-1** and **Figure 179-2**). The lesions had appeared suddenly, and the patient had experienced no prior similar episodes. The patient had been diagnosed with a case of pharyngitis earlier that week and was given a course of clindamycin. She had not experienced any nausea or vomiting, fever, abdominal cramping, or gross hematuria. Urine dipstick revealed blood in her urine, but no protein. The typical palpable purpura on the legs is consistent with Henoch-Schönlein purpura (HSP).

INTRODUCTION

Vasculitis refers to a group of disorders characterized by inflammation and damage in blood vessel walls. They may be limited to skin or may be a multisystem disorder. Cutaneous vasculitic diseases are classified according to the size (small versus medium to large vessel) and type of blood vessel involved (venule, arteriole, artery, or vein). Small- and medium-size vessels are found in the dermis and deep reticular dermis, respectively. The clinical presentation varies with the intensity of the inflammation, and the size and type of blood vessel involved.¹

SYNONYMS

Hypersensitivity vasculitis is also known as leukocytoclastic vasculitis.
HSP is a type of leukocytoclastic vasculitis.

EPIDEMIOLOGY

- HSP (**Figure 179-1** to **Figure 179-3**) occurs mainly in children with an incidence of approximately 1 in 5000 children annually.² It results from immunoglobulin (Ig) A-containing immune complexes in blood vessel walls in the skin, kidney, and GI tract. HSP is usually benign and self-limiting, and tends to occur in the springtime. A streptococcal or viral upper respiratory infection often precedes the disease by 1 to 3 weeks. Prodromal symptoms include anorexia and fever. Most children with HSP also have joint pain and swelling with the knees and ankles being most commonly involved (**Figure 179-3**). In half of the cases there are recurrences, typically in the first 3 months. Recurrences are more common in patients with nephritis and are milder than the original episode. To make the diagnosis of HSP, establish the presence of 3 or more of the following:³
 - Palpable purpura
 - Bowel angina (pain)

FIGURE 179-1 Henoch-Schönlein purpura presenting as palpable purpura on the lower extremity. The visible sock lines are from lesions that formed where the socks exerted pressure on the legs. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-2 Close-up of palpable purpura from the patient in **Figure 179-1**. Some lesions look like target lesions but this is Henoch-Schönlein purpura and not erythema multiforme. (Courtesy of Richard P. Usatine, MD.)

- GI bleeding
- Hematuria
- Onset ≤ 20 years
- No new medications
- Some patients with systemic lupus erythematosus (SLE) (**Figure 179-4** and **Figure 179-5**), rheumatoid arthritis (RA), relapsing polychondritis, and other connective tissue disorders develop an associated necrotizing vasculitis. It most frequently involves the small muscular arteries, arterioles, and venules. The blood vessels can become blocked leading to tissue necrosis (**Figure 179-4** and **Figure 179-5**). The skin and internal organs may be involved.
- Leukocytoclastic vasculitis (**Figure 179-6** to **Figure 179-8**) is the most commonly seen form of small vessel vasculitis. Prodromal symptoms include fever, malaise, myalgia, and joint pain. The palpable purpura begins as asymptomatic localized areas of cutaneous hemorrhage that become palpable. Few or many discrete lesions are most commonly seen on the lower extremities but may occur on any dependent area. Small lesions itch and are painful, but nodules, ulcers, and bullae may be very painful. Lesions appear in crops, last for 1 to 4 weeks, and may heal with residual scarring and hyperpigmentation. Patients may experience 1 episode (drug reaction or viral infection) or multiple episodes (RA or SLE). The disease is usually self-limited and confined to the skin. To make the diagnosis, look for presence of 3 or more of the following:⁴
 - Age older than 16 years
 - Use of a possible offending drug in temporal relation to the symptoms
 - Palpable purpura
 - Maculopapular rash
 - Biopsy of a skin lesion showing neutrophils around an arteriole or venule
- Systemic manifestations of leukocytoclastic vasculitis may include kidney disease, heart, nervous system, GI tract, lungs, and joint involvement.

ETIOLOGY AND PATHOPHYSIOLOGY

- Vasculitis is defined as inflammation of the blood vessel wall. The mechanisms of vascular damage consist of either a humoral response, immune complex deposition, or cell-mediated T-lymphocyte response with granuloma formation.⁵
- Vasculitis induced injury to blood vessels may lead to increased vascular permeability, vessel weakening, aneurysm formation, hemorrhage, intimal proliferation, and thrombosis that result in obstruction and local ischemia.⁵
- Small-vessel vasculitis is initiated by hypersensitivity to various antigens (drugs, chemicals, microorganisms, and endogenous antigens), with formation of circulating immune complexes that are deposited in walls of postcapillary venules. The vessel-bound immune complexes activate complement, which attracts polymorphonuclear leukocytes. They damage the walls of small veins by release of lysosomal enzymes. This causes vessel necrosis and local hemorrhage.

FIGURE 179-3 Henoch-Schönlein purpura in an 11-year-old girl. **A.** In addition to the palpable purpura, this patient also had abdominal pain. Note how the seam of her jeans is visible in the purpuric pattern. **B.** She also had knee pain and swelling and was walking with a limp. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-4 Necrotizing vasculitis in a young Asian woman with systemic lupus erythematosus. The circulation to the fingertips was compromised and the woman was treated with high-dose intravenous steroids and intravenous immunoglobulins to prevent tissue loss. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-5 Vasculitis ulcer on the leg of a woman with systemic lupus erythematosus. (Courtesy of Everett Allen, MD.)

FIGURE 179-7 Very palpable purpura on the leg of a middle-aged woman with leukocytoclastic vasculitis. (Courtesy of Eric Kraus, MD.)

FIGURE 179-6 Leukocytoclastic vasculitis on the leg of a woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-8 Vasculitis on the abdomen of a middle-aged woman who also has the vasculitis on her legs. (Courtesy of Everett Allen, MD.)

- Small-vessel vasculitis most commonly affects the skin and rarely causes serious internal organ dysfunction, except when the kidney is involved. Small-vessel vasculitis is associated with leukocytoclastic vasculitis, HSP, essential mixed cryoglobulinemia, connective tissue diseases or malignancies, serum sickness and serum sickness-like reactions, chronic urticaria, and acute hepatitis B or C infection.
- Hypersensitivity (leukocytoclastic) vasculitis causes acute inflammation and necrosis of venules in the dermis. The term *leukocytoclastic vasculitis* describes the histologic pattern produced when leukocytes fragment.

RISK FACTORS

- Viral infections
- Autoimmune disorders
- Drug hypersensitivity
- Cocaine (adulterated with levamisole) (**Figure 179-9**) (Chapter 239, Cocaine for additional images and information)

DIAGNOSIS

- Initially, determining the extent of visceral organ involvement is more important than identifying the type of vasculitis, so that organs at risk of damage are not jeopardized by delayed or inadequate treatment. It is critical to distinguish vasculitis occurring as a primary autoimmune disorder from vasculitis secondary to infection, drugs, malignancy, or connective tissue disease such as SLE or RA.⁵

CLINICAL FEATURES

- Small-vessel vasculitis is characterized by necrotizing inflammation of small blood vessels, and may be identified by the finding of “palpable purpura.” The lower extremities typically demonstrate “palpable purpura,” varying in size from a few millimeters to several centimeters (**Figure 179-2**, **Figure 179-6**, **Figure 179-7**, and **Figure 179-10**). In its early stages leukocytoclastic vasculitis may not be palpable.
- The clinical features of HSP include nonthrombocytopenic palpable purpura mainly on the lower extremities and buttocks (**Figure 179-1**, **Figure 179-2**, and **Figure 179-3**), GI symptoms, arthralgia, and nephritis.

TYPICAL DISTRIBUTION

- Cutaneous vasculitis is found most commonly on the legs, but may be seen on the hands and abdomen (**Figure 179-3**, **Figure 179-8**, and **Figure 179-10**).

LABORATORY TESTING

- Laboratory evaluation is geared to finding the antigenic source of the immunologic reaction. Consider throat culture, antistreptolysin-O titer, erythrocyte sedimentation rate, platelets, complete blood count (CBC), serum creatinine, urinalysis, antinuclear antibody,

FIGURE 179-9 A. Cutaneous vasculitis of the ear caused by levamisole-adulterated cocaine. (Courtesy of Jonathan Karnes, MD.) B. Cutaneous vasculitis in a retiform (net-like) pattern caused by the use of levamisole-adulterated cocaine. This is called *retiform purpura*. (Courtesy of John M. Martin IV, MD.)

serum protein electrophoresis, circulating immune complexes, hepatitis B surface antigen, hepatitis C antibody, cryoglobulins, and rheumatoid factor. The erythrocyte sedimentation rate is almost always elevated during active vasculitis. Immunofluorescent studies are best done within the first 24 hours after a lesion forms. The most common immunoreactants present in and around blood vessels are IgM, C3, and fibrin. The presence of IgA in blood vessels of a child with vasculitis suggests the diagnosis of HSP.

- Basic laboratory analysis to assess the degree and types of organs affected should include serum creatinine, creatinine kinase, liver function studies, hepatitis serologies, urinalysis, and possibly chest x-ray and ECG.

BIOPSY

- The clinical presentation is so characteristic that a biopsy is generally unnecessary. In doubtful cases, a punch biopsy should be taken from an early active (nonulcerated) lesion or, if necessary, from the edge of an ulcer (Figure 179-4).

DIFFERENTIAL DIAGNOSIS

- Pigmented purpuric dermatosis is a capillaritis characterized by extravasation of erythrocytes in the skin with marked hemosiderin deposition. It is not palpable. Schamberg disease is a type of pigmented purpuric dermatosis found most often on the lower legs in older persons (Figure 179-11 and Figure 179-12). It is described as a cayenne pepper-like appearance. Lichen aureus is a localized pigmented purpuric dermatosis seen in younger persons that may occur on the leg or in other parts of the body (Figure 179-13). The color may be yellow brown or golden brown. There is also a pigmented purpuric dermatosis of the Majocchi type that has an annular appearance with prominent elevated erythematous borders that may have telangiectasias (Figure 179-14). A dermatoscope can help to visualize the red or pink dots that represent inflamed capillaries in these conditions.
- Meningococemia that presents with purpura in severely ill patients with central nervous system symptoms (Figure 179-15 and Figure 179-16).
- Rocky Mountain spotted fever is a rickettsial infection that presents with pink to bright red, discrete 1- to 5-mm macules that blanch with pressure and may be pruritic. The lesions start distally and spread to the soles and palms (Figure 179-17).
- Malignancies, such as cutaneous T-cell lymphoma (mycosis fungoides) (Chapter 176, Mycosis Fungoides).
- Stevens-Johnson syndrome and toxic epidermal necrolysis (Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Idiopathic thrombocytopenia purpura can be easily distinguished from vasculitis by measuring the platelet count. Also, the purpura is usually not palpable and the petechiae can be scattered all over the body (Figure 179-18).
- Wegener granulomatosis is an unusual multisystem disease characterized by necrotizing granulomatous inflammation and vasculitis of the respiratory tract, kidneys, and skin.

FIGURE 179-10 Leukocytoclastic vasculitis in a 26-year-old man. **A.** Palpable purpura on the lower leg. **B.** Involvement of the lower abdomen. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-12 Schamberg disease with prominent petechiae and hemosiderin deposits. Note that this condition is not palpable. (Courtesy of Richard P. Usatine, MD.)

FIGURE 179-14 Pigmented purpuric dermatosis of the Majocchi type. Note the annular appearance and the prominent elevated erythematous borders. (Courtesy of Suraj Reddy, MD.)

FIGURE 179-13 Lichen aureus. A. On the leg of a 27-year-old woman. B. On the leg of a 16-year-old girl. (Courtesy of Richard P. Usatine, MD.)

- Churg-Strauss syndrome (allergic granulomatosis) that presents with a systemic vasculitis associated with asthma, transient pulmonary infiltrates, and hypereosinophilia.
- Cutaneous manifestations of cholesterol embolism, which are leg pain, livedo reticularis (blue-red mottling of the skin in a net-like pattern), and/or blue toes in the presence of good peripheral pulses.

MANAGEMENT

NONPHARMACOLOGIC

- The offending antigen should be identified and removed whenever possible. With a mild hypersensitivity vasculitis due to a drug, discontinuing the offending drug may be all the treatment that is necessary. **SOR C**

MEDICATIONS

- An antihistamine might be used for itching. **SOR C**
- Oral prednisone is used to treat visceral involvement and more severe cases of vasculitis of the skin. Short courses of prednisone (60 to 80 mg/day) are effective and should be tapered slowly.^{6,7} **SOR B**
- Colchicine (0.6 mg twice daily for 7 to 10 days) and dapsone (100 to 150 mg/day) may be used to inhibit neutrophil chemotaxis. **SOR B** They are tapered and discontinued when lesions resolve. Azathioprine, cyclophosphamide, and methotrexate have also been studied. **SOR C**
- In HSP and prolonged hypersensitivity vasculitis, treatment with nonsteroidal antiinflammatory drugs is usually preferred. Treatment with corticosteroids may be of more benefit in patients with more severe disease such as more pronounced abdominal pain and renal involvement.⁸ **SOR B** Adding cyclophosphamide to the steroids may also be effective. **SOR C** Azathioprine also may be used.⁹

REFER OR HOSPITALIZE

- Refer or hospitalize with significant internal organ involvement or prolonged disease course.

PROGNOSIS

- In leukocytoclastic (hypersensitivity) vasculitis, the cutaneous lesions usually resolve without sequelae. Visceral involvement (such as kidney and lung) most commonly occurs in HSP, cryoglobulinemia and vasculitis associated with SLE.¹⁰ Extensive internal organ involvement should prompt an investigation for coexistent medium-size vessel disease and referral to a rheumatologist.

FOLLOW-UP

- Relapses may occur, especially when the precipitating factor is an autoimmune disease. Regular monitoring is necessary.

PATIENT EDUCATION

- Reassure patients and parents that most cases of acute cutaneous vasculitis resolves spontaneously.

SECTION 15 CONNECTIVE TISSUE DISEASE

180 LUPUS: SYSTEMIC AND CUTANEOUS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 39-year-old black woman presented to the clinic with 2 months of swelling of her upper lip and cheeks with new dark spots on her face (**Figure 180-1**). An antinuclear antibody (ANA) was positive at a 1:80 dilution. A homogeneous nuclear pattern was present as commonly seen in systemic lupus erythematosus (SLE) and drug-induced lupus. The punch biopsy of a facial lesion was consistent with chronic cutaneous lupus erythematosus (discoid lupus). The remainder of her laboratory tests were normal. The patient's facial lesions did not respond to topical steroids and hence she was started on a short course of systemic steroids. The improvement was seen 3 weeks later (**Figure 180-2**). Hyperpigmentation remained but erythema, swelling, and pruritus were gone. The patient did not meet criteria for SLE and it is possible to have discoid lupus with a positive ANA. Treatment with hydroxychloroquine was discussed.

INTRODUCTION

SLE is a chronic inflammatory disease that can affect many organs of the body including the skin, joints, kidneys, lungs, nervous system, and mucous membranes. Cutaneous lupus can occur in one of three forms: chronic cutaneous (discoid) lupus erythematosus, subacute cutaneous lupus erythematosus, and acute cutaneous lupus erythematosus.

SYNONYMS

- Chronic cutaneous lupus erythematosus = discoid lupus = DLE.
- Lupus profundus = lupus panniculitis.

EPIDEMIOLOGY

- In the United States, the prevalence of SLE plus incomplete SLE (disease only partially meeting diagnostic requirements for SLE) is 40 to 50 cases per 100,000 persons.¹ It is more common in women and patients with African ancestry.¹ Worldwide, the highest SLE prevalences have been reported in Italy, Spain, Martinique, and the United Kingdom Afro-Caribbean population, but it is rarely reported among blacks who live in Africa.²
- Discoid lupus erythematosus (DLE) develops in up to 25% of patients with SLE, but may also occur in the absence of any other clinical feature of SLE.³ Patients with only DLE have a 5% to 10% risk of eventually developing SLE, which tends to follow a mild

FIGURE 180-1 Erythema, swelling, and hyperpigmentation on the cheeks and lips of a 39-year-old black woman as the initial presentation of chronic cutaneous lupus erythematosus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 180-2 Hyperpigmented malar rash 3 weeks later; the patient was treated with oral and topical steroids. The erythema and swelling are now gone and patient is feeling better. (Courtesy of Richard P. Usatine, MD.)

course.⁴ DLE lesions usually slowly expand with active inflammation at the periphery, and then to heal, leaving depressed central scars, atrophy, telangiectasias, and hypopigmentation.⁵ The female-to-male ratio of DLE is 2:1.

ETIOLOGY AND PATHOPHYSIOLOGY

- One proposed mechanism for the etiology of SLE involves the development of autoantibodies that result from a defect in apoptosis. It has been determined that the specific defect involves the “find-me” (and adenosine triphosphate [ATP]/uridine triphosphate [UTP]) or “eat-me” (phosphatidylserine) signals that should be activated when red cell nuclei are extruded. With no apoptosis, the nuclei break down, causing inflammation and the development of autoimmunity.⁶ Many of the signs and symptoms of lupus erythematosus (LE) are caused by the circulating immune complexes or by the direct effects of antibodies to cells.
- A genetic predisposition for SLE exists. The concordance rate in monozygotic twins is between 25% and 70%. If a mother has SLE, her daughter’s risk of developing the disease is 1:40 and her son’s risk is 1:250.
- The course of SLE is one of intermittent remissions punctuated by disease flares. Organ damage often progresses over time.
- Rarely, neonates may develop a lupus rash from acquired antibodies through transplacental transmission from mother if she has active SLE (**Figure 180-3**).

RISK FACTORS

Precipitating factors for SLE include:

- Exposure to the sunlight (UV light, especially UVB).
- Infections.
- Stress.
- Trauma or surgery.
- Pregnancy (especially in the postpartum period).

Precipitating factors for cutaneous lupus include:

- Exposure to the sunlight (UV light, especially UVB).

DIAGNOSIS

CLINICAL FEATURES OF SYSTEMIC LUPUS ERYTHEMATOSUS

- SLE is a chronic, recurrent, potentially fatal inflammatory disorder that can be difficult to diagnose. It is an autoimmune disease involving multiple organ systems that is defined clinically with associated autoantibodies directed against cell nuclei. The disease has no single diagnostic sign or marker. Accurate diagnosis is important because treatment can reduce morbidity and mortality.⁷
- SLE most often presents with a mixture of constitutional symptoms including fatigue, fever, myalgia, anorexia, nausea, and weight loss. The mean length of time between onset of symptoms and diagnosis is 5 years.

FIGURE 180-3 Neonatal lupus from acquired antibodies through transplacental transmission from the mother with active SLE. (From Warner AM, Frey KA, Connolly S. Annular rash on a newborn. *J Fam Pract.* 2006;55(2):127-129. Reproduced with permission from Frontline Medical Communications.)

- The disease is characterized by exacerbations and remissions as well as symptoms.
- The diagnosis of SLE is made if four or more of the manifestations mentioned below (and categorized in **Table 180-1**) are either present, serially or simultaneously, in the patient at the time of presentation or were present in the past. If two to three manifestations are present, some clinicians refer to the syndrome as “incomplete lupus.”⁸
 - Arthralgias, which are often the initial complaint, are usually disproportionate to physical findings. The polyarthritis is symmetric, nonerosive, and usually nondeforming. In longstanding disease, rheumatoid-like deformities with swan-neck fingers are commonly seen.
 - A malar or butterfly rash is fixed erythema over the cheeks and bridge of the nose sparing the nasolabial folds (**Figures 180-2, 180-4, and 180-5**). It may also involve the chin and ears. More severe malar rashes may cause severe atrophy, scarring, and hypopigmentation (**Figure 180-5**).
 - Rash associated with photosensitivity to UV light.
 - A discoid rash consisting of erythematous raised patches with adherent keratotic scaling and follicular plugging. Atrophic scarring may occur in older lesions.
 - Ulcers (usually painless) in the nose, mouth, or vagina are frequent complaints.
 - Pleuritis as evidenced by a convincing history of pleuritic pain or rub or evidence of pleural effusion.
 - Pericarditis as documented by ECG, rub, or evidence of pericardial effusion.
 - Renal disorder such as cellular casts or persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation not performed.
 - Central nervous system (CNS) symptoms ranging from mild cognitive dysfunction to psychosis or seizures. Any region of CNS can be involved. Intractable headaches and difficulties with memory and reasoning are the most common features of neurologic disease in lupus patients.
 - Hematologic disorders such as hemolytic anemia, leukopenia ($<4000/\text{mm}^3$ total on two or more occasions), lymphopenia ($<1500/\text{mm}^3$ on two or more occasions), or thrombocytopenia ($<100,000/\text{mm}^3$ in the absence of precipitating drugs).
 - GI symptoms may include abdominal pain, diarrhea, and vomiting. Intestinal perforation and vasculitis are important diagnoses to exclude.
 - Vasculitis (**Figures 180-6 to 180-8**) can be severe and can include retinal vasculitis.
 - Immunologic disorders such as a positive antiphospholipid antibody, anti-DNA, anti-Smith antigen, or a false-positive serologic test for syphilis (known to be positive for at least 6 months and confirmed by a negative treponema specific test).
 - An abnormal titer of ANA at any point in time and in the absence of drugs associated with “drug-induced lupus.”

CLINICAL FEATURES OF CUTANEOUS LUPUS

Cutaneous lupus can be divided up into three types:

1. Chronic cutaneous lupus (discoid lupus).
 2. Subacute cutaneous lupus.
 3. Acute cutaneous lupus, which is part of an SLE flare.
- Chronic cutaneous lupus (DLE) lesions are characterized by discrete, erythematous, slightly infiltrated papules or plaques covered by a

FIGURE 180-4 Malar rash in adolescent Hispanic girl with SLE. Note the relative sparing of the nasolabial fold. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 180-5 Malar rash with severe atrophy, scarring, and hypopigmentation in a young woman with arthritis and other signs of more systemic lupus. (Courtesy of Richard P. Usatine, MD.)

well-formed adherent scale (**Figures 180-9 to 180-15**). As the lesion progresses, the scale often thickens and becomes adherent. Hypopigmentation develops in the central area and hyperpigmentation develops at the active border. Resolution of the active lesion results in atrophy and scarring. When they occur in the scalp, scarring alopecia often results (**Figures 180-12 and 180-15**). If the scale on the scalp is removed, it may leave a “carpet tack sign” from follicular plugging.

- Subacute cutaneous lupus occurs most commonly in sun-exposed areas. The lesions are erythematous with scale and distinct borders or they may be annular in shape (**Figure 180-16**). The photosensitivity that exists explains the distribution of the lesions. Fortunately, these lesions do not scar or itch, but they may heal with postinflammatory hyperpigmentation.
- Acute cutaneous lupus is the name given for the cutaneous manifestations of systemic lupus such as the malar rash. This malar rash is also called a butterfly rash (**Figure 180-4**). This rash may heal without scarring.
- Raynaud phenomenon, libido reticularis, and palmar erythema also occur in persons with lupus (**Figure 180-17**). All three of these conditions can be made worse by cold weather.

TYPICAL DISTRIBUTION

- Discoid lesions are most often seen on the face, neck, and scalp, but also occur on the ears, and, infrequently, on the upper torso.
- DLE lesions may be localized or widespread. Localized DLE occurs only in the head and neck area, whereas widespread DLE occurs anywhere. Patients with widespread involvement are more likely to develop SLE.
- Subacute cutaneous lupus lesions are most commonly found in the sun-exposed areas of the face, neck, and arms (**Figure 180-16**).
- Acute cutaneous lupus is generally seen in the malar rash distribution, although it can occur on other parts of the body.
- Lupus panniculitis, or lupus profundus, is a variant of LE that primarily affects subcutaneous fat. It usually involves the proximal extremities, trunk, breasts, buttocks, and face (**Figure 180-18**).

LABORATORY TESTING

- The American College of Rheumatology recommends ANA testing in patients who have two or more unexplained signs or symptoms that could be lupus. Elevation of the ANA titer to or above 1:80 is the most sensitive of the American College of Rheumatology diagnostic criteria. Although many patients may have a negative ANA titer early in the disease, more than 99% of SLE patients will eventually have an elevated ANA titer.⁹ The ANA test is not specific for lupus, and the most common reason for a positive ANA test without SLE (usually at titers <1:80) is the presence of another connective tissue disease.
- Active SLE is often heralded by a rise in immunoglobulin (Ig) G anti-double-stranded DNA titers and/or a fall in complement levels.¹⁰
- Patients with only DLE generally have negative or low-titer ANA titers, and rarely have low titers of anti-Ro antibodies.¹¹

BIOPSY

A biopsy is often needed to confirm the diagnosis, even when the pattern seems typical. A 4-mm punch biopsy should provide adequate

FIGURE 180-6 Necrotizing angitis in a 28-year-old Japanese American woman with a severe lupus flare. Palpable purpura was evident on both feet and hands. (Courtesy of Richard P. Usatine, MD.)

FIGURE 180-7 Necrotizing angitis on the hand of the patient in Figure 180-6 with lupus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 180-8 Leukocytoclastic vasculitis on the foot of a 69-year-old woman with systemic lupus. (Courtesy of Richard P. Usatine, MD.)

tissue to the pathologist. Biopsy confirmation is particularly helpful before starting potentially toxic medications.

DIFFERENTIAL DIAGNOSIS

- Drug-induced lupus is a lupus-like syndrome most strongly associated with procainamide, hydralazine, isoniazid, chlorpromazine, methyldopa, and quinidine.
- Scleroderma presents with thickening of the skin and multisystem sclerosis (see Chapter 182, Scleroderma and Morphea).
- Actinic keratosis on the face may become confluent but lacks the systemic symptoms of lupus (see Chapter 166, Actinic Keratosis and Bowen Disease).
- Dermatomyositis presents with facial swelling, “heliotrope” rash around the eyes, Gottron papules and periungual erythema in the hands, and proximal muscular limb girdle weakness. It is often associated with internal malignancy (see Chapter 181, Dermatomyositis).
- Lichen planus produces a polygonal pruritic purple papular rash (see Chapter 154, Lichen Planus).
- Psoriasis demonstrates silver-white plaques that cover the elbows, knees, scalp, back, or vulva. There may also be nail and scalp involvement (see Chapter 152, Psoriasis).
- Rosacea is associated with midfacial skin erythema, papules, and pustules without the systemic symptoms of LE, and usually involves the nasolabial folds (see Chapter 113, Rosacea).
- Sarcoidosis may produce skin plaques but without the central clearing and atrophy of LE (see Chapter 175, Sarcoidosis).
- Syphilis may produce a plaque-like rash that can be confused with DLE. The short course of the disease and serologic testing can distinguish the diseases. However, lupus autoantibodies may produce a false-positive screening test for syphilis (see Chapter 216, Syphilis).

MANAGEMENT

NONPHARMACOLOGIC

- Because UV light can flare SLE, sunscreen use, preferably one that blocks both UVA and UVB, should be encouraged. **SOR C**

MEDICATIONS

- Conservative management for SLE with NSAIDs or cyclooxygenase-2 selective inhibitors are recommended for arthritis, arthralgias, and myalgias. **SOR B**
- Antimalarial drugs (hydroxychloroquine [Plaquenil] 200 mg bid, maximum 6.5 mg/kg per day) most commonly for skin manifestations and for musculoskeletal complaints that do not adequately respond to NSAIDs. They may also prevent major damage to the kidneys and CNS and reduce the risk of disease flares. **SOR B**
- Systemic glucocorticoids (1 to 2 mg/kg per day of prednisone or equivalent) alone or with immunosuppressive agents for patients with significant renal and CNS disease or any other organ-threatening manifestation. **SOR B** Lower doses of glucocorticoids (prednisone 10 to 20 mg/day) for symptomatic relief of severe or unresponsive musculoskeletal symptoms. In severe, life-threatening

TABLE 180-1 American College of Rheumatology Criteria for Diagnosis of Systemic Lupus Erythematosus

Criterion	Definition
1. Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
2. Discoid rash	Erythematous-raised patches with adherent keratotic scaling and follicular plugging and later atrophic scarring
3. Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by history or physician observation
4. Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
5. Arthritis	Nonerosive arthritis involving 2 or more peripheral joints, characterized by tenderness, swelling, or effusion
6. Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion or pericarditis documented by ECG, rub, or evidence of pericardial effusion
7. Renal disorder	Persistent proteinuria greater than 0.5 g/day or greater than 3+ if quantitation not performed or red cell, hemoglobin, granular, tubular, or mixed cellular casts
8. Neurologic disorder	Seizures or psychosis—in the absence of offending drugs or known metabolic derangements (uremia, ketoacidosis, or electrolyte imbalance)
9. Hematologic disorder	Hemolytic anemia with reticulocytosis or leukopenia ($<4,000/\text{mm}^3$ on 2 or more occasions) or lymphopenia ($<1,500/\text{mm}^3$ on 2 or more occasions) or thrombocytopenia ($<100,000/\text{mm}^3$) in the absence of offending drugs
10. Immunologic disorders	Positive antiphospholipid antibody or anti-DNA antibody to native DNA in abnormal titer or anti-Smith antibody—presence of antibody to Smith nuclear antigen or false-positive serologic test for syphilis known to be positive for at least 6 months and confirmed by <i>Treponema pallidum</i> immobilization or fluorescent treponemal antibody absorption test
11. Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with “drug-induced lupus” syndrome

SLE can be diagnosed if any 4 or more of the 11 criteria are present, serially or simultaneously, during any interval of observation. Source: Modified from Callahan LF, Pincus T. Mortality in the rheumatic diseases. *Arthritis Care Res.* 1995;8:229. Reproduced with permission of Wiley Inc.

situations, methylprednisolone bolus (1 g IV/day) can be given for 3 consecutive days.

- Immunosuppressive medications (e.g., methotrexate, cyclophosphamide, azathioprine, mycophenolate, or rituximab) are generally reserved for patients with significant organ involvement, or who have had an inadequate response to glucocorticoids. **SOR B**¹⁵
- Belimumab (10 mg/kg IV every 2 weeks for 3 doses then every 4 weeks) may be used in patients with active SLE who are not responding to standard therapy, such as NSAIDs, glucocorticoids, antimalarials, and/or immunosuppressives.¹⁶
- Patients with thrombosis, usually associated to the presence of antiphospholipid antibodies, require anticoagulation with warfarin, for a target international normalized ratio (INR) of 3:3.5 for arterial thrombosis and 2:3 for venous thrombosis.¹⁷
- DLE therapy includes corticosteroids (topical or intralesional) and antimalarials. **SOR C** Alternative therapies include auranofin, oral or topical retinoids, and immunosuppressive agents.

PREVENTION

- Avoiding precipitating factors may decrease exacerbations.

PROGNOSIS

- SLE can have a varied clinical course, ranging from a relatively benign illness to a rapidly progressive disease with organ failure and death. Most patients have a relapsing and remitting course.
- Poor prognostic factors for survival in SLE include:¹⁸
 - Renal disease (especially diffuse proliferative glomerulonephritis).
 - Hypertension.
 - Male sex.
 - Young age.
 - Older age at presentation.
 - Poor socioeconomic status.
 - Black race, which may primarily reflect low socioeconomic status.
 - Presence of antiphospholipid antibodies.
 - Antiphospholipid syndrome.
 - High overall disease activity.

FOLLOW-UP

- The patient should have regular follow-up appointments to monitor for and attempt to prevent end organ damage. Regular follow-up visits are needed to monitor medication benefits and side effects and to coordinate care of the whole person.

PATIENT EDUCATION

- Educate the patient on the necessity of protection from the sun, as UV exposure can cause lupus flares. They should use a sunscreen, preferably one that blocks both UVA and UVB, with a minimum skin protection factor (SPF) of 30.
- Because cigarette smoking may increase the risk of developing SLE and smokers generally have more active disease, smokers with SLE should be counseled to quit smoking.
- Have patients report any signs of superinfection in their rash, as this requires antibiotic therapy.
- If possible, avoid sulfa drugs, which are related to lupus flares.

181 DERMATOMYOSITIS

Margaret L. Burks, BA
Anna Allred, MD
Richard P. Usatine, MD

PATIENT STORY

A 55-year-old Hispanic woman presents to her family physician with a diffuse rash and increasing muscle weakness. The initial rash (without weakness) 2 months prior was thought to be a photosensitivity reaction to her new hydrochlorothiazide (HCTZ) prescription. She stopped the HCTZ and the rash initially improved with some topical corticosteroids. At the time of her current presentation, she had trouble getting up from a chair, walking, and lifting her arms over her head. The rash was prominent in sun-exposed areas, but was also seen in a shawl-like distribution in non-sun-exposed areas (**Figure 181-1**). Aside from her hypertension and obesity, the patient did not have any previous chronic medical conditions. She was afebrile with no other pertinent findings on physical exam.

This is a classic presentation of dermatomyositis with the typical rash and proximal muscle weakness. Close attention to the rash around her eyes demonstrates the pathognomonic heliotrope rash of dermatomyositis (**Figures 181-2** and **181-3**). Also the patient has Gottron papules on the fingers, seen best in this case over the proximal interphalangeal (PIP) joint of the third finger (**Figure 181-4**). There was periungual erythema and ragged cuticles. The scalp was red and scaly. Her neurologic exam was consistent with proximal myopathy. She also had some trouble swallowing bread; and dysphagia is not unusual in dermatomyositis. Laboratory tests showed mild elevations in muscle enzymes with the aspartate aminotransferase (AST) having the greatest elevation. In other cases, the creatine kinase (CK) can be very elevated.

The family physician started the patient on 60 mg of prednisone daily and topical steroids for the affected areas. The patient responded well to prednisone and 2 weeks later was feeling stronger and the rash was fading (**Figure 181-5**). After 4 weeks of 60 mg/day of prednisone she was started on 10 mg/wk of methotrexate in order to eventually taper her steroids. The patient has continued to do well, but the rash and muscle weakness tend to recur when her steroids are being tapered. The patient was sent for physical therapy and started on calcium and vitamin D supplementation to protect her from steroid-induced osteoporosis. She was also given 1 mg/day of folic acid to minimize the adverse effects of methotrexate. As dermatomyositis may be precipitated by an underlying malignancy, the physician screened the patient for internal cancers, especially ovarian cancer. Fortunately, the mammogram, Papanicolaou (Pap) smear, colonoscopy, transvaginal ultrasound for ovarian imaging, and abdominal/pelvic CT scans were all normal.

INTRODUCTION

Dermatomyositis is a rare, idiopathic inflammatory disease involving the striated muscles and the skin. The disease is characterized by

FIGURE 181-1 Initial presentation of dermatomyositis in a 55-year-old Hispanic woman. Prominent violaceous erythema with scale is visible on the chest, face, and arms. Deep-red erythema is especially visible on the side of the face. The scalp is red and scaling. (Courtesy of Richard P. Usatine, MD.)

FIGURE 181-2 Close-up of the heliotrope (violaceous) rash around the eyes of the patient in **Figure 181-1**. (Courtesy of Richard P. Usatine, MD.)

progressive, symmetrical, proximal muscle weakness. Dermatologic manifestations may occur with or without muscular diseases and include the characteristic heliotrope rash (Figures 181-2, 181-3, 181-5, and 181-6), “shawl sign,” and Gottron papules of the PIP joints. Although primarily a disease of muscle and skin, dermatomyositis has a clear relationship with myocarditis and interstitial lung disease, as well as an increased risk of associated malignancy.

EPIDEMIOLOGY

- Annual incidence of 5 to 8.9 per 1 million population.¹
- Seen more commonly in women.¹
- Can affect any age; however, it is more common in children and older adults.¹
- Thirty-five percent to 40% of patients with dermatomyositis also have interstitial lung disease. It is the most common internal organ manifestation of the disease and greatly affects morbidity and mortality.^{1,2}
- Has been linked to malignancy in up to 15% to 24% of adults.³
- Cancers most commonly associated are breast, ovary, lung, and GI tract. The most common type of cancer is adenocarcinoma. Ovarian cancer is overrepresented in those patients with dermatomyositis and cancer. Cancer is not typically seen in children with dermatomyositis.
- In adults, the presence of anti-p155 autoantibodies has shown to be strongly associated with malignancy, with a 27-fold increase in odds.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Dermatomyositis is considered an autoimmune disease of unknown etiology. Environmental exposure and infectious agents may play a role in disease pathogenesis.
- Dermatomyositis has been shown to be a microangiopathy that affects the skin and muscle. The muscle weakness and skin manifestations may be a result of activation and deposition of complement, which cause lysis of endomysial capillaries and muscle ischemia.

DIAGNOSIS

- Diagnosis includes 5 criteria: “definite” (skin findings plus any 3 of criteria 1 to 4), “probable” (skin findings plus 2 of any criteria 1 to 4), or “possible” (skin findings plus any 1 of criteria 1 to 4).^{2,5,6}
 - Proximal symmetric muscle weakness that progresses over weeks to months.
 - Elevated serum levels of muscle enzymes (CK, AST, lactate dehydrogenase [LDH] and aldolase).
 - Abnormal electromyogram.

FIGURE 181-3 View showing the bilateral heliotrope rash of the patient in Figure 181-1. A pathognomonic sign of dermatomyositis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 181-4 Hand involvement showing two Gottron papules over the knuckles (arrows) and erythematous nailfolds (periungual erythema) on the patient in Figure 181-1. (Courtesy of Richard P. Usatine, MD.)

- Abnormal muscle biopsy.
- Skin findings—Presence of cutaneous disease characteristic of dermatomyositis (heliotrope rash; Gottron papules are considered pathognomonic) (**Figures 181-2 to 181-8**). Nonpathognomonic manifestations include malar erythema, and periungual and cuticular changes (**Figure 181-9**).
- These criteria are still considered the “gold standard,” although they are old (1975) and currently under critical review because of several limitations. The criteria do not include specific autoantibodies or MRI findings.^{2,7,8}

Recent studies indicate that the dilated nailfold capillary loops (**Figure 181-10**) often seen in patients with dermatomyositis may help in earlier diagnosis and predicting patients with poor prognosis. Dilated nailfold capillary loops have shown promise in juvenile dermatomyositis as a marker for both skin and muscle disease activity to guide treatment. Some authors propose adding this finding to criteria for diagnosis.^{9,10}

CLINICAL FEATURES

- Bilateral periorbital heliotrope erythema (pathognomonic) (**Figures 181-2, 181-3, 181-5, and 181-6**) and scaling violaceous papular dermatitis in a patient complaining of proximal muscle weakness points to dermatomyositis.
- The patient may classically complain of difficulty climbing stairs, rising from a seat, or combing their hair. Notably the skin manifestations may precede, follow, or present simultaneously with muscle involvement; a patient may even have skin manifestations for longer than a year prior to developing muscle weakness.
- Hand involvement includes abnormal nailfolds and Gottron papules. “Moth-eaten” cuticles, also called the Samitz sign, are evidenced by periungual erythema and telangiectasias (**Figures 181-7 to 181-9**).
- Gottron papules, smooth, purple-to-red papules and plaques, are classically located over the knuckles and on the sides of fingers (**Figures 181-4, 181-7, and 181-8**). Plaques may be present over the knuckles instead of or in addition to papules. The papules are much more evident upon presentation of juvenile-onset dermatomyositis (**Figure 181-8**).
- Dysphagia can be present as a consequence of pharyngeal muscle involvement with risk of aspiration and pneumonia.
- Patients with concurrent interstitial lung disease may also present with fatigue, cough, dyspnea on exertion, and decreased exercise tolerance. Lung involvement usually appears following symptoms of myositis, although this is not always the case.²

TYPICAL DISTRIBUTION

- Face—The characteristic heliotrope rash occurs around the eyes. The color “heliotrope” is a pink-purple tint named after the color of the heliotrope flower. This color is best seen in **Figure 181-6**. The heliotrope rash can also be a dusky-red color as seen in **Figures 181-1 to 181-5**. This heliotrope rash is bilaterally symmetrical.

FIGURE 181-5 Patient improving after 2 weeks of oral prednisone. The heliotrope rash is still visible around the eyes and upper chest. The hairline erythema is from scalp involvement. (Courtesy of Richard P. Usatine, MD.)

FIGURE 181-6 Classic heliotrope rash around the eyes of this 19-year-old woman newly diagnosed with dermatomyositis. The color “heliotrope” is a pink-purple tint named after the color of the heliotrope flower. As expected, her heliotrope rash is bilaterally symmetrical. This rash resolved on prednisone and hydroxychloroquine. (Courtesy of Richard P. Usatine, MD, and from Goodall J, Usatine RP. Skin rash and muscle weakness. *J Fam Pract.* 2005;54(10):864-868. Reproduced with permission from Frontline Medical Communications.)

- Hands—There is usually hand involvement with Gottron papules (and plaques) and abnormal nailfolds and cuticles (**Figures 181-4** and **181-7** to **181-9**).
- Neck and upper trunk—A red or poikiloderma-type rash can be seen in a V-neck (**Figure 181-11**) or in a shawl distribution (**Figure 181-12**). Poikiloderma refers to hyperpigmentation of the skin demonstrating a variety of shades and associated with telangiectasias. The rash here can be scaling and look psoriasiform.
- Extremities may have erythematous plaques and papules with scale.
- Scalp is often involved with erythema and scale and appears similar to seborrhea or psoriasis.
- Sun-exposed areas are often involved and worsen with sun exposure. This is why so many of the skin findings are on the face and upper chest (**Figure 181-13**). However, patients rarely complain of sun sensitivity.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

- Elevated muscle enzymes, evidence of inflammation on electromyography (EMG), and inflammatory infiltrates on muscle biopsy confirm the diagnosis of dermatomyositis. The following serum muscle enzymes can be drawn during the acute active phase and may be found to be elevated: CK, LDH, alanine aminotransferase, AST, and aldolase. Of note, it is necessary to measure all of the aforementioned enzymes as only one of them may be elevated.
- The diagnosis may be made with confidence in a patient with characteristic skin findings and elevated muscle enzymes. If the presentation is not straightforward, then EMG and muscle biopsy should be performed.
- The diagnosis can be supported with positive antibodies such as antinuclear antibody (ANA), anti-Mi-2, and anti-Jo-1. It is not necessary to order these antibodies to make the diagnosis of dermatomyositis. In fact, these myositis-specific antibodies are only positive in 30% of patients with dermatomyositis. Patients with anti-Mi-2 generally have a better overall prognosis.
- Other papulosquamous diseases, such as lichen planus and psoriasis, may be differentiated from dermatomyositis with a punch biopsy, but the histology of dermatomyositis is indistinguishable from cutaneous lupus erythematosus.
- Some experts recommend initial pulmonary function tests (PFTs), chest radiograph, and high-resolution CT to identify patients with interstitial lung disease early, regardless of presence or absence of respiratory symptoms.¹¹
- PFTs demonstrate a restrictive pattern with presence of interstitial lung disease. Abnormal results must be confirmed by CT scan as PFT results may also reflect coexisting respiratory muscle weakness. Changes over time can be used to determine response to therapy, although intervals for testing are not clearly defined.²

BIOPSY

Muscle biopsy of dermatomyositis will show inflammatory cells around intramuscular blood vessels. Atrophic muscle fibers are seen around the periphery of muscle fascicles (“perifascicular atrophy”).¹

FIGURE 181-7 Hand involvement in the 19-year-old woman in **Figure 181-6** with Gottron papules over the finger joints. She has nailfold erythema and ragged cuticles (Samitz sign). (Courtesy of Richard P. Usatine, MD, and from Goodall J, Usatine RP. Skin rash and muscle weakness. *J Fam Pract.* 2005;54(10):864-868. Reproduced with permission from Frontline Medical Communications.)

FIGURE 181-8 Juvenile dermatomyositis in a young boy. Note how the erythematous papules and plaques are most prominent over the finger joints and spare the space between joints. This is a good example of Gottron papules being very visible in juvenile dermatomyositis. (Courtesy of Richard P. Usatine, MD, and from Goodall J, Usatine RP. Skin rash and muscle weakness. *J Fam Pract.* 2005;54(10):864-868. Reproduced with permission from Frontline Medical Communications.)

DIFFERENTIAL DIAGNOSIS

- Polymyositis is another form of inflammatory myopathy. It is distinguished from dermatomyositis by its lack of cutaneous involvement. Dermatomyositis can also occur without muscle involvement. This is called *dermatomyositis sine myositis* or *amyopathic dermatomyositis*.
- Polymorphous light eruption or other photosensitivity reactions may be mistaken for the dermatologic findings of dermatomyositis. As in the case of our patient, her cutaneous findings preceded her muscle weakness and the cutaneous findings were only in light-exposed areas. Therefore, it is essential in the management and follow-up with patients with suspected photosensitivity reactions to inquire about muscle weakness and to look for other signs of dermatomyositis. Examination of the hands and tests for muscle enzyme elevations might help to distinguish dermatomyositis from photosensitivity reactions (see Chapter 199, Photosensitivity).
- Hypothyroidism can cause a proximal myopathy just like polymyositis and dermatomyositis. Although hypothyroidism can cause a dermopathy, it does not resemble the skin findings of dermatomyositis. All patients with proximal muscle weakness should have a screening thyroid-stimulating hormone (TSH) to rule out hypothyroidism regardless of their skin findings (see Chapter 226, Goitrous Hypothyroidism).
- Rosacea causes an erythematous rash on the face as is often seen in dermatomyositis. Of course rosacea does not cause muscle weakness and the erythema of rosacea is generally confined to the face only (see Chapter 113, Rosacea).
- Steroid myopathy may develop as a side effect of systemic steroid therapy. The symptoms develop 4 to 6 weeks after starting oral steroids for dermatomyositis and other autoimmune diseases. Therefore if muscle weakness recurs after improving it could be from the steroids not the disease.
- Dermatomyositis-like reaction rarely may present with similar skin findings with initiation of the following medications and improvement with their discontinuation: penicillamine, NSAIDs, and carbamazepine.
- Overlap syndrome—The term *overlap* denotes that certain signs are seen in both dermatomyositis and other connective tissue diseases, such as scleroderma, rheumatoid arthritis, and lupus erythematosus. Scleroderma and dermatomyositis are the most commonly associated conditions and have been termed sclerodermatomyositis or mixed connective disease. In mixed connective tissue disease, features of systemic lupus erythematosus (SLE), scleroderma, and polymyositis are evident, such as malar rash, alopecia, Raynaud phenomenon, waxy-appearing skin, and proximal muscle weakness.

MANAGEMENT

Given the autoimmune mechanism likely central to the disease process, treatment is geared toward the proximal muscle weakness and skin changes using immunosuppressive or immunomodulatory therapy. Treatment is nonspecific as the target antigen remains elusive.⁴

FIGURE 181-9 Dermatomyositis in a man showing cuticular changes that are thick, rough, and hyperkeratotic with telangiectasias. This moth-eaten appearance of the cuticles is called the Samitz sign. The hands also have the appearance of “mechanic’s hands,” another sign seen in dermatomyositis. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

Cutaneous manifestations do not always parallel muscle disease in response to therapy. Clinical improvement should guide treatment regimen, and serum CK level should not be used as a sole guide for gauging responsiveness to therapy. Effective therapies for the myopathy are oral corticosteroids, immunosuppressant, biologic agents, and/or intravenous immunoglobulin. Effective therapies for the skin disease are sun protection, topical corticosteroids, antimalarials, methotrexate, and/or immunoglobulin. Drug therapy for dermatomyositis continues to be based on empirical rather than evidence-based practice because of lack of controlled trials.¹²

NONPHARMACOLOGIC

- Physical and/or occupational therapy to regain strength is highly recommended. Physical therapy will preserve muscle function and help to prevent atrophy and contractures.¹³
- In combination with exercise, oral creatine supplement was recently shown to improve muscle endurance and functionality in patients with dermatomyositis compared to placebo.¹⁴
- Photoprotection consisting of a broad-spectrum sunscreen, protective outerwear, and limiting sun exposure.^{15–17} **SOR B**

TOPICAL TREATMENT

- Therapy of the skin disease begins with high-potency topical corticosteroids.^{15,16,18} **SOR B** Triamcinolone ointment may be used for less-severe areas or on the face at first. Consider a short course of a very-high potency steroid, such as clobetasol, for more severe involvement not on the face.⁵
- Topical tacrolimus 0.1% is a useful adjunct in the treatment of refractory skin manifestations.¹³ **SOR B**

ORAL TREATMENT

- First-line therapy for muscle disease is high-dose (1 mg/kg single daily dose) systemic corticosteroids, usually prednisone, with or without an immunosuppressive (“steroid-sparing”) agent—methotrexate, cyclosporine, mycophenolate mofetil, or azathioprine.³
- Corticosteroids (either IV or oral) are also the first-line treatment for interstitial lung disease in patients with dermatomyositis. Approximately half of patients show response in respiratory symptoms. Refractory cases are treated with second-line calcineurin inhibitors (cyclosporine) or cyclophosphamide (oral or IV pulse), with or without corticosteroids. Methotrexate use is cautioned when there is coexisting lung disease, as it is a known cause of drug-induced interstitial lung disease.^{2,19}
- Steroid taper (20% to 25% reduction monthly) should be initiated based on clinical responsiveness (increased muscle strength, energy) after 3 to 4 weeks on high-dose treatment.
- If no response by 3 months to oral high-dose steroids, another treatment approach should begin along with a reexamination of the diagnosis.^{3,13} **SOR B**
- Methotrexate is effective in treating the muscular symptoms of childhood and adult refractory dermatomyositis as a steroid-sparing agent. Methotrexate significantly improves skin lesions as well.²⁰ **SOR B**

FIGURE 181-10 A. Dilated nailfold capillary loops visible with dermoscopy in a young woman with newly diagnosed dermatomyositis. B. She also had dilated capillary loops on the gingival borders of her teeth seen with dermoscopy. C. Marginal gingivitis in the same young woman with newly diagnosed dermatomyositis. The nailfold findings and gingival findings both resolved with treatment. (Courtesy of Richard P. Usatine, MD.)

- Methotrexate dosing starts at 10 to 15 mg/wk. The dose is then increased 2.5 mg/wk until a total dose of 15 to 25 mg/wk is reached. The total dose of methotrexate is also determined by how well the patient can tolerate this medication. Improvement is typically noted after 4 to 8 weeks of therapy.^{13,18}
- Using methotrexate safely requires a number of precautions. All patients should have a purified protein derivative (PPD) placed or a quanta figure on gold assay performed to make sure that tuberculosis will not be activated. Patients with active liver disease, including hepatitis C and alcoholic cirrhosis, should receive alternative forms of therapy. Women should avoid becoming pregnant during therapy. Persons started on methotrexate should also be given 1 mg of folic acid daily to minimize the risk of side effects. The patient should be followed with regular laboratory testing, including complete blood counts and comprehensive metabolic profiles. Methotrexate should only be prescribed by doctors familiar with its risks and benefits.
- As the methotrexate dosage is increased, the dosage of prednisone should be tapered.
- Cyclosporine plus methotrexate has shown some benefit in the treatment of refractory juvenile and adult dermatomyositis.¹³
SOR B Cyclosporine should cautiously be used with monitoring of blood pressure, renal function, liver function, and hematologic parameters.
- New data shows that methotrexate and cyclosporine both resulted in clinical improvement with no difference in efficacy or toxicity.¹³
- Azathioprine is commonly used in chronic inflammatory diseases as a steroid-sparing agent. It is usually administered up to 2 to 3 mg/kg per day. The combination of azathioprine and methotrexate may be more efficacious together with fewer side effects than when used alone. Azathioprine has been shown to have a slower clinical effect than methotrexate, but no difference was noted in efficacy.¹³ Like all the other immunosuppressive agents, azathioprine must be used cautiously by physicians familiar with its risks.
- Tacrolimus has effects similar to cyclosporine, but has greater potency and is effective in refractory juvenile dermatomyositis.¹³
- Mycophenolate mofetil, an inhibitor of T- and B-cell proliferation, is a possible corticosteroid-sparing agent and affects both refractory cutaneous and muscular disease; however, concern regarding central nervous system (CNS) B-cell lymphoma and lack of controlled trials limits its use. It is also more costly than methotrexate or azathioprine.
- Cyclophosphamide is an alkylating agent that has been used sparingly in refractory cases of dermatomyositis. Lack of solid evidence of efficacy in dermatomyositis along with concerns that the agent may lead to later malignancies limits its use to severely refractory patients.
- Hydroxychloroquine is one option for a steroid-sparing agent, especially for the rash of dermatomyositis, that may be considered for young women with mild disease.**SOR C** Quinacrine and isotretinoin have shown promise in rashes that are unresponsive to hydroxychloroquine.¹³

FIGURE 181-11 Poikiloderma (erythema and mottled hyperpigmentation) on the neck of a 35-year-old Hispanic woman with dermatomyositis. The V-neck distribution is related to sun exposure. (Courtesy of Richard P. Usatine, MD, and from Goodall J, Usatine RP. Skin rash and muscle weakness. *J Fam Pract.* 2005;54(10):864-868. Reproduced with permission from Frontline Medical Communications.)

FIGURE 181-12 The shawl distribution of dermatomyositis. (Courtesy of Richard P. Usatine, MD.)

- Various combination therapies with two of the following agents have been studied, but are still empirical: azathioprine, cyclosporine, intramuscular methotrexate, and oral methotrexate.^{17,18,21} SOR C
- Biologics, including tumor necrosis factor (TNF)- α inhibitors, are currently being tested for use in juvenile and adult dermatomyositis. Conflicting and discouraging initial results prompt the need for further clinical trials. Interferon- β , monoclonal complement antibodies, and anti-T-cell signaling drugs are currently under investigation.
- It is important to look at these medications' side-effect profile and monitor the patient accordingly during treatment. Patients must not get pregnant while on these medications and various labs need to be followed. A liver biopsy may be needed for patients taking methotrexate after a 1.5-g cumulative dose.

INTRAVENOUS TREATMENT

- Pulsed intravenous methylprednisolone has been advocated for severe disease (especially juvenile cases) and in refractory cases of myositis.²³ SOR C This treatment has also been recommended as first-line therapy for patients with associated interstitial lung disease.¹
- In patients who are not responsive to traditional therapies, recent studies have found intravenous immunoglobulin (IVIG) to be an effective and relatively safe second-line therapy. Studies show improvement in muscle histology and cutaneous disease. Higher remission rates after 4 years are seen in patients receiving IVIG as part of therapy. IVIG is dosed 2 g/kg over 3 to 6 months with treatment for 2 to 5 consecutive days each month. High cost limits current use.^{12,13} SOR C
- In one study, intravenous rituximab was shown to statistically increase long-term muscle strength in patients refractory to conventional therapy.²² Thirteen patients were treated with rituximab 1000 mg IV, twice, with a 2-week interval, and followed for a median of 27 months. Patients experienced an increase in muscle strength and improvement in scores of disease activity, general health, functional ability, and health-related quality of life with sustained effect. Although rituximab is very expensive, these results are very promising for patients who are unresponsive to prednisone, methotrexate, and other conventional therapies.²²

MALIGNANCY WORK-UP

- All patients with dermatomyositis, regardless of age, should undergo an age- and gender-relevant malignancy work-up beginning at the time of diagnosis. Cancer may be diagnosed before or after the diagnosis of dermatomyositis, but malignancy risk is highest at time of diagnosis or within 1 year. Some studies show an increased risk up to 5 years following diagnosis.^{8,23}
- Screening should be performed with risks attributed to age, gender, ethnicity, and family history in mind.²⁴
- For women newly diagnosed, a pelvic and transvaginal ultrasound, mammogram, CT thorax and abdomen, along with measurement of cancer antigen (CA)-125 level should be performed. Colonoscopy is recommended in patients older than age 50 years or with risk factors.²⁰

FIGURE 181-13 A flare of dermatomyositis in a patient previously under control on medications now showing erythema on the lateral face, upper chest, and proximal arm. (Courtesy of Richard P. Usatine, MD.)

- For men, a testicular and prostate exam should be performed at diagnosis with colonoscopy if age older than 50 years.²⁵
- If primary screening is negative, some experts recommend that a patient should be screened in 3 to 6 months and every 6 months up to 4 years following diagnosis. The value of surveillance of tumor markers such as CA-125 and CA-19-9 is debatable.^{24,25}
- Given its suggestive high predictive value, some experts recommend more intensive and frequent screening for patients positive for the anti-p155 antibody.⁴
- In one study, conventional cancer screening (thoracoabdominal CT, mammography, gynecologic examination, ultrasound, and tumor marker analysis) and fluorodeoxyglucose-positron emission tomography (FDG-PET)/CT total-body screening had equivalent overall predictive values for diagnosing malignancy in patients with myositis.²⁶

PROGNOSIS

Recent reports indicate that approximately 20% to 40% of patients treated achieve remission, although 80% of treated patients remained disabled. One study found the mortality ratio of patients with dermatomyositis to be 3-fold higher than the rest of the population. Cancer, lung, and cardiac complications are the most common cause of death. Poor prognostic indicators include older age, cardiac and lung involvement (interstitial lung disease [ILD]), and dysphagia. Certain antibodies have also been linked to higher mortality rates and greater risk of malignancy.⁷

FOLLOW-UP

The patients need very close and frequent follow-up to manage their medications and overall care, as well as continued surveillance for malignancy. High doses of steroids and steroid-sparing agents, such as methotrexate, have numerous potential side effects. The patients need to be closely followed with laboratory tests and careful titration of the toxic medicines used for treatment. Also the patients need physical therapy, periodic eye exams for cataracts and glaucoma, and specific supplements including calcium, vitamin D and folic acid to prevent some of the side effects of the strong medications being prescribed. Patients on long-term corticosteroids especially need efforts made to prevent and detect osteoporosis.

PATIENT EDUCATION

Discuss the importance of sun protection as sun exposure does make the cutaneous manifestations worse. Counseling about the serious nature of the disease and prognosis is important as many patients are left with residual weakness even after good disease control is obtained. Patients need to understand that the medications being used have many risks along with their benefits and need to report side effects to their physicians. Pregnancy prevention is needed for women of childbearing potential while on a number of the medications used to treat this disease.

182 SCLERODERMA AND MORPHEA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 35-year-old woman presented with areas of shiny tough skin in patches over her abdomen (**Figure 182-1**). The patient was otherwise in good health and was puzzled by this new condition. She feared that all her skin would become this way. The skin was slightly uncomfortable but not painful. A 3-mm punch biopsy confirmed the clinical suspicion of morphea or localized scleroderma. The patient was treated with topical clobetasol and calcipotriol with some improvement in skin quality and symptoms. An antinuclear antibody (ANA) test was positive, but she has not developed progressive systemic sclerosis.

INTRODUCTION

Scleroderma (from the Greek *scleros*, to harden) is a term that describes the presence of thickened, hardened skin. It may affect only limited areas of the skin (morphea), most or all of the skin (scleroderma), or also involve internal organs (systemic sclerosis).

EPIDEMIOLOGY

- The prevalence rates of diseases that share scleroderma as a clinical feature are reported ranging from 4 to 253 cases per 1 million individuals.¹
- Systemic sclerosis has an annual incidence of 1 to 2 per 100,000 individuals in the United States.¹ The peak onset is between the ages of 30 and 50 years.¹
- In the United States, the incidence of morphea has been estimated at 25 cases per 1 million individuals per year.¹
- Worldwide, there are higher rates in the United States and Australia than in Japan or Europe.²
- Pulmonary fibrosis and pulmonary arterial hypertension are the leading causes of death as a consequence of these diseases.³

ETIOLOGY AND PATHOPHYSIOLOGY

- The scleroderma disorders can be subdivided into three groups: localized scleroderma (morphea; **Figures 182-1 to 182-3**), systemic sclerosis (**Figures 182-4 to 182-9**), and other scleroderma-like disorders that are marked by the presence of thickened, sclerotic skin lesions.
- The most common vascular dysfunction associated with scleroderma is Raynaud phenomenon (**Figure 182-10**). Raynaud phenomenon is produced by arterial constriction in the digits. The

FIGURE 182-1 Morphea on the abdomen in a 35-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 182-2 Linear morphea on the forehead called "en coup de sabre," meaning the blow of a sword. (Courtesy of John Gonzalez, MD.)

characteristic color changes progress from white pallor, to blue (acrocyanosis), to finally red (reperfusion hyperemia). Raynaud phenomenon generally precedes other disease manifestations, sometimes by years. Many patients develop progressive structural changes in their small blood vessels, which permanently impair blood flow, and can result in digital ulceration or infarction. Other forms of vascular injury include pulmonary artery hypertension, renal crisis, and gastric antral vascular ectasia.

- Systemic sclerosis is used to describe a systemic disease characterized by skin induration and thickening accompanied by variable tissue fibrosis and inflammatory infiltration in numerous visceral organs. Systemic sclerosis can be diffuse (DcSSc) or limited to the skin and adjacent tissues (limited cutaneous systemic sclerosis [LcSSc]).
- Patients with LcSSc usually have skin sclerosis restricted to the hands and, to a lesser extent, the face and neck. With time, some patients develop scleroderma of the distal forearm. They often display the CREST syndrome, which presents with Raynaud phenomenon (**Figure 182-10**), esophageal dysmotility, sclerodactyly (**Figures 182-4 to 182-7**), telangiectasias (**Figures 182-8 and 182-9**), and calcinosis cutis (**Figure 182-11**).
- Patients with DcSSc often present with sclerotic skin on the chest, abdomen, or upper arms and shoulders. The skin may take on a “salt-and-pepper” look (**Figure 182-12**). They are more likely to develop internal organ damage caused by ischemic injury and fibrosis than those with LcSSc or morphea.
- Almost 90% of patients with systemic sclerosis have some GI involvement,⁴ although half of these patients may be asymptomatic. Any part of the GI tract may be involved. Potential signs and symptoms include dysphagia, choking, heartburn, cough after swallowing, bloating, constipation and/or diarrhea, pseudoobstruction, malabsorption, and fecal incontinency. Chronic gastroesophageal reflux and recurrent episodes of aspiration may contribute to the development of interstitial lung disease. Vascular ectasia in the stomach (often referred to as “water-melon stomach” on endoscopy) is common, and may lead to GI bleeding and anemia.
- Pulmonary involvement is seen in more than 70% of patients, usually presenting as dyspnea on exertion and a nonproductive cough. Fine “Velcro” rales may be heard at the lung bases with lung auscultation. Pulmonary vascular disease occurs in 10% to 40% of patients with systemic sclerosis, and is more common in patients with limited cutaneous disease. The risk of lung cancer is increased approximately 5-fold in patients with scleroderma.
- Autopsy data suggest that 60% to 80% of patients with DcSSc have evidence of kidney damage.⁵ Some degree of proteinuria, a mild elevation in the plasma creatinine concentration, and/or hypertension are observed in as many as 50% of patients.⁶ Severe renal disease develops in 10% to 15% of patients, most commonly in patients with DcSSc.
- Symptomatic pericarditis occurs in 7% to 20% of patients, which has a 5-year mortality rate of 75%.⁷ Primary cardiac involvement includes pericarditis, pericardial effusion, myocardial fibrosis, heart failure, myocarditis associated with myositis, conduction disturbances, and arrhythmias.⁸ Patchy myocardial fibrosis is

FIGURE 182-3 Linear morphea that started 3 years before on the forehead of a 41-year-old Hispanic woman. Another example of “en coup de sabre,” meaning the blow of a sword. (Courtesy of Richard P. Usatine, MD.)

FIGURE 182-7 Scleroderma on the patient in Figure 182-6 showing leg involvement with muscle atrophy. (Courtesy of Jeffrey Meffert, MD.)

FIGURE 182-10 Raynaud phenomenon with severe ischemia leading to the necrosis of the fingertips. (Courtesy of Ricardo Zuniga-Montes, MD.)

characteristic of systemic sclerosis, and is thought to result from recurrent vasospasm of small vessels. Arrhythmias are common and are most caused by fibrosis of the conduction system.

- Pulmonary vascular disease occurs in 10% to 40% of patients with scleroderma, and is more common in patients with limited cutaneous disease. It may occur in the absence of significant interstitial lung disease, generally a late complication, and is usually progressive. Severe pulmonary arterial hypertension, sometimes with pulmonale and right-sided heart failure or thrombosis of the pulmonary vessels may develop.
- Joint pain, immobility and contractures may develop, with contractures of the fingers being most common (**Figure 182-6**). Neuropathies and central nervous system involvement, including headache, seizures, stroke, vascular disease, radiculopathy, and myelopathy, occur.
- Scleroderma produces sexual dysfunction in men and women. In men, it is very frequently associated with erectile dysfunction.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of systemic sclerosis and related disorders is based primarily upon the presence of characteristic clinical findings. Skin involvement is characterized by variable thickening and hardening of the skin. Skin pigmentary changes may occur, especially a salt-and-pepper appearance from spotty hypopigmentation (**Figure 182-12**). Other prominent skin manifestations include:
 - Pruritus and edema in the early stages.
 - Sclerodactyly (**Figures 182-4 to 182-6**).
 - Digital ulcers and pitting at the fingertips (**Figures 182-8 and 182-10**).
 - Telangiectasia (**Figures 182-8 and 182-9**).
 - Calcinosis cutis (**Figure 182-11**).
- The diagnosis of localized scleroderma (morphea) is suggested by the presence of typical skin thickening and hardening confined to one area (**Figures 182-1 to 182-3**). The diagnosis of systemic sclerosis is suggested by the presence of typical skin thickening and hardening (sclerosis) that is not confined to one area (i.e., not localized scleroderma). The combination of skin signs plus one or more of the typical systemic features supports the diagnosis of systemic sclerosis.
- The American College of Rheumatology criteria⁹ for the diagnosis of systemic sclerosis requires one major criterion or two minor criteria:
 - The major criterion is typical sclerodermatous skin changes: tightness, thickening, and nonpitting induration, excluding the localized forms of scleroderma including:
 - Sclerodactyly—Above-indicated changes limited to fingers and toes. This can include sausage fingers with tuft resorption (**Figure 182-13**).
 - Proximal scleroderma—Above-indicated changes proximal to the metacarpophalangeal or metatarsophalangeal joints, affecting other parts of the extremities, face, neck, or trunk (thorax or abdomen) almost always including sclerodactyly (**Figure 182-14**).

FIGURE 182-11 Calcinosis over the elbow in a patient with CREST syndrome. (Courtesy of Everett Allen, MD.)

FIGURE 182-12 Scleroderma with mottled hypopigmentation. The skin may have a salt-and-pepper appearance as shown here. (Courtesy of Ricardo Zuniga-Montes, MD.)

FIGURE 182-13 Sclerodactyly and sausage fingers in a 56-year-old woman with scleroderma and CREST syndrome. Note how the fingers are shortened secondary to digital tuft resorption and loss of substance from finger pads. There is also a salt-and-pepper appearance to the skin on the dorsum of the hands. (Courtesy of Richard P. Usatine, MD.)

- Minor criteria:
 - Digital pitting scars or a loss of substance from the finger pad (**Figure 182-15**).
 - Bilateral finger or hand pitting edema.
 - Abnormal skin pigmentation: hyperpigmentation often with areas of punctate or patchy hypopigmentation (**Figure 182-12**).
 - Raynaud phenomenon.
 - Bibasilar pulmonary fibrosis (**Figure 182-14**).
 - Lower (distal) esophageal dysmotility.
 - Colonic sacculations: wide-mouthed diverticula of colon located along the antimesenteric border.

LABORATORY TESTING

- A positive ANA with a speckled, homogenous, or nucleolar staining pattern is common in scleroderma. Anticentromere antibodies are often associated with LcSSc. Anti-DNA topoisomerase I (Scl-70) antibodies are highly specific for both systemic sclerosis, and related interstitial lung and renal disease.¹⁰ Although not very sensitive, anti-RNA polymerases I and III antibodies are specific for systemic sclerosis. Other testing for specific organ dysfunction is routinely done.
- The presence of characteristic autoantibodies, such as anticentromere, antitopoisomerase I (Scl-70), anti-RNA polymerase, or U3-RNP antibodies, is supportive of the diagnosis of systemic sclerosis.

IMAGING

All patients with systemic sclerosis should have a chest x-ray (CXR) and pulmonary function tests (PFTs) screening for pulmonary involvement. The most common types of pulmonary involvement are interstitial lung disease and pulmonary hypertension.

The diffusing capacity (as part of PFTs) is the most sensitive test for pulmonary disease in systemic sclerosis. High-resolution CT may be indicated for further evaluation of active pulmonary disease.

BIOPSY

- A punch biopsy can be used to diagnose morphea and scleroderma when the clinical diagnosis is not clear.

DIFFERENTIAL DIAGNOSIS

- Idiopathic occurrence of systemic sclerosis associated diseases such as Raynaud phenomenon, renal failure, and gastroesophageal reflux disease.
- Systemic lupus erythematosus (SLE) presents with systemic symptoms and a typical rash that may be scarring. ANA testing usually helps establish the diagnosis (see Chapter 180, Lupus: Systemic and Cutaneous).
- Discoid lupus erythematosus (DLE) presents as localized plaque lesion that eventually scar. Biopsy usually makes the diagnosis (see Chapter 180, Lupus: Systemic and Cutaneous).
- Myxedema is associated with hypothyroidism and is characterized by thickening and coarseness of the skin. Thyroid testing usually makes the diagnosis (see Chapter 226, Goitrous Hypothyroidism).

FIGURE 182-14 Proximal scleroderma on the face of a 56-year-old woman with scleroderma and CREST syndrome. Note the telangiectasias and a distinctive tightening of the skin around the lips. This patient also has pulmonary fibrosis as part of her progressive systemic sclerosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 182-15 Digital pitting scars and loss of substance from finger pads in this 27-year-old woman with scleroderma and sclerodactyly. (Courtesy of Richard P. Usatine, MD.)

- Lichen sclerosus when it occurs away from the genital area can resemble morphea. Although it most commonly affects the genital and perianal area, it can occur on the upper trunk, breasts, and upper arms. The plaques appear atrophic but a thin cigarette-paper crinkling appearance may help to differentiate it from morphea. A punch biopsy will lead to the correct diagnosis.
- Amyloidosis of the skin may result in thickening and stiffness of the skin. Skin biopsy reveals amyloid infiltration. Biopsy usually makes the diagnosis.
- Mycosis fungoides presents with purplish macules and plaques throughout the body. Biopsy usually makes the diagnosis (see Chapter 176, Mycosis Fungoides).

MANAGEMENT

NONPHARMACOLOGIC

- Localized scleroderma, including morphea, appears to soften with UVA light therapy.¹¹ **SOR B**
- For symptomatic therapy, skin lubrication, histamine 1 (H₁) and histamine 2 (H₂) blockers, oral doxepin, and low-dose oral glucocorticoids may be used to treat pruritus. **SOR C**
- Telangiectasias may be covered with foundation make-up or treated with laser therapy.

MEDICATIONS

- Treatment options for morphea include high-potency topical steroids such as clobetasol and topical calcipotriol.¹² **SOR B**
- Small localized lesions of morphea can be removed surgically. **SOR C**
- The combination of high-dose oral prednisone and low-dose oral methotrexate has been used successfully for scleroderma.¹³ **SOR B** Methotrexate can be started at 7.5 mg PO weekly and titrated up as needed. Of course the long-term goal is to taper the prednisone while using the oral methotrexate as a steroid-sparing agent.
- Calcium channel blockers, prazosin, prostaglandin derivatives, dipyridamole, aspirin, and topical nitrates may help symptoms of Raynaud phenomenon.^{14,15} **SOR B** Sildenafil (20 mg PO tid) has also been shown to be effective in patients with primary Raynaud phenomenon.¹⁶ **SOR B** Patients should be advised to avoid cold, stress, nicotine, caffeine, and sympathomimetic decongestant medications. Acid-reducing agents may be used empirically for gastroesophageal reflux disease. Prokinetic agents, such as erythromycin, may be useful for patients with esophageal hypomotility. **SOR C**
- Unapproved therapies for skin disease include interferon- γ , mycophenolate mofetil (1 to 1.5 g PO bid), and cyclophosphamide (50 to 150 mg/day PO in a single AM dose). Extensive skin disease is being experimentally treated with D-penicillamine (250 to 1500 mg/day PO bid/tid on an empty stomach).¹⁷ **SOR B**
- The mainstay of treatment of renal disease is control of blood pressure, with angiotensin-converting enzyme (ACE) inhibitors being

the first-line agent. **SOR C** Hemodialysis or peritoneal dialysis may be used as needed.

- Treatments of pulmonary hypertension associated with the systemic sclerosis being tested include the endothelin receptor antagonist bosentan (62.5 mg PO bid for 4 weeks, then increase to 125 mg PO bid), the phosphodiesterase-5 inhibitor sildenafil, and various prostacyclin analogs (e.g., epoprostenol, treprostinil, and iloprost). Pulmonary fibrosing alveolitis may be treated with cyclophosphamide.¹⁸ **SOR B**
- Myositis may be treated with oral prednisone, methotrexate, and azathioprine (50 to 150 mg daily). Doses of prednisone greater than 40 mg/day are associated with a higher incidence of sclerodermal renal crisis.¹⁹ **SOR B** Arthralgias can be treated with acetaminophen and NSAIDs. **SOR C**
- Any patient on long-term oral prednisone needs to be monitored for osteoporosis and diabetes. Osteoporosis prevention should include weight-bearing exercise, calcium, vitamin D supplements, and yearly dual-energy x-ray absorptiometry (DEXA) scanning to determine when and if additional medications are needed.

REFERRAL

Patients with systemic sclerosis should be referred to a rheumatologist as this is a complicated disease that requires the use of toxic medications. Depending upon the complications, patients with scleroderma may also need referral to pulmonology, cardiology, and nephrology.

PROGNOSIS

- There is an increase in the risk of premature death with systemic sclerosis. Most deaths among these patients are a result of pulmonary fibrosis and/or pulmonary hypertension. Mortality also results from renal crisis, cardiac disease, infections, malignancies, and cardiovascular disease.²⁰
- The prognosis for morphea is excellent as it only affects the skin. Although the appearance may be disturbing to the patient it is not life-threatening. If the morphea is extensive and over an extremity, it can affect function (**Figure 182-16**).

FOLLOW-UP

- The patient with systemic sclerosis needs to be evaluated at least every 3 to 6 months to monitor disease activity and progression.

PATIENT EDUCATION

- Instruct the patient to avoid skin trauma (especially the fingers), cold exposure, and smoking. Make patients aware of potential complications and have them watch for signs of systemic disease occurrence or progression.

FIGURE 182-16 Localized morphea of the leg in this young girl. Although her disease is not systemic, the tightening of the skin around the knee does cause problems with knee movement and ambulation. (Courtesy of Richard P. Usatine, MD.)

SECTION 16 BULLOUS DISEASE

183 OVERVIEW OF BULLOUS DISEASES

Richard P. Usatine, MD
Ana Treviño Saucedo, MD

PATIENT STORY

A 100-year-old black woman with diabetes was brought to the office by her family concerned about the large blister on her leg that started earlier that day (**Figure 183-1**). This large bulla appeared spontaneously without trauma and there was no surrounding erythema. The bulla contained clear fluid and there were no signs of infection. The bulla was drained with a sterile needle and no further bullae developed. The diagnosis is bullosis diabeticorum, a benign self-limited condition.

INTRODUCTION

Bullae are fluid-filled lesions on the skin that are larger than 5 mm in diameter. Bullous diseases are defined by the presence of bullae and vesicles (less than 5 mm in diameter). Bullous diseases are caused by many factors, including infections, bites, drug reactions, inflammatory conditions, and genetic and autoimmune diseases.

APPROACH TO THE DIAGNOSIS

The approach to a patient with a blistering disorder begins with a complete history and physical examination. To make the final diagnosis, laboratory investigations or tissue biopsies may be needed.

DIAGNOSIS**HISTORY**

- How did the eruption present?
- Has it changed in morphology or location?
- Has it responded to any therapies?
- Are there any associated symptoms or aggravating factors?
- How has it impacted the patient's life?
- Does the patient have any chronic medical conditions?
- Does the patient take any medications?
- Does the patient have any significant family history?

PHYSICAL EXAMINATION

- Note the location of the eruption.
- Are the bullae flaccid or tense (**Figure 183-2**)?

FIGURE 183-1 Bullosis diabeticorum on the lower leg of an older black woman with diabetes. This large bulla appeared spontaneously without trauma and there is no surrounding erythema. The bulla contained clear fluid and there was no infection. (Courtesy of Richard P. Usatine, MD.)

- Are there other lesions present (erosions, excoriations, papules, wheals)?
- Is Nikolsky sign positive or negative? (Does the skin shear off when lateral pressure is applied to unblistered skin?)
- Is Asboe-Hansen sign positive or negative? (**Figure 183-3**) (Do the bullae extend to surrounding skin when vertical pressure is applied?) Sometimes the Asboe-Hansen sign is also attributed to Nikolsky and called a Nikolsky sign, too.
- Is the Darier sign positive or negative? (Do wheals form with rubbing of the skin?)
- Note the skin background (sun-exposed skin, postinflammatory hyperpigmentation, lichenification and scarring).
- Does the patient have lymphadenopathy or hepatosplenomegaly?

CLINICAL FEATURES

- Autoimmune.
 - In bullous pemphigoid, patients have large, tense bullae that primarily involve the trunk, groin, axilla, proximal extremities, and flexor surfaces (**Figures 183-2A** and **183-3**; Chapter 184, Bullous Pemphigoid).¹
 - Pemphigus vulgaris is characterized by erosions and flaccid bullae that frequently involve the mouth (**Figure 183-4**; Chapter 185, Pemphigus). In fact, mucosal membrane involvement may be the initial presentation. If the skin is involved, then Nikolsky and Asboe-Hansen signs are positive.¹
 - Pemphigus foliaceus presents with cutaneous erosions and never involves the mucosal membranes (**Figure 183-2B**; Chapter 185, Pemphigus). Nikolsky and Asboe-Hansen signs are positive.¹
 - Pemphigoid gestationis is a condition during pregnancy or during the postpartum period that can have a bullous component. The patient usually presents with urticarial papules and plaques with bullae developing around the umbilicus and extremities. The eruption eventually generalizes and involves the palms and soles. There usually is sparing of the face, scalp, and oral mucosa (**Figure 183-5**).¹
 - Cicatricial pemphigoid involves the oral mucosa in 90% of cases and the conjunctiva in 66% of cases (**Figures 184-4** to **184-6** in Chapter 184, Bullous Pemphigoid). Patients frequently present with a desquamative gingivitis. Cutaneous lesions are seen in 25% of patients.¹
 - Epidermolysis bullosa acquisita presents with trauma-induced blistering and erosions usually on the distal extremities (**Figure 183-6**). The patient should have background scarring, milia, and nail dystrophy. This usually affects elderly persons.
 - Epidermolysis bullosa simplex also has trauma-induced blistering that can involve the trunk and extremities. This is the most common form of epidermolysis bullosa and usually starts at birth or early childhood. The bullae are intraepidermal (**Figure 183-7**).
 - Dermatitis herpetiformis classically is a symmetrical, pruritic eruption that involves the extensor surfaces, scalp, and buttocks. The patient presents with pruritic vesicles and crusted papules with overlying excoriations (**Figures 186-11** and **186-12** in Chapter 186, Other Bullous Diseases).¹
 - Linear immunoglobulin (Ig) A bullous dermatosis may produce a ring-like pattern of distribution and can occur in childhood (**Figure 183-10**). Patients may have mucous membrane involvement in up to 50% of cases.¹

FIGURE 183-2 Comparison of the tense bullae seen in bullous pemphigoid and the more flaccid bullae seen in pemphigus. **A.** Tense bullae in bullous pemphigoid. **B.** Flaccid bulla on the leg of a patient with pemphigus foliaceus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 183-3 Testing for Asboe-Hansen sign on the back of a patient with bullous pemphigoid. The bulla did not extend with vertical pressure so the sign was negative. (Courtesy of Richard P. Usatine, MD.)

FIGURE 183-6 Epidermolysis bullosa acquisita in an elderly woman. Note the partially intact bulla over the knee along with other areas of erosions and hyperpigmentation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 183-4 Flaccid and partially crusted bulla on the breast of a 51-year-old woman with pemphigus vulgaris. She also has severe oral involvement with large mucosal erosions. (Courtesy of Richard P. Usatine, MD.)

FIGURE 183-7 Large trauma-induced bulla on the leg of a 13-year-old girl with epidermolysis bullosa simplex. (Courtesy of Richard P. Usatine, MD.)

- Traumatic/Physical Stress.
 - Friction blisters form at sites of pressure and friction, frequently on the distal lower extremities.¹
 - Bullosis diabeticorum is trauma-induced, painless blistering, frequently in an acral distribution, in individuals with diabetes mellitus (**Figure 183-11**).¹
 - Postburn blistering occurs in the hours after the insult, such as is seen in severe second degree sunburns.¹ Blistering after cold injury can also occur rapidly (**Figure 183-12**).
 - Miliaria is caused by keratinous obstruction of the eccrine ducts in response to heat. Small superficial vesicles may involve the face, trunk, or extremities.¹
- Metabolic.
 - Porphyria cutanea tarda (PCT) involves sun-exposed skin, particularly the dorsal hands, forearms, ears, and face. The patient will have associated milia, scarring, and background dyspigmentation. PCT has been associated with hepatitis C infection (**Figure 183-8**).¹
- Immunologic.
 - Pityriasis lichenoides et varioliformis acuta usually presents as a papulonecrotic eruption but may have vesicles resembling varicella (**Figure 183-9**). It usually involves the anterior trunk, flexor surfaces of the upper extremities, and the axilla. The general health of the patient is unaffected, although most have lymphadenopathy. CD8 T-cells are the predominant cell-type in lesional skin.¹ It is seen more frequently in young men and can go on to become chronic.
 - Allergic-contact and irritant-contact dermatitis, if severe, can cause blistering. Special attention should be placed on the location and pattern of involvement. For example, linear vesicles and bullae would suggest a plant-induced dermatitis such as poison ivy, poison oak, or poison sumac (**Figure 183-13**). Blistering in the periumbilical area is consistent with nickel dermatitis. Involvement of the dorsal feet is frequently seen with footwear dermatitis; likewise, involvement of the dorsal hands is consistent with glove dermatitis (Chapter 146, Contact Dermatitis).²
- Drug.
 - Bullous drug eruptions may be localized to 2 mucosal surfaces with minimal cutaneous involvement or may be generalized involving all mucosal surfaces and a majority of the skin surface area. Nikolsky and Asboe-Hansen signs are positive on affected skin (see Section 14: Hypersensitivity Syndromes and Chapter 203, Cutaneous Drug Reactions).¹ Even fixed-drug eruptions can be bullous (**Figure 183-14**).
- Infections and Bites.
 - Bullous arthropod reaction can occur after an insect bite (**Figure 183-15**).¹
 - Bacterial infections should be considered when evaluating a localized blistering eruption. Amongst these infections is bullous impetigo (**Figure 183-16**). When evaluating the extremities, vesiculation overlying cellulitis may be associated with the more severe staphylococcal and streptococcal infections, and a thorough evaluation should be conducted to rule out necrotizing fasciitis. As with most bacterial infections, the patient typically presents with fever and has an elevated white blood cell count.²

FIGURE 183-14 Bullous fixed-drug eruption on the ankle of a woman taking amoxicillin. She has had this reaction before in the same location while taking another penicillin antibiotic. Note the dusky color, annular erythema and the central bullae. (Courtesy of Richard P. Usatine, MD.)

- Herpes simplex viruses should always be considered when blistering of the mucosal surfaces is observed. Generalized blistering in the adult could be because of disseminated herpes and should prompt an evaluation for immunosuppression. Blistering in a dermatomal distribution is characteristic of herpes zoster (**Figures 183-17** and **183-18**).²
- Scabies, tinea, and *Candida* can also have bullous or pustular presentations in the classic sites of involvement.²
- Hydrostatic.
 - Edema blisters form from the osmotic pressure experienced during the third spacing of fluid. As such, patients usually have a diagnosis of heart failure, cirrhosis, or kidney failure.¹
- Childhood.
 - Transient neonatal pustular melanosis (TNPM) are pustules or vesicles without associated erythema located in clusters on the forehead, posterior ears, chin, neck, upper chest, back, buttocks, abdomen, and thighs, that spontaneously heal leaving behind pigmented macules. TNPM affects up to 4% of term infants and is more commonly seen in the African American population (Chapter 110, Pustular Diseases of Childhood).³
 - Acropustulosis of infancy develops during the first few weeks to months of life and spontaneously remits at 2 to 3 years of age. In this condition, crops of vesicles and pustules involve palms and soles, causing pruritus (Chapter 110, Pustular Diseases of Childhood).³
 - Neonatal pemphigus occurs in neonates whose mothers have active pemphigus vulgaris (not pemphigus foliaceus). The patient is born with bullae that spontaneously resolve within 1 to 2 weeks.³
 - Epidermolysis bullosa simplex is a hereditary condition in which minimal friction or trauma causes vesicles, bullae, and erosions. The distal extremities are frequently involved (**Figure 183-19**).⁴
 - Congenital infections with herpes simplex virus usually present with vesicles. In addition, a vesicular eruption in the neonate could be caused by neonatal syphilis, which is the only form of syphilis with a vesicular presentation.²
 - Bullous mastocytosis is caused by mast cell accumulation in the skin. The bullous presentation is very rare, but may involve any area of the body. On examination, the Darier sign should be positive and dermatographism should be present. Work-up should be conducted to determine the presence of systemic involvement, which may include a mast cell leukemia. A good lymph node and abdominal examination is recommended to evaluate for lymphadenopathy and hepatosplenomegaly.³

LABORATORY STUDIES AND WORK-UP

If the clinical picture is not clear, various laboratory studies may assist the clinician in making the diagnosis. Some diagnoses should be confirmed by histology even if the diagnosis appears clear. For example, all cases of suspected pemphigus should be biopsied because the management will involve long-term use of potentially toxic medications and it is crucial to know exactly what you are treating. The information in Chapters 184, Bullous Pemphigoid, and 185: Pemphigus, will help you to decide which tests to use in some of the autoimmune blistering diseases. Consulting a dermatologist is very appropriate for many of the more rare and lethal conditions.

FIGURE 183-15 Bullous arthropod bites secondary to fire ants. (From Lane K, Lumbang W. Pruritic blisters on legs and feet. *J Fam Pract.* 2008;57(3):177-180. Reproduced with permission from Frontline Medical Communications.)

FIGURE 183-16 Bullous impetigo on the face of a child. Note the honey crusts, vesicles and bulla. (Courtesy of Jack Resneck, Sr., MD.)

- Direct fluorescent antibody test can be done on a scraping of a lesion if herpes simplex or varicella zoster is suspected. In many laboratories, a result can be obtained within 24 hours.
- Mineral oil scraping for scabies (Chapter 143, Scabies).
- KOH scraping for possible blistering tinea infections (such as bullous tinea pedis). See Section 5: Fungal.
- Genetic studies for suspected genetic defects; consider referral to geneticist.

BIOPSY

- One 4-mm punch biopsy for pathologic evaluation—Biopsy an established lesion including the edge of the blister. A shave biopsy is an alternative as long as the epidermis of the blister stays attached to the specimen.
- Biopsy for direct immunofluorescence (DIF)—Biopsy the perilesional skin and send the specimen in special Michel media or sterile saline and let the lab know to transfer it to Michel media when it arrives. The easiest way to do this is to take a shave biopsy that includes the bulla and the perilesional skin. Then cut the specimen in half and send the perilesional skin for DIF and the blister for standard pathology.
- Consider sending part of the biopsy for bacterial, fungal, and viral cultures and stains if infections are suspected and cultures and other less-invasive studies are not providing the diagnosis. Send the specimens in a sterile urine cup on top of a sterile gauze pad soaked with sterile saline.

FURTHER EVALUATIONS

Patients with cicatricial pemphigoid and toxic epidermal necrolysis need an ophthalmologic evaluation. Patients with several of the epidermolysis bullosa diseases and dermatitis herpetiformis need a gastroenterologic evaluation.

For possible paraneoplastic conditions, such as in epidermolysis bullosa acquisita and cicatricial pemphigoid, thorough cancer screening and studies targeting the patient's symptomatology are indicated.

184 BULLOUS PEMPHIGOID

Asad K. Mohmand, MD
Richard P. Usatine, MD

PATIENT STORY

A native of Panama was seen for extensive bullous disease that is classic for bullous pemphigoid (BP) (**Figure 184-1**). The presence of numerous intact bullae would make pemphigus very unlikely. The patient was treated with oral prednisone and began to respond quickly. The patient eventually had a good outcome.

INTRODUCTION

BP is an autoimmune blistering disease of older adults that may cause significant morbidity and a poor quality of life. The term *pemphigoid* refers to its similarity to the blisters seen in pemphigus. However, BP is usually less severe than pemphigus vulgaris and is not considered a life-threatening condition.

EPIDEMIOLOGY

- BP is the most frequent autoimmune blistering disease of the skin (and mucosa).
- It typically affects persons older than 65 years of age but can occur at any age.
- There is no racial or gender predilection (a recent British population study, however, suggested an increased prevalence in women).¹
- Its incidence may be on the rise.¹
- Although it is not considered life threatening, it has been associated with an increased risk of mortality (hazard ratio [HR] 2.3, 95% confidence interval [CI] 2 to 2.7).¹

ETIOLOGY AND PATHOPHYSIOLOGY

- BP is a chronic autoimmune disorder of the skin.
- Immunoglobulin (Ig) G autoantibodies against BP180 antigen of the basement membrane protein are considered pathognomonic and can be found in up to 65% of patients.²
- Anti-BP230 antibodies are present in virtually all patients but are not considered pathognomonic.³
- Binding of antibodies to the basement membrane activates the complement system, leading to chemotaxis of inflammatory cells (eosinophils and mast cells), which release proteases. The subsequent degradation of hemidesmosomal proteins leads to blister formation.
- There are several morphologically distinct clinical presentations:
 - Generalized bullous form is the most common (**Figure 184-1**). Tense bullae occur on both erythematous and normal-appearing skin surfaces. The bullae usually heal without scarring.

FIGURE 184-1 A. Extensive untreated bullous pemphigoid in a Panamanian woman. B. Close-up of intact bulla and dark crusts. (Courtesy of Eric Kraus, MD.)

- Localized form of BP is less common and is limited to a small area of involvement (**Figure 184-2**).
- Vesicular (also known as “eczematous”) form is characterized by clusters of small tense blisters with an urticarial or erythematous base.
- Other forms are less common and include vegetative (intertriginous vegetating plaques), urticarial (without any bullae), nodular (resembling prurigo nodularis), acral (bullae on palms, soles, and face in children associated with vaccination), and generalized erythroderma (exfoliative lesions with or without vesicles/bullae).
- Pemphigoid gestationis is a variant of BP that occurs during or after pregnancy. Lesions resolve after delivery, but may recur with subsequent pregnancies, or in the nonpregnant state (Chapter 76, Pemphigoid Gestationis).⁴
- Drug-induced BP has been reported with drugs containing sulfhydryl groups, including penicillamine, furosemide, captopril, and sulfasalazine.

DIAGNOSIS

CLINICAL FEATURES

- Tense blisters that involve normal or inflamed skin or mucous membranes (**Figures 184-1** and **184-2**).
- Development of bullae is typically preceded by a prodromal phase characterized by intense pruritus with or without excoriations and eczematous (or urticarial) lesions. This phase can last for months, making early diagnosis difficult.⁵
- Nikolsky sign (wrinkling and sheet-like peeling of the skin when lateral pressure is applied to unblistered skin) is usually negative.⁶ Asboe-Hansen sign will be negative too. Bulla will not extend to surrounding skin when vertical pressure is applied (**Figure 184-2B**).

TYPICAL DISTRIBUTION

- Flexure surfaces of the arms and legs.
- Lower abdomen and groin.
- Mucous membranes are involved in 10% to 25% of cases.

BIOPSY

Biopsy is required for establishing diagnosis and to differentiate BP from other conditions that can have a similar clinical presentation:

- A scoop shave or 4-mm punch biopsy from edge of an early blister including part of the normal-appearing skin for H and E staining shows a subepidermal blister and an eosinophil-rich mixed dermal inflammatory infiltrate. If the scoop shave contains sufficient perilesional skin, cut this off and send it for direct immunofluorescence (DIF).
- The skin from the scoop shave or a second 4-mm punch biopsy from perilesional skin, transported in Michel’s medium for DIF. If Michel’s transport medium is not available, send the specimen for DIF in sterile saline soaked gauze and alert the laboratory to transfer the specimen into Michel’s medium ASAP. DIF demonstrates linear IgG and/or complement C3 deposits at the dermal–epidermal junction.

FIGURE 184-2 Localized bullous pemphigoid with large bulla on the thigh of this 91-year-old woman. Her biopsy for direct immunofluorescence demonstrated a linear band of IgG at the dermal-epidermal junction. **A.** Bullae on the thigh. **B.** One week later there is a new bulla and the Asboe-Hansen sign is negative. **C.** One week later the bullae are healing as the bullous pemphigoid is being treated with clobetasol topically and the patient is taking doxycycline and niacin orally. (Courtesy of Richard P. Usatine, MD.)

- Alternatively, an enzyme-linked immunosorbent assay (ELISA) blood test for BP180 antibodies (and if negative, then ELISA for BP230 antibodies) can be performed for characterization of circulating antibodies.⁷

DIFFERENTIAL DIAGNOSIS

- Cicatricial pemphigoid (**Figures 184-4 to 184-6**)—Predominant mucosal involvement; lesions heal with prominent scarring; IgG localizes to blister floor on IDIF.
- Dermatitis herpetiformis—Grouped vesicles; extensor distribution (Chapter 186, Other Bullous Diseases).
- Epidermolysis bullosa acquisita—IgG localizes to blister floor on IDIF (Chapter 186, Other Bullous Diseases).
- Erythema multiforme—Targetoid lesions; linear IgG immunofluorescence is negative (Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Linear IgA dermatosis—Usually drug-induced (e.g., vancomycin⁸); DIF demonstrates IgA deposits. Also called chronic bullous dermatosis of childhood (Chapter 183, Overview of Bullous Disease including **Figure 183-5**).

MANAGEMENT

The objectives of therapy in BP are to decrease the troublesome symptoms associated with the blistering lesions, resolve active lesions, and prevent recurrences.

- High-potency topical corticosteroids are considered first-line treatment for moderate to severe generalized disease (e.g., clobetasol).⁹ **SOR A** Initial disease control and 1-year survival rates in extensive BP are better with topical approach when compared with oral prednisolone.¹¹
- Oral corticosteroids.⁹ **SOR A**
- Prednisone 0.5 to 0.75 mg/kg per day.¹⁰
- Increase dose until new blisters cease to develop.
- Reduce dose approximately 10% every 2 to 3 weeks to reach dose of 15 to 20 mg/day.
- Adjuvant antibiotic treatment should be considered for all patients:
 - Tetracycline (1.5 to 2 g/day) with or without niacinamide (1.5 to 2 g/day).¹² **SOR B** Both tetracycline and niacinamide come in 500-mg capsules and may be taken 3 to 4 times daily. Niacinamide contains niacin (vitamin B₃) and is available over the counter. If tetracycline is not available, doxycycline 100 mg twice daily is an alternative.
 - Steroid-sparing drugs and adjuvant therapy for patients whose disease is not controlled with steroids and tetracycline:
 - Dapsone is an antineutrophilic antibiotic that is an alternative to tetracycline and doxycycline (**Figure 184-7**). Azathioprine 50 to 200 mg divided bid or tid (first-line adjuvant).⁹ **SOR B**
 - Mycophenolate mofetil 0.5 to 2 g/day divided bid or tid (less hepatotoxic than azathioprine).¹³ **SOR C**
 - Cyclophosphamide 1 to 5 mg/kg per day. **SOR C**

FIGURE 184-5 Cicatricial bullous pemphigoid with scarring connecting the lower lid to the cornea. (Courtesy of Eric Kraus, MD.)

FIGURE 184-6 Cicatricial bullous pemphigoid of the mouth showing gingivitis. More than 50% of cases of BP have oral involvement. (Courtesy of Eric Kraus, MD.)

- Disease resistant to combination of corticosteroids and steroid-sparing agents:
 - Intravenous immunoglobulin (IVIG) can produce a rapid and dramatic but very transient response; requires multiple cycles of IVIG. **SOR** **C**
 - Plasmapheresis can be considered for patients with severe resistant disease requiring high doses of systemic steroids to improve symptoms and reduce steroid dose. ¹⁴ **SOR** **C**
 - Case reports and small series of successful therapy of refractory BP with rituximab,¹⁵ etanercept,¹⁶ or omalizumab¹⁷ have been published in the recent medical literature.
- Consultations
 - Dermatology consultation for recommending therapy based on extent of disease and for changes in therapy when required.
 - Nutrition consultation if patient is having difficulty maintaining weight.

FOLLOW-UP

- Ask patient about recurrent lesions, pruritus, and side effects from treatment.
- Perform periodic skin examinations looking for new lesions to adjust dose of prednisone and to monitor for lymphadenopathy and skin cancer in patients using immunosuppressive medications.
- Monitor for drug-specific laboratory abnormalities (e.g., glucose and triglycerides with steroid use; complete blood count [CBC], renal function, and liver function tests for azathioprine).
- Make sure patients do not run out of their medications because this can result in recurrent lesions (**Figure 184-8**).
- Adjust treatment if patient relapses (e.g., increase steroid dose or add an immunosuppressive agent).
- Taper steroids slowly (as above) after dissipation of disease flare.

PATIENT EDUCATION

- Avoid mechanical irritation, direct sun exposure, dental prostheses, extremes of temperature.
- Recommend high-protein, low-carbohydrate and low-fat diet; calcium and vitamin D supplementation for patients on corticosteroids.
- Provide information on wound care, stress-reduction, appropriate exercise, and side effects of medications.

185 PEMP HIGUS

Richard P. Usatine, MD
Shashi Mittal, MD

PATIENT STORY

A young man presented with painful blisters on his face and mouth (Figure 185-1). The patient was referred to dermatology that day. The dermatologist recognized likely pemphigus vulgaris (PV) and did shave biopsies for histopathology and direct immunofluorescence of facial vesicles/bullae to confirm the presumed diagnosis. The patient was started on 60 mg of prednisone daily until the pathology confirmed PV. Steroid-sparing therapy was then discussed and started in 2 weeks from presentation.

INTRODUCTION

Pemphigus is a rare group of autoimmune bullous diseases of skin and mucous membranes characterized by flaccid bulla and erosions. The three main types of pemphigus are PV (with the pemphigus vegetans variant), pemphigus foliaceus (with the pemphigus erythematosus variant), and paraneoplastic pemphigus. All types of pemphigus cause significant morbidity and mortality. Although pemphigus is not curable, it can be controlled with systemic steroids and immunosuppressive medications. These medications can be lifesaving, but also place pemphigus patients at risk for a number of complications. The word *pemphigus* is derived from the Greek word *pemphix*, which means bubble or blister.

EPIDEMIOLOGY

Epidemiology of the three major types of pemphigus:

- PV (Figures 185-1 to 185-4):
 - Most common form of pemphigus in the United States.
 - Annual incidence is 0.75 to 5 cases per 1 million population.¹
 - Usually occurs between 30 and 50 years of age.²
 - Increased incidence in Ashkenazi Jews and persons of Mediterranean origin.²
 - Pemphigus vegetans is a variant form of PV (Figures 185-5 and 185-6).
- Pemphigus foliaceus (PF) (Figures 185-7 to 185-10): Superficial form of pemphigus.
 - More prevalent in Africa (Figures 185-11 and 185-12).¹
 - Variant forms include pemphigus erythematosus (resembles the malar rash of lupus erythematosus) and fogo selvagem.
 - Fogo selvagem is an endemic form of PF seen in Brazil and affects teenagers and individuals in their twenties.¹
- Paraneoplastic pemphigus (PNP)
 - Onset at age 60 years and older.
 - Associated with occult neoplasms commonly lymphoreticular.
 - Malignancies like non-Hodgkin lymphoma and chronic lymphocytic leukemia.

FIGURE 185-10 Widespread pemphigus foliaceus. (Courtesy of Eric Kraus, MD.)

FIGURE 185-9 Pemphigus foliaceus with large erosions on the back and extremities of this patient. (Courtesy of Eric Kraus, MD.)

FIGURE 185-11 Pemphigus foliaceus on the trunk and arms of a woman in Africa. Some of the lesions appear annular but they are all superficial erosions within the epidermis. (Courtesy of Richard P. Usatine, MD.)

- Also associated with benign neoplasms such as thymoma and Castleman disease (angiofollicular lymph node hyperplasia).²

ETIOLOGY AND PATHOPHYSIOLOGY

- The basic abnormality in all three types of pemphigus is acantholysis, a process of separating keratinocytes from one another. This occurs as a result of autoantibody formation against desmoglein (the adhesive molecule that holds epidermal cells together). Separation of epidermal cells leads to formation of intraepidermal clefts, which enlarge to form bullae.¹
- The mechanism that induces the production of these autoantibodies in most individuals is unknown. Yet PF may be triggered by drugs, most commonly thiol compounds like penicillamine, captopril, piroxicam, and others, like penicillin and imiquimod.³ An environmental trigger in the presence of susceptible human leukocyte antigen (HLA) gene is suggested to induce autoantibodies in fogo selvagem.¹
- The autoantibodies in pemphigus are usually directed against desmoglein 1 and 3 molecules (Dsg1 and Dsg3). Dsg1 is present predominantly in the superficial layers of the epidermis, whereas Dsg3 is expressed in deeper epidermal layers and in mucous membranes. As a result, clinical presentation depends on the antibody profile. In PV, a limited mucosal disease occurs when only anti-Dsg3 antibody is present, but extensive mucosal and cutaneous disease occurs when both anti-Dsg1 and Dsg3 antibodies are present. In PF, mucosal lesions are absent and the cutaneous lesions are superficial because of isolated anti-Dsg1 antibody.
- Patients with PNP demonstrate both anti-Dsg1 and Dsg3 antibodies. However, unlike PV, autoantibodies against plakin proteins (another adhesive molecule) are also observed in patients with PNP and these autoantibodies form a reliable marker for this type of pemphigus.

DIAGNOSIS

CLINICAL FEATURES

- Pemphigus vulgaris (**Figures 185-1 to 185-4**)—Classical lesions are flaccid bullae that rupture easily, creating erosions. Since bullae are short-lived, erosions are the more common presenting physical finding (**Figure 185-13**). Lesions are typically tender and heal with postinflammatory hyperpigmentation that resolves without scarring. A positive Asboe-Hansen or Nikolsky sign may be present, but neither sign is diagnostic. A positive Asboe-Hansen sign occurs when a bulla extends to surrounding skin while pressure is applied directly to the bulla. The Nikolsky sign is positive when skin shears off while lateral pressure is applied to unblistered skin during active disease. Sometimes the Asboe-Hansen sign is also attributed to Nikolsky and called a Nikolsky sign, too.
- Pemphigus vegetans is a variant of PV where healing is associated with vegetating proliferation of the epidermis (**Figures 185-5 and 185-6**).
- Pemphigus foliaceus: Multiple red, scaling, crusted, and pruritic lesions described as “corn flakes” are seen. Shallow erosions arise

FIGURE 185-12 Another case of pemphigus foliaceus in Africa. Pemphigus foliaceus is more prevalent in Africa. Note the hyperpigmentation of the healing lesions after treatment has begun. (Courtesy of Richard P. Usatine, MD.)

FIGURE 185-13 Pemphigus vulgaris involving the face and oral mucosa. The erosions are deeper than those seen in pemphigus foliaceus. The oral involvement points to pemphigus vulgaris. (Courtesy of Richard P. Usatine, MD.)

when crusts are removed, but intact blisters are rare as the disease is superficial (**Figures 185-7 to 185-12**).

- PNP (**Figure 185-14**)—Lesions are similar to PV, although lichen planus, morbilliform, or erythema multiforme-like lesions also may be seen in addition to blisters and erosions. Another distinctive feature is the presence of epithelial necrosis and lichenoid changes in the lesions. Pulmonary involvement secondary to acantholysis of bronchial mucosa is seen in 30% to 40% of cases of PNP.

TYPICAL DISTRIBUTION

- PV—Common mucosal site is oral mucosa, although any stratified squamous epithelium may be involved. Mucosal lesions may be followed by skin lesions after weeks to months usually on scalp, face, and upper torso. PV should be suspected if an oral ulcer persists beyond a month (**Figures 185-1, 185-3, and 185-15**).
- Pemphigus vegetans—Usually seen in intertriginous areas like the axilla, groin, and genital region (**Figures 185-5 and 185-6**).
- PF—Initially affects face and scalp, though may progress to involve chest and back (**Figures 185-7 to 185-12**). When the facial involvement in PF is in a lupus-like pattern, this is called pemphigus erythematosus (**Figure 185-16**).
- PNP—Common sites include oral mucosa and conjunctiva. (**Figure 185-14**) Columnar and transitional epithelia may also be involved besides stratified squamous epithelium.

LABORATORY STUDIES

- Circulating desmoglein antibodies levels may be measured in the blood using indirect immunofluorescence. This is usually not necessary unless the diagnosis is in question and further data are needed.
- Complete blood count and a comprehensive metabolic profile including liver function tests, creatinine, and glucose will be needed as a baseline, as all the systemic therapies have significant toxicities.
- Patients at risk for steroid-induced osteoporosis should have a dual-energy x-ray absorptiometry (DEXA) scan performed.

BIOPSY

- Skin biopsy is essential for accurate diagnosis. The depth of acantholysis and site of deposition of antibody complexes help differentiate pemphigus from other bullous diseases. Two specimens should be sent. Perform a shave of the edge of the bulla to include the surrounding normal appearing epidermis. This biopsy should be of the freshest lesion with an intact bulla, if possible. Cut the specimen in half and send the portion with the bulla in formalin for routine histopathology. The second half should be perilesional adjacent normal skin. This is sent on a gauze pad soaked in normal saline or Michel solution for direct immunofluorescence (DIF). Routine histopathology demonstrates suprabasal acantholysis and DIF shows antibody deposition in the intercellular spaces of the epidermis. The pattern of the DIF fluorescence is described as chicken wire (**Figure 185-17**).

DIFFERENTIAL DIAGNOSIS

- Bullous pemphigoid—Bullae are tense because they occur in the deeper subepidermal layer. Mucous membrane involvement is rare.

FIGURE 185-14 Paraneoplastic Pemphigus with severe erosions covering practically the entire mucosa of the oral cavity with partial sparing of the dorsum of the tongue. Lesions are extremely painful, interfering with adequate food intake. This patient had non-Hodgkin lymphoma as the underlying malignancy. (Courtesy of Wolff K, and Johnson RA. *Fitzpatrick's Color Atlas & Synopsis of Clinical Dermatology, Sixth Edition*. New York: McGraw-Hill; 2009, Fig.18-19.)

FIGURE 185-15 Pemphigus vulgaris involving the tongue and lips of a young woman. This is severely painful, making it difficult to eat or drink. (Courtesy of Richard P. Usatine, MD.)

Biopsy illustrates subepidermal acantholysis and immunoglobulin deposition along the basement membrane (Chapter 184, Bullous Pemphigoid).³

- Cicatricial pemphigoid—Also known as mucous membrane pemphigoid. Usually affects oral mucosa and conjunctiva. Lesions heal with scarring, which results in irreversible sequelae such as blindness, subglottic stenosis, and esophageal strictures.³ Histology demonstrates antibody complexes in the basement membrane with submucosal infiltrate and prominent fibroblast proliferation (Chapter 184, Bullous Pemphigoid).
- Dermatitis herpetiformis—Herpes-like lesions in the form of grouped vesicles and erosions occur especially on the elbows and extensor surfaces. It is associated with gluten-induced enteropathy. Biopsy reveals neutrophilic microabscesses at the tips of dermal papillae with deposition of immunoglobulin (Ig) A antibody complexes. Blood tests for antigliadin and antiendomysial antibodies can help diagnose the gluten-induced enteropathy (Chapter 186, Other Bullous Diseases).
- Linear IgA dermatosis—Typical lesions are described as “string of pearls,” which is an urticarial plaque surrounded by vesicles. Histologically, IgA antibodies are deposited in a linear fashion along the basement membrane (Chapter 183, Overview of Bullous Diseases).⁵
- Porphyria cutanea tarda—Bullae are seen on sun-exposed areas, especially on the dorsum of the hands. Histology shows antibody deposition in the capillary walls and dermoepidermal junction. Serum iron, ferritin, and transaminase levels are elevated as well as 24-hour urine porphyrins. Elevations in urine porphyrins are diagnostic (Chapter 186, Other Bullous Diseases).
- Hailey-Hailey disease (benign familial pemphigus)—A genodermatosis with crusted erosions and flaccid vesicles distributed in the intertriginous areas (**Figure 185-18**). It most closely resembles pemphigus vegetans clinically but has a completely different pathophysiology than true pemphigus. It is called benign because it is not life-threatening. A 4-mm punch biopsy is adequate to make this diagnosis as the histology is different than pemphigus.

MANAGEMENT

Treatment of pemphigus should be undertaken in consultation with a dermatologist. Treatment is directed initially at disease control and remission followed by disease suppression. The goal is to eventually discontinue all medications and achieve complete remission. Unfortunately this goal is hard to achieve.

SYSTEMIC THERAPY

Corticosteroids

Oral steroids with a steroid-sparing adjuvant agent is the most effective treatment (two randomized controlled trials [RCTs]).^{4,5} **SOR B**

- Treatment should begin with the corticosteroid.⁴⁻⁶ **SOR B** Mild disease may be controlled with prednisone 40 mg/day but for rapidly progressive and extensive disease, a higher dose prednisone 60 to 80 mg/day is initiated. **SOR C** The dose may be increased by 50% every 1 to 2 weeks until disease activity is controlled. In most cases, a dose of approximately 60 mg of prednisone daily will need

FIGURE 185-16 Pemphigus erythematosus creating a lupus-like pattern of facial involvement. Note how the pemphigus foliaceus lesions involve the malar areas bilaterally. (Courtesy of Richard P. Usatine, MD.)

FIGURE 185-17 Direct immunofluorescence against immunoglobulin (Ig) G antibodies surrounding cells of the epidermis in a patient with pemphigus vulgaris. Note the chicken-wire appearance. (Courtesy of Martin Fernandez, MD, and Richard P. Usatine, MD.)

to be continued for at least 1 month. Once remission is induced, the dose is tapered by 25% every 1 to 2 weeks to the lowest dose needed to suppress recurrence of new lesions.¹

- Pulse therapy with intravenous methylprednisolone 1 g/day for 5 days may be tried in severe cases in an attempt to decrease the cumulative dose of steroids, especially when high-dose oral steroids are ineffective.⁶ **SOR C**
- High-dose and prolonged treatment with steroids can have serious side effects. Consequently, it is advisable to start adjuvant steroid-sparing therapy within 2 to 4 weeks of treatment. Adjuvant agents have a lag period of 4 to 6 weeks before they become effective, so starting them sooner allows for earlier steroid taper. They may be used alone to maintain remission after steroid withdrawal.

Adjuvant agents

- Adjuvant agents include azathioprine, cyclophosphamide, mycophenolate, dapsone, and intravenous immunoglobulin.⁶⁻⁹ The efficacy of steroids have been shown to be enhanced when combined with a cytotoxic drug.⁵
- Azathioprine and mycophenolate mofetil (CellCept) are often the preferred adjuvants for PV.^{6,8,10} **SOR B**
- Azathioprine was less effective than mycophenolate mofetil in achieving remission in one study with 40 participants (risk ratio 0.72; 95% confidence interval [CI] 0.52 to 0.99).^{8,10} In 13 (72%) of 18 patients with pemphigus receiving oral methylprednisolone and azathioprine, complete remission was achieved after a mean of 74 (± 127) days compared with 20 (95%) of 21 patients receiving oral methylprednisolone and mycophenolate in whom complete remission occurred after a mean of 91 (± 113) days. A greater percentage of patients treated with azathioprine had adverse effects than those treated with mycophenolate.
- In one RCT open-label trial of four treatment regimens for PV, the most efficacious cytotoxic drug to reduce steroid was found to be azathioprine, followed by cyclophosphamide (IV pulse therapy), and mycophenolate mofetil.⁵ **SOR B**
- Standard dosing for azathioprine is 50 mg a day. Standard dosing for mycophenolate is 1000 mg to 1500 mg twice daily. Azathioprine is significantly less expensive but patients may experience more side effects. Both are acceptable, widely used treatments for pemphigus.^{4,5,8-10} **SOR B**
- Dapsone is an alternative adjuvant for pemphigus.⁶ **SOR C** In one small study, 8 (73%) of 11 patients receiving dapsone versus 3 (30%) of 10 receiving placebo reached the primary outcome of a prednisone dosage of 7.5 mg/day or less. This was not statistically significant and only showed a trend to efficacy of dapsone as a steroid-sparing drug in maintenance-phase PV.¹¹
- Intravenous immunoglobulin (IVIg) may be used as adjuvant therapy in refractory cases of pemphigus.^{6,12-14} **SOR B** In one RCT, it was used as a 5-day cycle to treat pemphigus that was relatively resistant to systemic steroids. In this multicenter study of 61 patients with PV or foliaceous, there was a decrease in disease activity subsequent to the cycle of IVIg.¹⁴ **SOR B**
- Rituximab is a chimeric monoclonal antibody against CD20 on B lymphocytes. It leads to depletion of pathogenic B cells for up to 12 months, resulting in a reduction of plasma cells secreting

FIGURE 185-18 Hailey-Hailey disease (benign familial pemphigus) with erythema and pustules in the axilla. This is not true pemphigus but resembles pemphigus vegetans. (Courtesy of Jonathan B. Karnes, MD.)

pathogenic autoantibodies. Rituximab is infused weekly for 4 consecutive weeks in addition to the standard immunosuppressive treatment. It has shown promise in several case reports and cohort studies in the treatment of PNP and refractory cases of PV and foliaceus.^{15,16} **SOR B**

Treating and preventing complications of therapy

- Osteoporosis prevention—Long-term therapy with oral prednisone is a significant risk factor for osteoporosis. All patients should receive supplemental calcium and vitamin D based upon their age, gender, and normal dietary intake. A DEXA scan early in the course of the disease can be a helpful baseline. One study showed that alendronate therapy given to patients with immunobullous disease on long-term steroids resulted in statistically significant increases in bone mineral density at the lumbar spine and femoral neck.¹⁷
- Thrush is a common complication of high-dose steroids in pemphigus (**Figure 185-19**). This should be treated with oral fluconazole or another antifungal to prevent *Candida* esophagitis. If the patient is complaining of pain or difficulty swallowing, consider the diagnosis of *Candida* esophagitis and treat accordingly.
- Steroid-induced diabetes may also occur. This can be treated with metformin and monitoring of blood sugars and hemoglobin A_{1c}.

LOCAL THERAPY

- Solitary lesions may be treated with topical high-potency steroids, such as clobetasol, or with intralesional steroid injections, for example, 20 mg/mL triamcinolone acetonide. Isolated oral lesions may be treated with steroid paste, sprays, or lozenges.
- Normal saline compresses or bacteriostatic solutions such as potassium permanganate are useful in keeping lesions clean. Oral hygiene is crucial. Mouthwashes such as chlorhexidine 0.2% or 1:4 hydrogen peroxide may be used. Topical anesthetics may be used for pain.⁶

PROGNOSIS

Pemphigus is a chronic group of diseases that are potentially life-threatening. There is no cure and the long-term use of steroids and immunosuppressive drugs places the patients at risk for a number of complications including infections, sepsis, steroid-induced diabetes, and steroid-induced osteoporosis. Some patients will be lucky and go into remission while others will need systemic therapy for life. Complications of treatment have become the greatest source of morbidity and mortality in pemphigus.

FOLLOW-UP

Prolonged follow-up is needed for medication adjustment and to monitor disease activity and drug side effects.

PATIENT EDUCATION

- Educate patients regarding disease, complications, and side effects of medications.

FIGURE 185-19 Thrush appearing in the mouth of a 50-year-old woman recently placed on oral prednisone for new-onset pemphigus vulgaris. Note the large erosion on the buccal mucosa and the adherent white *Candida* anterior to that and also on the tongue. KOH was positive and patient was treated with fluconazole. (Courtesy of Richard P. Usatine, MD.)

- Advise patients on avoiding trauma to skin such as with contact sports. Similarly, oral lesions may be aggravated by nuts, spicy foods, chips, and dental plates and bridges.
- Instruct patients on wound care to prevent infections and relieve local discomfort.
- Provide information on support groups such as the International Pemphigus Pemphigoid Foundation.

186 OTHER BULLOUS DISEASES

Jimmy H. Hara, MD, FAAFP
Richard P. Usatine, MD

INTRODUCTION

There are a number of bullous diseases other than pemphigus and bullous pemphigoid that are important to recognize. Porphyria cutanea tarda is a porphyria that has no extracutaneous manifestations (**Figures 186-1 to 186-3**). Dystrophic epidermolysis bullosa belongs to a family of inherited diseases where blister formation can be caused by even minor skin trauma. PLEVA (pityriasis lichenoides et varioliformis acuta) is a minor cutaneous lymphoid dyscrasia that can appear suddenly and persist for weeks to months. Dermatitis herpetiformis is a recurrent eruption that is usually associated with gluten and diet-related enteropathies.

PORPHYRIA CUTANEA TARDA

PATIENT STORY

A middle-aged woman presented with tense blisters on the dorsum of her hand (**Figure 186-1**). One bulla was intact and the others had ruptured, showing erosions. Work-up showed elevated porphyrins in the urine (which fluoresced orange-red under a Wood lamp) and the patient was diagnosed with porphyria cutanea tarda.

EPIDEMIOLOGY

- Porphyria cutanea tarda (PCT) occurs mostly in middle-aged adults (typically 30 to 50 years of age) and is rare in children.
- It is especially likely to occur in women on oral contraceptives and in men on estrogen therapy for prostate cancer.¹
- Alcohol, pesticides, and chloroquine have been implicated as chemicals that induce PCT.¹
- PCT is equally common in both genders.
- There is an increased incidence of PCT in persons with hepatitis C (**Figures 186-2 and 186-3**).

ETIOLOGY AND PATHOPHYSIOLOGY

- The porphyrias are a family of illnesses caused by various metabolic derangements in the metabolism of porphyrin, the chemical backbone of hemoglobin. Whereas the other porphyrias (acute intermittent porphyria and variegate porphyria) are associated

FIGURE 186-1 Porphyria cutanea tarda in a middle-aged woman. (Courtesy of Lewis Rose, MD.)

FIGURE 186-2 Porphyria cutanea tarda in a man with hepatitis C. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

with well-known systemic manifestations (abdominal pain, peripheral neuropathy, and pulmonary complications), PCT has no extracutaneous manifestations. Photosensitivity is seen (as with variegate porphyria). PCT is associated with a reduction in hepatic uroporphyrin decarboxylase.

RISK FACTORS

- Hepatitis C.
- Alcohol-induced liver injury.
- Hemochromatosis.²

DIAGNOSIS

CLINICAL FEATURES

The classic presentation is that of blistering (vesicles and tense bullae) on photosensitive “fragile skin” (similar to epidermolysis bullosa). Scleroderma-like heliotrope suffusion of the eyelids and face may be seen. As the blisters heal, the skin takes on an atrophic appearance. Hypertrichosis (especially on the cheeks and temples) is also common and may be the presenting feature.

TYPICAL DISTRIBUTION

Classically, the dorsa of the hands are affected (**Figures 186-1 to 186-3**). Facial suffusion (heliotrope) may be seen along with hypertrichosis of the cheeks and temples.

LABORATORY STUDIES

The diagnosis can be confirmed by the orange-red fluorescence of the urine when examined under a Wood lamp. Increased plasma iron may be seen (associated with increased hepatic iron in the Kupffer cells). Diabetes is said to occur in 25% of individuals.

- Twenty-four-hour urine collection for porphyrins—These will be elevated in PCT.
- Skin biopsy may help confirm PCT if the other information is not clear.
- Once the diagnosis is made, secondary causes of PCT should be investigated:
 - Serum for ferritin, iron, and iron-binding capacity to look for hemochromatosis.
 - Order liver function tests and if abnormal order tests for hepatitis B and C.
 - Consider α -fetoprotein and liver ultrasound if considering cirrhosis and/or hepatocellular carcinoma.
 - Order an HIV test if risk factors are present.

DIFFERENTIAL DIAGNOSIS

- The acral vesiculobullous lesions may suggest nummular or dyshidrotic eczema. In younger individuals, the acral blistering may suggest epidermolysis bullosa. The lesions may also suggest erythema multiforme bullosum. The heliotrope suffusion may suggest dermatomyositis and the atrophic changes may suggest systemic sclerosis.

FIGURE 186-3 Porphyria cutanea tarda in a man with hepatitis C and alcohol abuse. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

- If the onset is associated with alcohol ingestion, estrogen therapy, or exposure to pesticides, reducing exposure is warranted.²
- Phlebotomy of 500 mL of blood weekly until the hemoglobin is decreased to 10 g is associated with biochemical and clinical remission within a year.¹
- Low-dose chloroquine can help maintain remissions, whereas high-dose chloroquine can exacerbate the illness.¹

FOLLOW-UP

- Periodic clinical follow-up until remission is achieved is necessary along with constant education and reinforcement of the need to avoid precipitants.

PATIENT EDUCATION

- Avoidance of potential precipitants (alcohol, estrogens, pesticides) and avoidance of excess sunlight exposure (to avoid hypersensitivity) are important. Avoidance of trauma and careful wound care is also necessary.

EPIDERMOLYSIS BULLOSA

PATIENT STORY

A 34-year-old pregnant woman presents with active blistering in her axilla and past history revealed that she lost her fingernails and toenails (**Figure 186-4A**) as a young child. She was diagnosed as a child with recessive dystrophic epidermolysis bullosa. None of her children had been affected because her husband was neither affected nor a carrier (**Figure 186-4B**). A topical steroid ointment helped relieve the pain and calm the blistering in her axilla.

EPIDEMIOLOGY

- Dystrophic epidermolysis bullosa belongs to a family of inherited diseases characterized by skin fragility and blister formation caused by minor skin trauma.³ There are autosomal recessive and autosomal dominant types, the severity of this disease may vary widely. Onset is in childhood and in later years severe dystrophic deformities of hands and feet are characteristic (**Figure 186-5**). Malignant degeneration is common, especially squamous cell carcinoma, in sun-exposed areas.

FIGURE 186-4 A. Recessive dystrophic epidermolysis bullosa with loss of all her toenails as a young child. B. The same woman showing complete loss of her fingernails and the pregnant abdomen. Her daughter is touching the belly and does not have the disease and, therefore, has normal fingers. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Dystrophic epidermolysis bullosa has vesiculobullous skin separation occurring at the sub-basal lamina level, as opposed to junctional epidermolysis bullosa, which blisters at the intralamina lucida layer, and epidermolysis bullosa simplex (**Figure 186-6**), which blisters at the intraepidermal layer.^{4,5}

DIAGNOSIS

CLINICAL FEATURES

Acral skin fragility and blistering are the hallmark in childhood. Minor trauma can induce severe blistering. As the disease progresses initially, painful and ultimately debilitating dystrophic deformities are typical. Repeated blistering of the hands can lead to fusion of the fingers and the “mitten” deformity (**Figure 186-5**).

TYPICAL DISTRIBUTION

The typical distribution is acral (hands and feet), although blistering may extend proximally secondary to trauma.

LABORATORY STUDIES AND BIOPSY

There are no laboratory tests to confirm the diagnosis. A punch biopsy can provide adequate tissue for the dermatopathologist to differentiate between the different forms of epidermolysis bullosa: simplex, junctional, and dystrophic.

DIFFERENTIAL DIAGNOSIS

- Erythema multiforme bullosum may have a similar appearance, but the distribution is less apt to be limited to the distal extremities.
- The appearance of an acral blistering on fragile skin is also characteristic of PCT, but the age of onset of PCT is typically in middle age and not in childhood.
- The first appearance of the condition may be confused, with staphylococcal scalded skin syndrome (see Chapter 116, Impetigo).⁶

MANAGEMENT

Management is primarily prevention of trauma, careful wound care, and treatment of complicating infections. Other supportive measures such as pain management and nutritional support are often necessary. Screening the skin for squamous cell carcinoma is important in the dystrophic form.⁴

FOLLOW-UP

Periodic skin examinations should be done to help manage symptoms and screen for malignancy.

FIGURE 186-5 Severe recessive dystrophic epidermolysis bullosa in a 53-year-old Asian man. **A.** Complete loss of fingers from the disease on his hands. This is referred to as the mitten deformity. He has also had multiple squamous cell carcinomas excised from his hands. **B.** Similar foot deformities with loss of normal toes. (Courtesy of Richard P. Usatine, MD.)

PATIENT EDUCATION

Avoid trauma and come in early if there are any signs of infection or malignancy.

PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA

PATIENT STORY

A 22-year-old man presented with a varicelliform eruption that he has had for 6 weeks (**Figure 186-7**). Initially, he was diagnosed with varicella and given a course of acyclovir. Then he was misdiagnosed with scabies and treated with permethrin. A correct diagnosis was made of PLEVA by clinical appearance and confirmed with biopsy. His skin lesions cleared with oral tetracycline.

EPIDEMIOLOGY

- PLEVA or Mucha-Habermann disease and pityriasis lichenoides chronica are maculopapular erythematous eruptions that can occur in crops of vesicles that can become hemorrhagic over a course of weeks to months (**Figures 186-7 and 186-8**).⁷
- There is a predilection for males in the second and third decades.
- PLEVA occurs in preschool and preadolescent children as well.⁸

ETIOLOGY AND PATHOPHYSIOLOGY

- PLEVA has traditionally been classified as a benign papulosquamous disease. However, there is increasing evidence that suggests that PLEVA should be considered a form of cutaneous lymphoid dyscrasia.⁹ It may even, represent an indolent form of mycosis fungoides (see Chapter 176, Cutaneous T-Cell Lymphoma).

DIAGNOSIS

CLINICAL FEATURES

PLEVA occurs with crops of maculopapular and papulosquamous lesions that can vesiculate and form hemorrhagic vesicles (**Figures 186-7 and 186-8**). Although it resembles varicella, new crops of lesions continue to appear over weeks and months. It can be thought of as “chickenpox that lasts for weeks to months.”

TYPICAL DISTRIBUTION

Lesions typically occur over the anterior trunk and flexural aspects of the proximal extremities. The face is spared.

FIGURE 186-6 A 12-year-old girl with the Dowling-Meara type of epidermolysis bullosa simplex. It is the most severe form with extensive, severe blistering over many areas of the body including, the (A) trunk, (B) extremities, and (C) the hands. (Courtesy of Richard P, Usatine, MD.)

LABORATORY STUDIES

There are no specific laboratory tests for PLEVA except biopsy.

BIOPSY

A punch biopsy is helpful in making the diagnosis. It may be necessary to differentiate PLEVA from lymphomatoid papulosis (see “Differential Diagnosis” below).

DIFFERENTIAL DIAGNOSIS

- **Varicella**—A varicella direct fluorescent antibody test can confirm acute varicella. If no viral testing was done and what appeared to be varicella persists, PLEVA should be considered (Chapter 123, Chickenpox).
- **Pityriasis lichenoides chronica** is the chronic form of PLEVA and can be distinguished from PLEVA by length of time and biopsy (**Figure 186-9**). It has a more low-grade clinical course than PLEVA and the lesions appear over a longer course of time.
- **Erythema multiforme** is a hypersensitivity syndrome in which target lesions are seen. The target lesions have epidermal disruption in the center with vesicles and/or erosions. Look for the target lesions to help differentiate this from PLEVA (see Section 14, Hypersensitivity Syndromes).
- **Lymphomatoid papulosis** presents in a manner similar to PLEVA with recurrent crops of pruritic papules at different stages of development that appear on the trunk and extremities. Although it has histologic features that suggest lymphoma, lymphomatoid papulosis alone is not fatal. It is important to differentiate this from PLEVA because these patients need to be worked up for coexisting malignancy. These patients tend to be older and a punch biopsy can make the diagnosis.
- **Gianotti-Crosti syndrome** (papular acrodermatitis of childhood) may resemble PLEVA but the lesions are usually acral in distribution (**Figure 186-10**).⁵ The erythematous papules and vesicles are found on the extremities and sometimes on the face. It is a benign syndrome associated with many childhood viruses that may last 2 to 8 weeks.

MANAGEMENT

- UV A1 phototherapy has been deployed with some success.¹⁰ Various reports suggest the efficacy of macrolides and tetracyclines, probably more for their antiinflammatory properties than for their antibacterial effects.

FOLLOW-UP

Needed only if the disease does not resolve.

PATIENT EDUCATION

This is usually a temporary disease but if it becomes chronic there are treatments that could help such as oral macrolides or tetracycline.

FIGURE 186-7 A 22-year-old man with pityriasis lichenoides et varioliformis acuta. His skin lesions cleared with oral tetracycline. (Courtesy of Richard P, Usatine, MD.)

FIGURE 186-8 A young woman with pityriasis lichenoides et varioliformis acuta. The individual lesions look like varicella but are unrelated to the varicella virus. (Courtesy of David Anderson, MD.)

DERMATITIS HERPETIFORMIS

PATIENT STORY

A young man with a past history of diarrhea and malabsorption carries a past diagnosis of gluten-induced enteropathy. Despite a gluten-free diet he continues to have a pruritic eruption on his shoulders, back, extremities and buttocks. (Figures 186-11 and 186-12). While the most likely diagnosis is dermatitis herpetiformis, a punch biopsy was performed to confirm this before starting the patient on oral dapsone.

EPIDEMIOLOGY

- Dermatitis herpetiformis is a chronic recurrent symmetric vesicular eruption that is usually associated with diet-related enteropathy.¹¹ It most commonly occurs in the 20 to 40 years of age group. Men are affected more often than women.

ETIOLOGY AND PATHOPHYSIOLOGY

- The disease is related to gluten and other diet-related antigens that cause the development of circulating immune complexes and their subsequent deposition in the skin. The term *herpetiformis* refers to the grouped vesicles that appear on extensor aspects of the extremities and trunk and is not a viral infection or related to the herpes viruses. The disease is characterized by the deposition of immunoglobulin (Ig) A along the tips of the dermal papillae. The majority of patients will also have blunting and flattening of jejunal villi, which leads to diarrhea even to the point of steatorrhea and malabsorption.

DIAGNOSIS

CLINICAL FEATURES

The clinical eruption is characterized by severe itching, burning, or stinging in the characteristic extensor distribution. Herpetiform vesicles and urticarial plaques may be seen. Because of the intense pruritus, characteristic lesions may be excoriated beyond recognition (Figures 186-11 and 186-12).

TYPICAL DISTRIBUTION

Classically, the lesions (or excoriations) are seen in the extensor aspects of the extremities, shoulders (Figures 186-11), lower back, and buttocks (Figures 186-12).

LABORATORY STUDIES

If the patient has gluten-induced enteropathy, antigliadin and antientomysial antibodies may be present. A blood test for antigliadin antibody is a sensitive test for gluten-induced enteropathy.

BIOPSY

Diagnosis is confirmed by a punch biopsy. It is best to biopsy new crops of lesions. A standard histologic examination will show

FIGURE 186-9 Pityriasis lichenoides chronica is the chronic form of pityriasis lichenoides et varioliformis acuta that may persist for months to years. (Courtesy of Richard P. Usatine, MD.)

FIGURE 186-10 Gianotti-Crosti syndrome, "papular acrodermatitis of childhood," in a 7-month-old child. The acral eruption started just after a viral upper respiratory infection and involved the feet, lower legs, and buttocks. (Courtesy of Richard P. Usatine, MD.)

eosinophils and microabscesses of neutrophils in the dermal papillae and subepidermal vesicles. Direct immunofluorescence reveals deposits of IgA and complement within the dermal papillae.

DIFFERENTIAL DIAGNOSIS

- Scabies may have a similar appearance with pruritus, papules, and vesicles. If the lesions and distribution suggest scabies, it should be ruled out with skin scraping looking for the mite, feces, and eggs. If the scraping is negative, but the clinical appearance suggests scabies, empiric treatment with permethrin should be considered as well. If the lesions persist, consider a punch biopsy to look for dermatitis herpetiformis (Chapter 143, Scabies).
- Nummular and dyshidrotic eczema may also be diagnostic considerations, but response to steroids in eczema may be helpful in differentiation (Chapters 145, Atopic Dermatitis and 147, Hand Eczema).
- The classic differential for PCT is pseudoporphyria (caused by NSAIDs like Naprosyn), epidermolysis bullosa acquisita, and variegate porphyria.

MANAGEMENT

- With a gluten-free diet, 80% of patients will show improvement in the skin lesions (**Figure 186-12**). The degree of benefit is dependent upon the strictness of the diet.¹¹
- A gluten-free diet may help the enteropathy and decrease the subsequent development of small bowel lymphoma.
- Dapsone at an initial dose of 100 to 200 mg daily with gradual reduction to a 25- to 50-mg maintenance level may be necessary indefinitely.¹²

FOLLOW-UP

Follow-up is needed to control the disease and monitor nutritional status.

PATIENT EDUCATION

Nutritional counseling is important for all patients with gluten-induced enteropathy. Persons with dermatitis herpetiformis and gluten-induced, enteropathy should not eat wheat and barley but can eat rice, oats and corn.

SECTION 17 HAIR AND NAIL CONDITIONS

187 ALOPECIA AREATA

Richard P. Usatine, MD
James W. Haynes, MD

PATIENT STORY

An 8-year-old Hispanic girl was brought to her physician by her mother, who noticed two bald spots on the back of her daughter's scalp while brushing her hair. The child had no itching or pain. The mother was more worried that her beautiful girl would become bald. The girl was pleased that the bald spots could be completely covered with her long hair, as she did not want anyone to see them. The child was otherwise healthy. When the mother lifted the hair in the back, two round areas of hair loss were evident (**Figure 187-1**). On close inspection, there was no scaling or scarring. The mother and child were reassured that alopecia areata (AA) is a condition in which the hair is likely to regrow without treatment. Neither of them wanted intrale-sional injections or topical therapies. During a well-child examination 1 year later, it was noted that the girl's hair had fully regrown.¹

INTRODUCTION

AA is a common disorder that causes patches of hair loss without inflammation or scarring. The areas of hair loss are often round and the scalp is often very smooth at the site of hair loss.

SYNONYMS

Alopecia totalis involves the whole scalp (**Figure 187-2**). Alopecia universalis (AU) involves the whole scalp, head, and body.

EPIDEMIOLOGY

Alopecia affects approximately 0.2% of the population at any given time with approximately 1.7% of the population experiencing an episode during their lifetime.^{2,3}

- Men and women are equally affected.
- Most patients are younger than age 40 years at disease onset, with the average age being 25 to 27 years.^{2,4}

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology is unknown but experts presume that the AA spectrum of disorders is secondary to an autoimmune phenomenon involving antibodies, T cells, and cytokines.

FIGURE 187-1 Alopecia areata in an 8-year-old girl. (From Usatine R. Bald spots on a young girl. *J Fam Pract.* 2004;53(1):33-36. Reproduced with permission from Frontline Medical Communications.)

FIGURE 187-2 Alopecia totalis for more than 10 years in this adult man. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Previous episode of AA
- Family history of AA—In one study, the estimated lifetime risks were 7.1% in siblings, 7.8% in parents, and 5.7% in offspring of patients with AA.⁵

DIAGNOSIS

CLINICAL FEATURES

- Sudden onset of 1 or more 1- to 4-cm areas of hair loss on the scalp (**Figures 187-1** and **187-3**). This can occur in the beard, eyebrows, or other areas of hair (**Figure 187-4**).
- The affected skin is smooth and may have short stubble hair growth.
- “Exclamation point” hairs are often noted (**Figure 187-5**). These hairs are characterized by proximal thinning while the distal portion remains of normal caliber.
- When hair begins to regrow, it often comes in as fine white hair (**Figure 187-6**).

TYPICAL DISTRIBUTION

- Scalp, beard, and eyebrows but can involve total-body hair loss.

LABORATORY STUDIES

- Typically, the diagnosis can be made with history and physical examination alone.
- Thyroid abnormalities, vitiligo, and pernicious anemia often accompany AA. Consequently, screening laboratory tests (e.g., thyroid-stimulating hormone, complete blood count [CBC]) may be helpful to look for thyroid disorders and anemia (**Figure 187-7**).

BIOPSY

Not needed unless the diagnosis is uncertain. Histology examination shows peribulbar lymphocytic infiltration, frequently including eosinophils and the above-mentioned (see “Clinical Features”) “exclamation point” hairs.

DIFFERENTIAL DIAGNOSIS

- Trichotillomania—History of hair pulling; short, “broken” hairs are seen (see Chapter 188, Traction Alopecia and Trichotillomania).
- Telogen effluvium—Even distribution of hair loss; may be drug-induced (e.g., warfarin, β blockers, lithium) or occur after pregnancy (see Chapter 74, Skin Findings in Pregnancy).
- Anagen effluvium—History of drug use (e.g., antimetabolic agents); even distribution of hair loss.
- Tinea capitis—Skin scaling and inflammation; KOH prep or fungal culture, if necessary (see Chapter 137, Tinea Capitis).
- Secondary syphilis—“Moth-eaten” appearance in beard or scalp; risk factors and rapid plasma reagin (RPR) will help distinguish (see Chapter 216, Syphilis).

FIGURE 187-3 Extensive alopecia areata for more than 6 months in an adult woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 187-4 Alopecia areata can be seen in the beard in this young man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 187-5 Exclamation point hairs (arrows) can be seen in this case of alopecia areata. The hair is narrow at the base, short and wide at the end. (Courtesy of Richard P. Usatine, MD.)

- Lupus erythematosus—Skin scarring; antinuclear antibody (ANA) if clinical presentation compatible with this diagnosis (see Chapter 180, Lupus: Systemic and Cutaneous).
- Follicular mucinosis with or without mycosis fungoides can cause similar areas of hair loss to AA (**Figure 187-8**).

MANAGEMENT

- Many patients with AA will have significant comorbid anxiety and depression, so the management of psychological implications is paramount to successful management.
- Treatment for alopecia includes immune-modulating agents (e.g., corticosteroids, anthralin, psoralen plus ultraviolet A [PUVA]), contact sensitizers (e.g., dinitrochlorobenzene, squaric acid dibutyl ester, diphenylcyclopropenone), and biologic response modifiers (e.g., minoxidil).^{6,7} **SOR C**
 - A commonly used treatment in patients older than 10 years of age with less than 50% scalp involvement is intralesional steroids (**Figure 187-9**). **SOR B**
 - In one randomized controlled trial (RCT), intralesional triamcinolone acetonide (10 mg/mL every 3 weeks) was better than betamethasone valerate foam in management of localized AA.⁸ There was no satisfactory hair regrowth in the tacrolimus group.⁸ Although 10 mg/mL triamcinolone is often used as treatment, there is a higher rate of scalp atrophy than when using 5 mg/mL. We recommend starting with 5 mg/mL and increasing to 10 mg/mL if needed and when the patient accepts the higher risk of atrophy.
 - Triamcinolone acetonide (Kenalog)—Dilute with sterile saline to 5 mg/mL. Inject with a 3-mL or 5-mL syringe and a 27- or 30-gauge needle. Inject into the dermis of the involved areas but not to exceed 4 mL per visit. Use 2.5 mg/mL for involved areas of the eyebrows or beard. **SOR C**
 - Skin atrophy can be reduced by injecting intradermally and limiting both the volume per site and the frequency of injections (4 to 6 weeks between injections). Do not reinject areas that show atrophy and in most cases, the atrophy will resolve spontaneously. **SOR C**
 - Because spontaneous regrowth can occur, steroid injections should be discontinued after 6 months if there is no response.
 - For patients younger than age 10 years, 5% minoxidil, midpotency topical steroids, and/or anthralin can be used. The combination of anthralin with topical steroids and/or minoxidil is a good choice for children and for those with extensive disease because of its easy use and effectiveness without skin irritation. **SOR C**
 - For patients with more than 50% of scalp involvement, topical immunotherapy with contact sensitizers may be an effective treatment.
 - Topical diphenylcyclopropenone (DPCP) is a contact immunotherapy that has some proven benefit with extensive AA. In one study, 56 patients with chronic, extensive AA (duration ranging from 1 to 10 years, involving 30% to 100% of the scalp) were treated with progressively higher concentrations of DPCP in a randomized crossover trial. Twenty-five of 56 patients had total hair regrowth at 6 months, and no relapse occurred in 60% of patients.⁷ **SOR B**

FIGURE 187-6 New growth of white hair after 7 months of alopecia areata in this middle-age woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 187-7 A patient with alopecia areata who was hyperthyroid. He had symptoms of hyperthyroidism and his thyroid-stimulating hormone was low. (Courtesy of Richard P. Usatine, MD.)

- These contact sensitizers have potential severe side effects, including mutagenesis, blistering, hyperpigmentation, and scarring, and thus should be used by clinicians with significant experience with these agents or in consultation with a dermatologic specialist.
- Minoxidil, PUVA, and anthralin have been used with varying effectiveness and can be considered.

A Cochrane review in 2008 concluded that most trials have been reported poorly and are so small that any important clinical benefits are inconclusive.⁹ They stated that considering the possibility of spontaneous remission (especially for those in the early stages of the disease) the options of not treating or wearing a wig are reasonable alternatives.⁹

- Hairpieces and transplantation may be used for those patients with unresponsive, recalcitrant disease.
- One RCT showed aromatherapy with topical essential oils to be a safe and effective treatment for AA.¹⁰ **SOR B**

PATIENT EDUCATION AND PROGNOSIS

- Although spontaneous recovery usually occurs, the course of AA is unpredictable and often characterized by recurrent periods of hair loss and regrowth.
- Spontaneous long-term regrowth in alopecia totalis and AU is poor.
- Prognosis is worse if the alopecia persists longer than 1 year.

FOLLOW-UP

- Spontaneous recovery usually occurs within 6 to 12 months and the prognosis for total permanent regrowth with limited involvement (AA) is excellent.
- The regrown hair is usually of the same texture and color but may be fine and white at first (**Figure 187-5**).
- Ten percent of patients never regrow hair and advance to chronic disease. Clinicians should provide contact information to the National Alopecia Areata Foundation and offer follow-up in the office as necessary.
- Patients with a family history of AA, younger age at onset, coexisting immune disorders, nail dystrophy, atopy, and widespread hair loss have a poorer prognosis.⁵

PATIENT RESOURCES

- The National Alopecia Areata Foundation (<http://www.naaf.org/>) publishes a newsletter and can provide information regarding these support groups as well as hairpiece information.

188 TRACTION ALOPECIA AND TRICHOTILLOMANIA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 38-year-old woman was found to have hair thinning on the anterior scalp. She had long thick heavy hair that she always styled in a bun on the top of her head. She was concerned about the slow, steady loss of hair that she was experiencing. **Figure 188-1** shows the appearance of the thinned hair as a result of chronic traction. A 4-mm punch biopsy was performed to confirm the clinical impression and the histology was supportive of this diagnosis.

INTRODUCTION

Traction alopecia is hair loss caused by damage to the dermal papilla and hair follicle by constant pulling or tension over a long period. It often occurs in persons who wear tight braids, especially “cornrows” that lead to high tension, pulling, and breakage of hair. Trichotillomania (Greek for “hair-pulling madness”) is a traction alopecia related to a compulsive disorder caused when patients pull on and pluck hairs, often creating bizarre patterns of hair loss.

EPIDEMIOLOGY

- The prevalence of traction alopecia (**Figures 188-1** and **188-2**) is unknown and varies by cultural hairstyle practices. It is most commonly seen in females and children.¹
- The prevalence of trichotillomania (**Figures 188-3** to **188-6**) is also difficult to determine, but is estimated to be approximately 1.5% of males and 3.4% of females in the United States. The mean age of onset of trichotillomania is 8 years in boys and 12 years in girls, and it is the most common cause of childhood alopecia.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Traction alopecia is seen in individuals who place chronic tension on the hair shafts with tight braids, heavy natural hair, use of hair prostheses, or chronic pulling (**Figures 188-1** and **188-2**).¹ It also occurs commonly in female athletes who pull their hair into tight ponytails.
- Chronic tension on the hair shaft seems to create inflammation within the hair follicle that eventually leads to cessation of hair growth. Because hair loss from traction alopecia may become permanent, prevention and early treatment are important.
- It is seen most frequently in black women who tightly braid or pull the hair into a hairstyle during youth and on into adulthood. May also be seen in individuals who wear hair prostheses or extensions for a prolonged period of time. It is also seen in Sikh men of India and Japanese women whose traditional hairstyles may pull and damage hair.

FIGURE 188-1 Traction alopecia from pulling the hair up in a tight bun. (Courtesy of Richard P. Usatine, MD.)

FIGURE 188-2 Traction alopecia in a young African American girl whose mom braids her hair tightly. (Courtesy of Richard P. Usatine, MD.)

- Trichotillomania is a subtype of traction alopecia manifested by chronic hair pulling (**Figures 188-3 to 188-6**) and sometimes hair eating (trichophagy), which can lead to a trichobezoar. It is classified as a psychiatric impulse-control disorder.³
- Trichotillomania may be a manifestation of the inability to cope with stress rather than more severe mental disorders.
- Children who exhibit trichotillomania may discontinue the hair pulling with parental support and maturity. Adults who exhibit trichotillomania, even though they are aware of the problem, may require psychiatric intervention to limit the behavior. The hair loss is initially reversible but may become permanent if the habits persist.

DIAGNOSIS

CLINICAL FEATURES

In patients with traction alopecia, there are decreased follicular ostia in the affected area coupled with decreased hair density. The hair loss usually occurs in the frontal and temporal areas but depends on the precipitating hairstyle (**Figures 188-1 and 188-2**). No scalp inflammation or scaling is typically visible. No pain or other discomfort is associated with the condition. Patients with trichotillomania often demonstrate short, broken hairs (**Figure 188-6**) without the presence of inflammation or skin scale early in the disease. The affected areas are not bald, but rather possess hairs of varying length. There may be telltale stubble of hairs too short to pull. The hair loss often follows bizarre patterns with incomplete areas of clearing. The scalp may appear normal or have areas of erythema and pustule formation. With chronic pulling, the hair loss becomes permanent (**Figure 188-4**). The patient may be observed pulling or twisting the hair by friends or family members.

TYPICAL DISTRIBUTION

Trichotillomania most commonly occurs on the scalp and can involve any area of the body that can be reached by the patient.¹ Traction alopecia can occur anywhere on the scalp, but is most commonly seen at the anterior hairline. This is the site where the hair is pulled back from the face into braids or a bun.

LABORATORY STUDIES

Laboratory tests are not needed to make the diagnosis. A hand lens can be used to examine the affected scalp for decreased follicular ostia, if desired. A scalp biopsy (4-mm punch biopsy) may be necessary to make the diagnosis and rule out other etiologies, especially in trichotillomania, because patients may not acknowledge the habit.

Hypothyroidism or hyperthyroidism may be associated with telogen effluvium or alopecia areata. It may be worth ordering a thyroid-stimulating hormone (TSH) if the history and physical exam are not completely convincing for self-induced hair loss.

DIFFERENTIAL DIAGNOSIS¹

- Alopecia areata is characterized by the total absence of hair in an area and the presence of exclamation point hairs. These hairs are

FIGURE 188-3 Trichotillomania in an 11-year-old boy. Note the incomplete hair loss and unusual geometric pattern. He was receiving help and the hair is now growing in. (Courtesy of Richard P. Usatine, MD.)

FIGURE 188-4 Chronic hair loss in a 39-year-old woman with trichotillomania. (Courtesy of E.J. Mayeaux, Jr., MD.)

thinner in diameter closer to the scalp and thicker in diameter away from the scalp, creating the appearance of an exclamation point. Hairs are often white when they start to regrow (see Chapter 187, Alopecia Areata).

- Tinea capitis exhibits hairs broken off at the skin surface and the presence of scale and/or inflammation. Some varieties fluoresce when examined with a Wood light (UV light). Microscopy of a KOH preparation may detect the dermatophyte. Sometimes it is necessary to culture some hairs and scale to make this diagnosis (see Chapter 137, Tinea Capitis).
- Scarring alopecia (lichen planopilaris, folliculitis decalvans) is observed as loss of the follicular ostia and the absence of hairs. The scalp may appear scarred with changes in pigmentation (see Chapter 189, Scarring Alopecia).
- Telogen effluvium (postpregnancy hair loss) is associated with hair loss during the postpartum period and can happen after other stressful events such as surgery or severe illness (see Chapter 74, Skin Findings in Pregnancy). The hair loss is evenly distributed across the head and the hair is thinned all over rather than in patches as in traction alopecia.
- Androgenetic alopecia produces central thinning in women and temple and crown thinning in males. It should be considered in women with symptoms of hormonal abnormalities such as hirsutism, amenorrhea, or infertility.

MANAGEMENT

NONPHARMACOLOGIC

- Stop hairstyling practices that led to the traction alopecia. No tight braiding or buns should be worn.¹ SOR C
- For trichotillomania, open discussions with the patient, and the family, if appropriate, are important to understand the reason for the behavior. Many times there are secondary social or emotional issues that must be resolved before the trichotillomania ceases.
 - Cognitive behavioral treatment is the most effective treatment for trichotillomania.^{1,3} SOR B
 - Cognitive-behavioral therapy usually is successful if the patient is recalcitrant to simple education.⁵ SOR C

MEDICATIONS

- Topical corticosteroids can be used to decrease scalp inflammation if erythema or itching is present. SOR C
- Topical minoxidil is sometimes used to speed hair regrowth in the area. SOR C
- Fluoxetine hydrochloride (Prozac) 20 to 40 mg/day in adults or clomipramine (Anafranil) 25 to 250 mg/day in adults or a maximum of 3 mg/kg per day in children has had some success for alleviating compulsive hair pulling.⁴⁻⁶ SOR B

Olanzapine (Zyprexa) has been studied for the treatment of trichotillomania in a 12-week, randomized, double-blind, placebo-controlled trial. A dose of 10 mg/day showed a significant decrease in the CGI-Severity of Illness scale in 85% of subjects.⁷ SOR B

FIGURE 188-5 Trichotillomania in his 17-year-old honors student who is currently taking four Advanced Placement courses simultaneously. (Courtesy of Richard P. Usatine, MD.)

Methylphenidate also has showed limited efficacy in trichotillomania patients with comorbid attention deficit hyperactivity disorder (ADHD) in a 12-week study.⁸ **SOR B**

PATIENT EDUCATION

Explain that in traction alopecia, current grooming practices are responsible for the hair loss and a new hairstyle must be selected. It is important to tell the patient that some of the hair loss may be permanent and no guarantee can be given regarding the amount of expected hair regrowth. Similar hair grooming practices should be avoided in the patient's children to prevent traction alopecia from occurring. Prevention is definitely the best treatment.

Explain that trichotillomania is a self-induced disease that can often resolve if the hair pulling or twisting is discontinued. Patients may exhibit hair pulling or twisting unconsciously when stressed or use it as a calming activity when relaxing or going to sleep. The underlying reasons for the behavior should be explored and discussed. Sometimes trichotillomania can be substituted with another behavior, such as playing with beads or rubbing a stone.

FOLLOW-UP

Specific follow-up is not required for traction alopecia but psychiatric/behavioral counseling follow-up is indicated for trichotillomania.

189 SCARRING ALOPECIA

Richard P. Usatine, MD

PATIENT STORY

A 32-year-old man presents with hair loss along with chronic pustular eruptions of his scalp. Previous biopsy has shown folliculitis decalvans. He has had many courses of antibiotics, but the hair loss continues to progress. The active pustular lesions are cultured and grow out methicillin-resistant *Staphylococcus aureus*. The patient is treated with trimethoprim-sulfamethoxazole twice daily and mupirocin to the nasal mucosa, twice daily for 5 days. Two weeks later, the pustular lesions are less prominent although the alopecia is permanent (Figures 189-1 and 189-2).

INTRODUCTION

Scarring alopecia is a group of inflammatory disorders in which there is permanent destruction of the pilosebaceous unit. Although it is mostly seen on the scalp, it can involve other areas, such as the eyebrows.

In primary cicatricial alopecia, the hair follicle is the primary target of destruction by inflammation. In secondary cicatricial alopecia, the follicular destruction is incidental to a nonfollicular process such as infection, tumor, burn, radiation, or traction.

SYNONYM

Cicatricial alopecia.

EPIDEMIOLOGY

Primary cicatricial alopecias are rare.

The annual incidence rate of lichen planopilaris (LPP) in 4 hair loss centers in the United States varied from 1.15% to 7.59% as defined by new biopsy-proven LPP—all new patients with hair loss seen over a 1-year period.¹

PATHOPHYSIOLOGY

Scarring alopecia occurs when there is inflammation and destruction of the hair follicles leading to fibrous tissue formation.²

Hair loss in scarring alopecia is irreversible because the inflammatory infiltrate results in destruction of the hair follicle stem cells and the sebaceous glands.³

The inflammatory infiltrates are either predominantly lymphocytic, neutrophilic, or mixed. These differences are used to classify the scarring alopecias. See **Table 189-1**.

FIGURE 189-1 Folliculitis decalvans in a 32-year-old man. He has an active area of pustular lesions on the periphery with wide areas of scarring and hair loss. (Courtesy of Richard P. Usatine, MD.)

FIGURE 189-2 Same patient (Figure 189-1) showing permanent hair loss on the top of the head with some small active pustular lesions. (Courtesy of Richard P. Usatine, MD.)

TABLE 189-1 Classification of Cicatricial Alopecia

Lymphocytic	Lichen planopilaris (LPP) Frontal fibrosing alopecia (FFA) Central centrifugal cicatricial alopecia (CCCA) Discoid lupus erythematosus (DLE)*
Neutrophilic	Folliculitis decalvans Tufted folliculitis
Mixed	Dissecting cellulitis* Acne keloidalis nuchae*
End-stage	Nonspecific

*Not a primary cicatricial alopecia.

Source: Adapted from Olsen EA, Bergfeld WF, Cotsarelis G, et al.⁴

DIAGNOSIS

Scarring alopecias can vary by distribution and appearance. Most patients will need a biopsy to confirm the clinical impression and determine the specific type of alopecia.

CLINICAL PRESENTATION

- Hair loss with itching, pain, and/or burning of the scalp. Some cases are asymptomatic.

PHYSICAL EXAM

The “pull test” is used to see how active the hair loss is in general and in specific areas of the scalp. Always ask the patient if you can pull on the hair as part of your diagnosis.

- With the thumb and forefinger grasp approximately 30 to 40 hairs close to the scalp.
- Gently, but firmly, slide the fingers away from the scalp at a 90-degree angle along the entire length of the hair swatch. Do not tug or jerk.

Interpreting the pull test results:

- Negative pull test = 1 to 4 telogen hairs (small bulbs at bottom).
- Positive pull test = 5 or more hairs (including anagen hairs that have longer follicle sheath at the bottom of the hair).⁵

Forms of primary cicatricial alopecia include:

- LPP most commonly affects middle-age women. It mostly occurs on the frontal and parietal scalp and causes follicular hyperkeratosis, pruritus, perifollicular erythema, violaceous color of scalp, and scalp pain (**Figure 189-3**).² It may also affect other hair-bearing sites such as the groin and axilla.² Most patients with LPP do not have lichen planus even though the names are very similar.
- Central centrifugal scarring alopecia (CCCA) is a slowly progressive alopecia that begins in the vertex and advances to surrounding areas. It may be related to chemicals used on the hair, heat from hot combs, or chronic tension on the hair.² It is seen more commonly in African American women (**Figure 189-4**).

FIGURE 189-3 Lichen planopilaris in a 45-year-old woman causing hair loss with perifollicular scale. (Courtesy of Richard P. Usatine, MD.)

FIGURE 189-4 Central centrifugal scarring alopecia in a middle-age African American woman. Note how the vertex is most affected. Patient has used many hair chemicals, hot combs, and braids over the years. (Courtesy of Richard P. Usatine, MD.)

- Frontal fibrosing alopecia (FFA) presents with a progressive recession of the frontal hairline affecting particularly postmenopausal women. It is considered to be a variant of LPP on the basis of its clinical, histologic, and immunohistochemical features (**Figure 189-5**).⁶
- Folliculitis decalvans is a chronic painful neutrophilic bacterial folliculitis characterized by boggy or induration of the scalp with pustules, erosions, crusts, and scale.² It is postulated that this results from an abnormal host response to *S. aureus*, which is often cultured from the lesions (**Figures 189-1 and 189-2**). In one case series, the disease ran a protracted course with temporary improvement while on antibiotic and flare-up of disease when antibiotics were stopped.⁷
- Tufted folliculitis can be considered to be a milder version of folliculitis decalvans with less surface area of the scalp involved and a better prognosis (**Figure 189-6**). However, these hair tufts can be seen in other types of scarring alopecias.

Secondary forms of scarring alopecia:

- Dissecting cellulitis presents with deep inflammatory nodules, primarily over the occiput, that progress to coalescing regions of boggy scalp.¹ Sinus tracts may form and *S. aureus* is frequently cultured from the inflamed lesions. When dissecting cellulitis occurs with acne conglobata and hidradenitis suppurativa, the syndrome is referred to as the follicular occlusion triad (**Figures 189-7 and 189-8**).
- Acne keloidalis nuchae (folliculitis keloidalis) presents with a chronic papular and pustular eruption at the nape of the neck. This can lead to scarring alopecia with large keloidal scarring. It is seen most commonly in men of color but also can be seen in women. It is often made worse by shaving the hair (see Chapter 114, Pseudo-folliculitis and Acne Keloidalis Nuchae) (**Figure 189-9**).
- Discoid lupus erythematosus (DLE) presents with lesions that can be erythematous, atrophic, and/or hypopigmented. Scarring alopecia may be accompanied by follicular plugging on the scalp. Hypopigmentation may develop in the central area of the inflammatory lesions and hyperpigmentation may develop at the active border. The external ear and ear canal are often involved (**Figure 189-10**) (Chapter 180, Lupus: Systemic and Cutaneous).

LABORATORY STUDIES

If there is purulence, perform a bacterial culture. *S. aureus* and methicillin-resistant *S. aureus* are frequently seen in the neutrophilic alopecias. Consider obtaining various tests such as thyroid-stimulating hormone (TSH), serum iron level, complete blood count (CBC), and rapid plasma reagin (RPR) to rule out treatable causes of alopecia. Do a KOH smear and/or culture if tinea capitis is suspected.

BIOPSY

- Biopsy is almost always recommended to diagnose primary scarring alopecia.⁵ Usually a single 4-mm punch biopsy for histology is adequate. Some dermatopathologists will prefer two 4-mm punch biopsies at the same time so that they may cut the specimens both tangentially and vertically for analysis. Discuss this with your dermatopathologist or pathologist. Make sure to biopsy at the margin of the active disease and include hair follicles in the specimen.

FIGURE 189-5 Frontal fibrosing alopecia with progressive recession of the frontal hairline in a postmenopausal African American woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 189-6 Tufted folliculitis showing multiple hairs growing from the same follicle along with purulence and hair loss. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Alopecia areata presents with hair loss and a very smooth scalp. The hair loss is usually in round punched-out patterns and the scalp otherwise appears normal (Chapter 187, Alopecia Areata).
- Androgenetic alopecia is the standard hair loss that males experience with aging. There are a number of male pattern types of hair loss. Women also get androgenic alopecia, but the pattern tends to be more diffuse and frontal. Both are treatable with topical minoxidil and oral finasteride.
- Drug-induced alopecia is from chemotherapy and other toxic drugs.
- Sarcoidosis of the scalp can resemble DLE, but treatment will be different, hence the importance of a biopsy diagnosis (see Chapter 175, Sarcoidosis).⁸
- Seborrheic dermatitis may cause some hair loss. The presence of scale on the scalp with minimal to no hair loss helps to differentiate this from scarring alopecia (see Chapter 151, Seborrheic Dermatitis).
- Secondary syphilis with moth-eaten alopecia is rare but should be considered. A highly positive RPR can easily make this diagnosis (see Chapter 216, Syphilis).
- Telogen effluvium is a type of non-scarring alopecia that occurs after childbirth or other traumatic events. The skin on the scalp appears normal.
- Tinea capitis presents with scale and hair loss. It is diagnosed by a positive KOH and/or fungal culture. Do not miss this diagnosis because it is much easier to treat than any of the scarring alopecias (see Chapter 137, Tinea Capitis).
- Trichotillomania is defined as self-induced hair loss caused by pulling at the hairs. The pattern of hair loss may be distinctive and the behavior may be discovered on history. The scalp appears normal and there is a distinctive pattern seen on biopsy (see Chapter 188, Traction Alopecia and Trichotillomania).
- Traction alopecia occurs when the hair is pulled too tight for braids or ponytails (see Chapter 188, Traction Alopecia and Trichotillomania).
- Various metabolic and nutritional problems can lead to alopecia. It is worth doing a CBC, ferritin, vitamin D 25-OH, and TSH to rule out iron deficiency, vitamin D deficiency, and hyper- or hypothyroidism.⁵

MANAGEMENT

- Scarring alopecias are such rare conditions that there are few randomized controlled trials available to guide therapy.
- One paradigm for treating primary scarring alopecia is to treat those containing predominantly lymphocytic infiltrates with immunomodulating agents and those with predominantly neutrophilic infiltrates with antimicrobial agents.^{5,9} **SOR C**

Lymphocytic infiltrate predominates (LPP, CCCA, FFA). According to Price, treatment can be split into the following categories:⁵

- Tier 1—Start here with one of the two oral agents combined with topical/intralesional medications:

FIGURE 189-7 Dissecting cellulitis of the scalp in a young Hispanic man with many active sinus tracts and alopecia. (Courtesy of Richard P. Usatine, MD.)

FIGURE 189-8 Dissecting cellulitis of the scalp causing painful purulent nodules and sinus tracts leading to scarring alopecia. The patient also has severe hidradenitis suppurativa and therefore has two of three elements of the follicular occlusion triad (he does not have acne conglobata). The arrow points to one sinus tract. (Courtesy of Richard P. Usatine, MD.)

- Doxycycline 100 mg bid, or
- Hydroxychloroquine 200 mg bid.
- After 6 to 12 months, if symptoms and signs persist, move to tier 2.
- Tier 2
 - Mycophenolate mofetil 0.5 gm bid for 1 month, then 1 g bid for 5 months.
 - Cyclosporine 3 to 5 mg/kg per day, or 100 mg tid.¹⁰
 - Pioglitazone 15 mg daily.¹¹
- Topical/intralesional medications:
 - Intralesional triamcinolone acetonide 10 mg/mL to inflamed, symptomatic sites (inject margins not bare center).
 - High-potency topical corticosteroids or topical tacrolimus or pimecrolimus.
 - Derma-Smoothe/FS scalp oil—Some patients prefer the oil-based vehicle on a dry scalp.

Studies that support this tiered approach for LPP include:

- In a retrospective review of 40 patients with LPP and its variant FFA, the investigators found that those treated with hydroxychloroquine daily had a 69% reduction in symptoms and signs after 6 months, and 89% improved after 12 months.¹² **SOR B**
- In another retrospective review of 16 patients with LPP treated with at least 6 months of mycophenolate mofetil in an open-label, single-center study, 5 of 12 patients were complete responders, 5 of 12 patients were partial responders, and 2 of 12 patients were treatment failures. Four patients withdrew from the trial because of adverse events.¹³
- In FFA the loss of eyebrows is common. Intralesional injection of triamcinolone acetonide showed regrowth response in 9 of 10 patients.¹⁴

Neutrophilic infiltrate predominates (folliculitis decalvans and tufted folliculitis):

- Start by culturing pustules and using oral antibiotics based upon the pathogens cultured.
- Powell et al. introduced a treatment regimen for patients with folliculitis decalvans that combines oral rifampicin 600 mg daily and oral clindamycin 300 mg bid together for 10 weeks.¹⁵ **SOR B** Ten of the 18 patients responded well with no evidence of recurrence 2 to 22 months after 1 course of treatment, and 15 of the 18 responded after 2 or 3 courses.¹⁵
- For methicillin-sensitive *S. aureus* cephalexin 500 mg qid × 10 weeks with oral rifampin 600 mg × 10 days is an alternative treatment.
- For methicillin-resistant *S. aureus* (MRSA) treat with oral clindamycin 300 mg bid, or oral trimethoprim-sulfamethoxazole DS bid, or oral doxycycline 100 mg bid for 10 weeks combined with rifampin 600 mg × 10 days.⁵
- If the patient is a *S. aureus* carrier, add mupirocin ointment intranasally qd for 1 week, then monthly thereafter.⁵ **SOR C**
- Dapsone at 75 to 100 mg/day for 4 to 6 months was well tolerated and rapidly effective in treating 2 cases of folliculitis decalvans. Long-term low-dose (25 mg/day) maintenance treatment avoided disease relapses. Paquet and Pierard chose dapsone because of its antimicrobial activity and its antiinflammatory action directed to the neutrophil metabolism.¹⁶ **SOR C**

FIGURE 189-9 Acne keloidalis nuchae in a 45-year-old African American woman. Note the significant hair loss. Although acne keloidalis nuchae is more common in men, it can occur in women too. (Courtesy of Richard P. Usatine, MD.)

FIGURE 189-10 Chronic cutaneous lupus erythematosus showing scarring alopecia. Prominent hypopigmentation and skin atrophy are visible on the scalp and ear. (Courtesy of Richard P. Usatine, MD.)

Mixed infiltrates (dissecting cellulitis):

- Start by culturing any purulence and using oral antibiotics based upon the pathogens cultured.
- Just as for neutrophilic infiltrates, treat with oral clindamycin 300 mg bid, or oral trimethoprim-sulfamethoxazole DS bid, or oral doxycycline 100 mg bid for 10 weeks combined with rifampin 600 mg \times 10 days.
- Isotretinoin may be effective in inducing a prolonged remission. Price suggests starting with 20 mg daily, to avoid a flare, and then slowly increase to 1 mg/kg per day for many months.⁵ SOR C

Primary and secondary scarring alopecias:

- Imiquimod cream 5% was reported to cause regression of discoid lupus of the scalp and face in a single patient when applied to the lesions once a day 3 times a week. After 20 applications, Gul et al. reported that the lesions had regressed significantly.¹⁷ SOR C
- Surgical excision of cicatricial alopecias includes excision and tissue expansion. Unfortunately, the outcomes have been disappointing to the patients and surgeons.¹⁸ SOR C

FOLLOW-UP

Close follow-up is needed for patients put on oral agents. Monitoring for side effects is agent specific.

PATIENT EDUCATION

The following points are based upon information from the Cicatricial Alopecia Research Foundation (<http://www.carfintl.org/faq.html>):

- The goal of treatment is to control scalp inflammation and stop the progression of the disease. Hair regrowth is not possible.
- Scarring alopecias often reactivate after a quiet period of 1 or more years. Patients should be encouraged to self-monitor for recurrence and to seek care early to prevent hair loss.
- It is safe to wash the hair with gentle hair products, if desired, even daily.
- When severe hair loss occurs, hats, scarves, hairpieces, and wigs may be used safely for cosmetic purposes.

190 NORMAL NAIL VARIANTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 28-year-old man is in the office for a work physical and asks about the white streaks on his fingernail (**Figure 190-1**). He has had them on and off all of his adult life, but recently developed more of them and was concerned he may have a vitamin deficiency. He was reassured that this is a normal nail finding often associated with minor trauma.

INTRODUCTION

The anatomy of the nail unit is shown in **Figure 190-2**. The nail unit includes the nail matrix, nail plate, nail bed, cuticle, proximal and lateral folds, and fibrocollagenous supportive tissues. The proximal matrix produces the superficial aspects of the plate, and the distal matrix the deeper portions. The nail plate is composed of hard and soft keratins, is formed via onychokeratinization, which is similar to hair sheath keratinization.¹ Most normal nail variants occur as a result of accentuation or disruption of normal nail formation.

SYNONYMS

- Leukonychia.
 - Transverse striate leukonychia.
 - Leukonychia punctata.
 - White nails.
- Longitudinal melanonychia (LM).
 - Racial melanonychia in African Americans.
- Nail hypertrophy and onychogryphosis (also known as onychogryposis).
 - Ram’s horn nail.
 - Oyster-like deformity.
 - Lateral nail hypertrophy.
 - Thickened toenail.

EPIDEMIOLOGY

Melanonychia often involves several nails and is a more common occurrence in those patients with darker skin types. Among African Americans, benign melanonychia affects up to 77% of young adults and nearly 100% of those age 50 years or older. In the Japanese, LM affects 10% to 20% of adults.¹ Nail matrix nevi have been reported to represent approximately 12% of LM in adults and 48% in children.² The incidences of most other benign nail findings are not well established.

FIGURE 190-1 Transverse striate leukonychia (transverse white streaks) in a healthy patient. Note that the lines do not extend all of the way to the lateral folds, which indicates a probable benign process. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-2 The anatomy of the nail unit. (Courtesy of Usatine R, Pfenninger J, Stulberg D, Small R. *Dermatologic and Cosmetic Procedures in Office Practice*. Elsevier, Inc., Philadelphia. 2012.)

ETIOLOGY AND PATHOPHYSIOLOGY

- *Leukonychia* represents benign, single or multiple, white spots or lines in the nails. Patchy patterns of partial, transverse white streaks (transverse striate leukonychia, see **Figure 190-1**) or spots (leukonychia punctata, **Figure 190-3**) are the most common patterns of leukonychia.³ Leukonychia is common in children and becomes less frequent with age. Parents may fear that it represents a dietary deficiency, in particular a lack of calcium, but this concern is almost always unfounded.
- Most commonly, no specific cause for leukonychia can be found. It is usually the result of minor trauma to the nail cuticle or matrix and is the most commonly found nail condition in children.⁴ When the lesions are caused by overly aggressive manicuring or nervous habit, behavior modification often is helpful. Leukonychia can also be an indirect manifestation of autoimmunity, including alopecia areata or thyroid disease. Histologically, the nail plate contains a greater number of nucleated cells that are associated with lack of cohesion between the corneocytes, producing reflective properties of the nail.
- Longitudinal melanonychia (LM) (**Figure 190-4**) represents a longitudinal pigmented band in the nail plate. Melanonychia is ultimately caused by melanocyte activation. Causes of nongenetic nail matrix melanocyte activation include drugs, inflammatory processes, trauma, mycosis, systemic diseases, and neoplasms (melanomas).¹ LM is often caused by lentigines, benign melanocytic hyperplasia, or nevus of the nail matrix. However, it must be differentiated from subungual melanoma (see Chapter 191, Pigmented Nail Disorders). Benign causes of LM produce melanocytic activation with bands that usually measure 3 to 5 mm or less in width, whereas melanoma tends to produce wider bands. Most lentigines and nevi display a band with a tan-to-brown hue. A benign nail band is generally relatively homogeneous with respect to color and color intensity and if it expands, tends to expand slowly.¹
- *Nail hypertrophy and onychogryphosis* (ram's horn nail—lateral hypertrophy, **Figure 190-5**) is the development of opaque thickened nails with exaggerated upward, or lateral growth. It may be associated with age, fungal infections and trauma. It can cause pain with pressure.
- *Habit-tic deformity* (**Figures 190-6 and 190-7**) is caused by habitual picking of the proximal nail fold. The resulting inflammation induces the nail plate to be wavy and ridged, while its substance remains intact and hard.
- *Beau lines* are transverse linear depressions in the nail plate (**Figures 190-8 and 190-9**). They are thought to result from suppressed nail growth secondary to local trauma or severe illness.⁵ They most commonly appear symmetrically in several or all nails and may have associated white lines. They usually grow out over several months. One may estimate the time since onset of systemic illness by measuring the distance from the Beau line to the proximal nail fold and applying the conversion factor of 6 to 10 days per millimeter of growth.⁴

FIGURE 190-3 Leukonychia punctata showing distinct punctate white spots and lines on the fingernails. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-4 Longitudinal melanonychia in multiple fingers in a young adult. These bands of translucent nail pigmentation in multiple fingers are typical of racial longitudinal melanonychia and not suspicious for melanoma. Note the dark pigment on the proximal nail folds represents a pseudo-Hutchinson sign. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-5 Onychogryphosis (ram's horn nail) is a type of lateral nail hypertrophy most frequently found in the toenails and often associated with onychomycosis. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Leukonychia
 - Use of nail enamels, nail hardeners, or artificial nails as a result of trauma and allergic reactions.
 - Repetitive trauma from work, sports, or leisure activities.
- LM.
 - Race.
 - Age.
- Nail hypertrophy and onychogryphosis.
 - Age.
- Habit-tic deformity.
 - Psychological dysfunctions.
- Beau lines.
 - Severe illness.
 - High fever.

DIAGNOSIS

CLINICAL FEATURES

- All diagnoses of nail disorders should begin with a focused history and physical exam. It is especially important to ask about trauma and recent illnesses.

LABORATORY TESTING

- If renal disease is suspected, order a urinalysis and a serum creatinine.

IMAGING

- The use of nail plate or matrix dermoscopy has been proposed as a way to further define areas to biopsy in LM, but their accuracy in the diagnosis of subungual melanoma has not been established.² **SOR** 

BIOPSY

- Definitive diagnosis of a nail discoloration may be made with a biopsy of the nail or matrix. Patients with darker skin tones and multiple digits with translucent LM often need only be observed. A new dark line in a single nail should be biopsied. A 3-mm punch biopsy can be performed at the origin of the darkest part of a dark band. This usually involves reflecting the skin of the proximal nail fold back while performing a punch biopsy of the distal matrix. Histologic diagnosis of atypical melanocytic hyperplasia necessitates the complete removal of the lesion.¹ **SOR** 

DIFFERENTIAL DIAGNOSIS

- Pigmented lesions in the nail bed do not cause LM, only nail matrix lesions do. Nail bed lesions make spots under the nails but do not grow out as stripes. These are viewed through the nail as a grayish to brown or black spot.⁶
- The diagnosis of subungual melanoma must always be considered in patients with LM. A biopsy should be performed in an adult if the cause of LM is not apparent. Extension of pigmentation to the skin adjacent to the nail plate involving the nail folds or the

FIGURE 190-6 Habit-tic deformity of the thumbnail caused by a conscious or unconscious rubbing or picking of the proximal nails and nail folds. Horizontal grooves are formed proximally and move distally with fingernail growth. The thumbnails are most often affected. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-7 Habit-tic deformity of the large toenail in a man that walks barefoot often. He acknowledged that he picks at the nail and cuticle. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-8 Beau lines in the fingernails of a young boy that had erythema multiforme and exfoliation approximately 2 months prior to this visit. (Courtesy of Richard P. Usatine, MD.)

TABLE 190-1 Signs That Help Differentiate Local Trauma-Induced Nail Changes from Those Associated with Systemic Disease

Characteristic	Mees Lines (Figure 190-10)	Muehrcke Lines (Figure 190-11)	Beau lines (Figures 190-8 and 190-9)	Leukonychia (Figures 190-1 and 190-3)
Number of Nails involved	Tend to be single but may occur on several nails at once	Tend to occur on several nails at once	Appear symmetrically in several or all nails	Usually on 1 or 2 nails
Nail coverage	Spread transversely across the entire breadth of the nail	Spread across the entire breadth of the nail bed or plate, often disappear with nail plate pressure	Spread transversely across the entire breadth of the nail	Often do not span the entire breadth of the nail plate
Line shape	Tend to have contour similar to the distal lunula, with a rounded distal edge	White transverse lines that have contour similar to the distal lunula, with a rounded distal edge	Tend to have contour similar to the distal lunula, with a rounded distal edge	More linear and resemble the contour of the proximal nail fold
Nail surface changes	Absent	Absent	Usually depressed	Absent
Etiology	Fragmented nail plate structure as a result of a compromised nail matrix	Abnormality of the nail vascular bed	Suppressed nail growth	Disruption of nail plate formation
Associated conditions	History of a systemic insult correlated with the onset of the lines such as chemotherapy, heart failure, and heavy-metal poisoning	Chronic hypoalbuminemia (hepatic and renal disease)	History of a physiologic stressor such as surgery or a severe illness	History of physical trauma (often not identified)

FIGURE 190-9 Beau lines in the fingernails of a young girl who was hospitalized with pneumonia 4 months prior to this visit. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-10 Mees lines that spread transversely across the entire breadth of the nail and are somewhat rounded with a contour similar to the distal lunula. (Courtesy of Jeffrey Meffert, MD.)

finger tip is called Hutchinson sign, which is an important indicator of nail melanoma (see Chapter 191, Pigmented Nail Disorders).

- Hematoma may be confused with LM, but the color grows out with the nail plate, exhibiting a proximal border that reproduces the shape of the lunula. A hole punched in the nail plate allows for the visualization of the underlying nail bed and confirmation of the nature of the coloration.
- Mees and Muehrcke lines may be confused with leukonychia or Beau lines. Mees lines are multiple white transverse lines that begin in the nail matrix and extend completely across the nail plate (**Figure 190-10**). They are caused by heavy-metal poisoning or severe systemic insults. Muehrcke lines are white transverse lines that represent an abnormality of the nail vascular bed and may occur with chronic hypoalbuminemia or renal disease (**Figure 190-11**). In contrast to Beau lines, they are not grooved and they do not move with nail growth. **Table 190-1** lists the clinical signs that help differentiate local trauma-induced lesions from those associated with systemic disease.
 - Leukonychia must also be differentiated from localized white onychomycosis, half-and-half nails, which are white proximal nails and pink or brown distal nails seen in renal failure (**Figure 190-12**), and Terry nails, which are white proximal nails and reddened distal nails that are seen in liver cirrhosis.
- The differential diagnosis of habit-tic deformity includes several nail dystrophies. In median nail, dystrophy produces a distinctive longitudinal split in the center of the nail plate with several cracks projecting laterally. Chronic paronychia is a *Candida* induced inflammation of the proximal nail folds that may induce ripples that can mimic the habit-tic deformity. Chronic eczematous inflammation may produce similar changes. Onychomycosis, Beau lines, and psoriatic nail lesions may also appear similar to habit-tic deformity.⁷

Twenty-nail dystrophy (**Figure 190-13**) is an idiopathic nail dystrophy that starts in childhood and resolves slowly with age. The nails lose their luster and develop longitudinal striations. It often starts with the fingernails and then affects the toenails.

MANAGEMENT

NONPHARMACOLOGIC

- Grinding of the nail at regular intervals is useful for onychogryphosis.

MEDICATIONS

- Fluoxetine has been reported as being helpful in the treatment of habit-tic deformity.⁸ **SOR** 

SURGICAL

- Removal of the nail and ablation of the nail bed for onychogryphosis. **SOR** 

FIGURE 190-11 Muehrcke lines in a patient with chronic hypoalbuminemia from nephrotic syndrome. The white transverse lines extend across the full nail bed and represent an abnormality of the nail vascular bed. (Courtesy of Wikimedia Commons and Lyr1 at http://commons.wikimedia.org/wiki/File:Muehrcke%27s_lines.JPG)

FIGURE 190-12 Half-and-half nail (“Lindsay nails”) with the proximal portion of the nail being white and the distal portion pink. Note the sharp line of demarcation between the two halves. The patient had just started dialysis for renal failure. (Courtesy of Richard P. Usatine, MD.)

FIGURE 190-13 Twenty-nail dystrophy in a healthy 8-year-old girl. Note how all the fingernails are uniformly affected with longitudinal striations and loss of nail luster. Her skin is otherwise normal. (Courtesy of Richard P. Usatine, MD.)

191 PIGMENTED NAIL DISORDERS

E.J. Mayeaux, Jr., MD

PATIENT STORY

An African American medical student presented with a new dark band on her index finger for 1 year (**Figure 191-1**). The dark color and the lack of melanonychia in other fingers made this concerning. A biopsy of the nail matrix was performed and the result showed a benign nevus.

INTRODUCTION

Atypical pigmentation of the nail plate may result from many nonmalignant causes, such as longitudinal melanonychia (LM), inflammatory changes, benign melanocytic hyperplasia, nevi, drugs, and endocrine disorders. It may also result from development of subungual melanoma. The challenge for the clinician is separating the malignant from the nonmalignant sources.

LM is the most common cause and it represents a longitudinal pigmented band in the nail plate (**Figures 191-1 and 191-2**). It may involve of 1 or several digits, vary in color from light brown to black, vary in width (most range from 2 to 4 mm), and have sharp or blurred borders.

EPIDEMIOLOGY

- LM is more common in more darkly pigmented persons. It occurs in 77% of African Americans older than age 20 years and in almost 100% of those older than age 50 years.^{1,2} It also occurs in 10% to 20% of persons of Japanese descent. LM is common in Hispanic and other dark-skinned groups. LM is unusual in whites, occurring in only approximately 1% of the population.¹
- Melanoma is the seventh most common cause of cancer in patients in the United States. Subungual melanoma is a relatively rare tumor with reported incidences between 0.7% and 3.5% of all melanoma cases in the general population.³

ETIOLOGY AND PATHOPHYSIOLOGY

- LM originates in the nail matrix and results from increased deposition of melanin within the nail plate. This deposition may result from greater melanin synthesis or from an increase in the total number of melanocytes. Pigment clinically localized within the dorsal half of the nail plate indicates a proximal matrix origin, and pigment localized within the ventral nail plate indicates a distal matrix origin. Look at the distal edge of the nail in a cross-sectional view to see whether the pigment is dorsal or ventral (a dermatoscope may help).

FIGURE 191-1 Longitudinal melanonychia—a single dark band of nail pigment appearing in the matrix region and extended to the tip of the nail. This is concerning for melanoma. The widening of the band in the proximal nail shows that the melanocytic lesion in the matrix is growing. This young woman had a biopsy that showed a benign nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE 191-2 Close up of longitudinal melanonychia in a single finger. Note the color band is translucent. (Courtesy of E.J. Mayeaux, Jr., MD.)

- LM may also be caused by chronic trauma, especially in the great toes.
- Inflammatory changes accompanying skin diseases located in the nail unit, such as psoriasis, lichen planus, amyloidosis, and localized scleroderma, rarely may result in LM.
- Benign melanocytic hyperplasia (lentigo) is observed in 9% of the adult cases and 30% of the pediatric cases of single-biopsied LM.⁴
- Nevi represent 12% of LM in adults, but almost 50% of cases in children. A brown-black coloration is observed in two thirds of the cases and periungual pigmentation (benign pseudo-Hutchinson sign) in one third.
- Certain drugs may also cause LM, especially chemotherapeutic agents (**Figure 191-3**), and antimalarial drugs (mepacrine, amodiaquine, and chloroquine).
- Endocrine disorders, such as Addison disease, Cushing syndrome, hyperthyroidism, and acromegaly, can be responsible for LM.
- The diagnosis of subungual melanoma must always be considered in patients with LM (**Figures 191-4** and **191-5**). Separating benign from malignant lesions is often difficult. Both arise most often in the thumb or index fingers, and both are more common in dark-skinned persons.⁵ A biopsy should be performed in an adult if the cause of LM is uncertain. **Table 191-1** lists diagnostic clues for subungual melanomas.
- Hutchinson sign is the extension of pigmentation to the skin adjacent to the nail plate involving the nail folds or the fingertip. It is an important indicator for nail melanoma (**Figures 191-4** to **191-6**).⁶
- Pseudo-Hutchinson sign is the presence of dark pigment around the proximal nail fold secondary to benign conditions such as racial melanosis and not melanoma (**Figure 191-7**). Another cause of

FIGURE 191-3 Melanonychia secondary to chemotherapy for metastatic penile cancer. (Courtesy of Richard P. Usatine, MD.)

TABLE 191-1 Diagnostic Clues That Indicate Longitudinal Melanonychia Is Suspicious for Subungual Melanoma

Hutchinson sign (melanoma until proven otherwise)
In a single digit
Sixth decade of life or later
Develops abruptly in a previously normal nail plate
Suddenly darkens or widens (change in the LM morphology)
Occurs in either the thumb, index finger, or great toe
History of digital trauma
Dark-skinned patient, particularly if the thumb or great toe is affected
Blurred, rather than sharp, lateral borders
Personal history of malignant melanoma
Increased risk for melanoma (e.g., familial atypical mole and melanoma [FAMM] syndrome)
Nail dystrophy, such as partial nail destruction or disappearance

FIGURE 191-4 Advanced acrolentiginous melanoma of the thumb with destruction of the nail plate and ulceration. Note the hyperpigmentation of the proximal nail fold (Hutchinson sign), which is strongly indicative of melanoma. (Courtesy of Dr. Dubin at <http://www.skinatlas.com>.)

pseudo-Hutchinson sign is a translucent cuticle below which the pigment of LM is visible. Trauma and drug-induced pigmentation can also produce a pseudo-Hutchinson sign.

- Subungual melanoma arises on the hand in 45% to 60% of cases, and most of those occur in the thumb (**Figures 191-4 to 191-6**).⁴ On the foot, subungual melanoma usually occurs in the great toe.⁵ The median age at which subungual melanoma is usually diagnosed is in the sixth and seventh decades. It appears with equal frequency in males and females.⁵

RISK FACTORS

Table 191-1 lists diagnostic clues that indicate an increased risk for the presence of subungual melanoma.

DIAGNOSIS

CLINICAL FEATURES

There is an ABCDEF mnemonic system that applies to subungual melanoma:

- In this system “A” stands for age (peak incidence being between the fifth to seventh decades) and African Americans, Asians, and Native Americans in whom subungual melanoma accounts for one third of melanoma cases.
- “B” stands for “brown to black” and with “breadth” of 3 mm or more.
- “C” stands for change in the nail band coloration or lack of change after adequate treatment.
- “D” stands for the digit most commonly involved.
- “E” stands for extension of the pigment onto the proximal and/or lateral nailfold (Hutchinson sign).
- “F” stands for family or personal history of dysplastic nevus or melanoma.

TYPICAL DISTRIBUTION

The digits used for grasping (thumb, index finger, and middle finger) are the most commonly involved in LM and melanoma, but either may be found in any finger or toe.

BIOPSY

Definitive diagnosis of a nail discoloration may be made with a biopsy of the nail matrix. Patients with darker skin color and multiple digits with translucent LM often need only be observed. Single dark lines in whites should always be biopsied. A 3-mm punch biopsy can be performed at the origin of the darkest part of a dark band within the nail matrix (**Figure 191-8**). Histologic diagnosis of atypical melanocytic hyperplasia necessitates the complete removal of the lesion.

DIFFERENTIAL DIAGNOSIS

- Pigmented lesions in the nail bed usually do not cause LM and are viewed through the nail as a grayish to brown or black spot.⁷

FIGURE 191-5 Acral lentiginous melanoma of the thumb with a very positive Hutchinson sign. Note how the pigmented band on the nail is greater than 3 mm in width. (Courtesy of Robert T. Gilson, MD.)

FIGURE 191-6 Acral lentiginous melanoma of the thumb with a very positive Hutchinson sign showing dark hyperpigmentation of the nail folds. Note how the light brown pigmented band on the nail is much greater than 3 mm in width. (Courtesy of Ryan O’Quinn, MD.)

- Subungual hematoma may be confused with LM, but the color grows out with the nail plate, exhibiting a proximal border that reproduces the shape of the lunula. A hole punched in the nail plate allows for the visualization of the underlying nail bed and confirmation of the nature of the coloration (see Chapter 196, Subungual Hematoma).

MANAGEMENT

NONPHARMACOLOGIC

No treatment is required for benign LM.

REFERRAL OR HOSPITALIZATION

Treatment of primary subungual melanomas includes amputation at the level of the interphalangeal joint for thumb lesions **SOR B**, the distal interphalangeal joint for fingers **SOR C**, and the metatarsophalangeal joint for toes.⁸ For melanoma in situ, it may be possible to remove the full nail apparatus and save the digit. Regional lymph node dissection can help with establishment of disease stage. Chemotherapy is recommended for nodal or visceral metastases.

PROGNOSIS

The 5-year survival is approximately 74% for patients with stage I and 40% for patients with stage II disease. Prognostic variables negatively affecting survival include stage at diagnosis, deeper Clark level of invasion, African American race, and ulceration.⁹

FOLLOW-UP

Because LM may indicate an undiagnosed melanoma of the nail unit, regular monitoring is extremely important. Have the patient report any rapid changes in pigmentation of the nail plate or nail folds, and strongly consider biopsy in these individuals.

192 INGROWN TOENAIL

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 14-year-old boy presents with a history of multiple ingrown nails of both great toes. Today his right big toe is swollen and painful (**Figure 192-1**). He has a 2-week history of pain, redness, and swelling of the lateral nail fold of the right great toe. Soaking the toe in Epsom salts has not helped. A partial nail removal after a digital block was successful. The nail matrix was also ablated with phenol to prevent recurrence of the ingrown nail.

INTRODUCTION

Onychocryptosis (ingrown toenails) is a common childhood and adult problem. Patients often seek treatment because of the significant levels of discomfort and disability associated with the condition.

SYNONYMS

Onychocryptosis, unguis incarnatus.

EPIDEMIOLOGY

The prevalence of onychocryptosis is unknown as many patients do not seek medical care and it is not a reportable disease. The toenails, especially the great toenail, are most commonly affected. Ingrown toenails at birth and in early childhood do occur, but are very rare.

ETIOLOGY AND PATHOPHYSIOLOGY

Onychocryptosis occurs when the lateral nail plate damages the lateral nail fold. The lateral edge of the nail plate penetrates and perforates the adjacent nailfold skin. Perforation of the lateral fold skin results in painful inflammation that manifests clinically as mild edema, erythema, and pain. In advanced stages, drainage, infection, and ulceration may be present. Hypertrophy of the lateral nail wall occurs, and granulation tissue forms over the nail plate and the nailfold during healing of the ulcerated skin.¹ It is a common affliction that can result from a variety of conditions that cause improper fit of the nail plate in the lateral nail groove (**Figure 192-1**).

RISK FACTORS¹

- Genetic predisposition.
- Poor-fitting footwear.
- Excessive trimming of the lateral nail plate.
- Pincer nail deformity (**Figure 192-2**).
- Trauma.

FIGURE 192-1 Ingrown toenail of the lateral aspect of the right great toe showing inflammation and granulation tissue. (Courtesy of Richard P. Usatine, MD.)

FIGURE 192-2 The curved infolding of the lateral edges of the nail plate indicates this patient has a pincer nail, which predisposes to onychocryptosis. (Courtesy of Richard P. Usatine, MD.)

- Sports in which kicking or running is important.
- Hyperhidrosis.
- Anatomic features such as nailfold width.
- Congenital malalignment of the digit.
- Overcurvature of the nail plate.
- Onychomycosis and other diseases that result in abnormal changes in the nail plate.

DIAGNOSIS

CLINICAL FEATURES: HISTORY AND PHYSICAL

The diagnosis is based upon clinical appearance and rarely is difficult. Characteristic signs and symptoms include pain, edema, exudate, and granulation tissue (**Figure 192-1**).

TYPICAL DISTRIBUTION

The great toe is most commonly affected; fingers are rarely involved except when nail biting is present.

DIFFERENTIAL DIAGNOSIS

- Cellulitis—Presents with redness, pain, and swelling beyond the nail fold (see Chapter 120, Cellulitis).
- Paronychia—Presents with redness and abscess formation (pus) in a nail fold (see Chapter 194, Paronychia).

MANAGEMENT

The treatment of ingrown toenails depends upon the age of the patient and the severity of the lesion.

NONPHARMACOLOGIC

- Lesions characterized by minimal to moderate pain and no discharge can be treated conservatively with soaking the affected foot in warm water for 20 minutes, 3 times per day, and pushing the lateral nailfold away from the nail plate.² **SOR C**
 - Other palliative measures include cotton wedging underneath the lateral nail plate and trimming the lateral part of the nail plate below the area of nailfold irritation.
- Numerous alternative methods of conservative treatment have been described, including splints and commercially available devices. Devices that have shown promise include shape memory alloys (SMAs), either of a Cu-Al-Mn base or a Ni-Ti base.³⁻⁵

MEDICATIONS

- Although many elect to treat apparent infections with oral antibiotics, studies show the use of antibiotics does not decrease healing time or postprocedure morbidity in otherwise normal patients.⁶ **SOR A**
- A medium- to high-potency topical corticosteroid can be applied after soaking to decrease inflammation, but is often unnecessary.

FIGURE 192-3 Status post partial nail avulsion procedure for an ingrown toenail. (Courtesy of Richard P. Usatine, MD.)

- If nail avulsion and/or matrix ablation is used, pain relievers for mild to moderate pain may be necessary.
- When placing digital blocks for surgical procedures, the best evidence indicates the use of lidocaine with epinephrine is equally safe and efficacious for anesthesia.⁷

SURGICAL

- Nonresponders to conservative therapy and patients with more severe lesions (substantial erythema, granulation tissue, and pus) need surgical therapy.^{8,9} **SOR C**
- Surgical intervention involves partial or full nail plate avulsion. Usually it is only necessary to remove the part of the nail that is placing pressure on the lateral nailfold (**Figure 192-3**). **SOR C**
- Patients who develop recurrent ingrown toenails benefit from permanent nail ablation of the lateral nail matrix. This may be achieved with the combination of partial nail plate avulsion plus phenol matrixectomy, which can cut recurrence rates by 90% (**Figure 192-4**).⁸⁻¹⁰ **SOR A**
- In a Cochrane Systematic Review of surgical treatments for ingrowing toenails nail avulsion with the use of phenol is more effective at preventing symptomatic recurrence than nail avulsion without the use of phenol.¹⁰ Unfortunately the use of phenol does increase the risk of postoperative infection (by 5 times) compared with simple nail avulsion.¹⁰ **SOR A**
- Chemical matrixectomy is performed mainly by phenol (full-strength 88%), but 10% sodium hydroxide is another alternative. In a comparison study of the use of chemical matrixectomy for the treatment of ingrown toenails, the overall success rates were 95% for both phenol and sodium hydroxide.¹¹ **SOR A**
- One study found that partial nail avulsion with phenolization gave better results than partial avulsion with matrix excision.¹² Local antibiotics applied to the surgical site did not reduce signs of infection or recurrence. The use of phenol did not produce more signs of infection than matrix excision.¹² **SOR B**
- Electrosurgical ablation can be performed with electrocautery units on the fulguration setting or using a special matrixectomy electrode with a high-frequency electrocautery unit (**Figure 192-5**). **SOR C**

FOLLOW-UP

After surgical intervention, consider follow-up in 3 to 4 days to assess treatment and exclude cellulitis.

PATIENT EDUCATION

- Patients should be educated about proper nail trimming so as to minimize trauma to the lateral nailfold. The lateral nail plate should be allowed to grow well beyond the lateral nailfold before trimming horizontally.
- Patients should also be educated about the importance of avoiding shoes that are too tight over the toes to help minimize recurrences.

FIGURE 192-4 Phenol matrixectomy to destroy a portion of the nail matrix to prevent a recurrent ingrown toenail. Note the use of a tourniquet to decrease bleeding while applying the phenol with a twisting motion.

FIGURE 192-5 Use of electrocautery to ablate the lateral nail matrix. This results in a narrower nail and a decreased likelihood of onychocryptosis recurrence. (Courtesy of Richard P. Usatine, MD.)

193 ONYCHOMYCOSIS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 29-year-old woman presents with thickened and discolored toenails for 1 year (**Figure 193-1**). She is embarrassed to wear sandals and wants treatment. The entire nail plates are involved and there is subungual keratosis. She did not realize that she had tinea pedis, but a fine scale was seen on the soles and sides of the feet indicative of tinea pedis in a moccasin distribution. A KOH scraping from the subungual debris was positive for hyphae. She has no history of liver disease or risk factors for liver disease. An oral antifungal was prescribed for 3 months.

INTRODUCTION

Onychomycosis is a term used to denote nail infections caused by any fungus, including dermatophytes, yeasts, and nondermatophyte molds. One, some, and occasionally all of the toenails and/or fingernails may be involved. Although most toenail onychomycosis is caused by dermatophytes, many cases of fingernail onychomycosis are caused by yeast. Onychomycosis may involve the nail plate and other parts of the nail unit, including the nail matrix.

SYNONYMS

Toenail fungus, tinea unguium, dermatophytosis of nails.

EPIDEMIOLOGY

- The incidence of onychomycosis has been reported to be 2% to 13% in North America.¹
- Most patients (7.6%) only have toenail involvement and only 0.15% have fingernail involvement alone.²
- The prevalence of onychomycosis varies from 4% to 18%.^{3,4}
- The disease is very common in adults, but may also occur in children.

ETIOLOGY AND PATHOPHYSIOLOGY

- Dermatophytes are responsible for most finger and toenail infections.
- Nonpathogenic fungi and *Candida* (in the rare syndrome of chronic mucocutaneous candidiasis) also can infect the nail plate (**Figure 193-2**).
- Dermatophytic onychomycosis (tinea unguium) occurs in three distinct forms: distal subungual, proximal subungual, and white superficial.
- The vast majority of distal and proximal subungual onychomycosis results from *Trichophyton rubrum* (**Figure 193-3**).

FIGURE 193-1 Onychomycosis in all toenails of this 29-year-old woman. Note the nail plate thickening and discoloration along with the subungual keratosis. She also has tinea pedis in a moccasin distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 193-2 *Candida* infection of the skin and nails in an immunosuppressed patient with chronic mucocutaneous candidiasis. (Courtesy of Richard P. Usatine, MD.)

- White superficial onychomycosis is usually caused by *Trichophyton mentagrophytes*, although cases caused by *T. rubrum* have also been reported (Figure 193-4).
- Yeast onychomycosis is most common in the fingers caused by *Candida albicans*.

RISK FACTORS

- Tinea pedis.⁵
- Trauma predisposes to infection but can also cause a dystrophic nail that can be confused for onychomycosis.⁵
- Older age.⁵
- Swimming.⁵
- Diabetes.⁵
- Living with family members who have onychomycosis.⁵
- Immunosuppression (Figures 193-5 and 193-6).⁶

DIAGNOSIS

CLINICAL FEATURES

- Distal subungual onychomycosis is the most common presentation.
- Distal subungual onychomycosis begins with a whitish, yellowish, or brownish discoloration of a distal corner of the nail, which gradually spreads to involve the entire width of the nail plate and extends slowly toward the cuticle. Keratin debris collecting between the nail plate and its bed is the cause of the discoloration (Figures 193-1, 193-3, and 193-7).
- Proximal subungual onychomycosis progresses in a manner similar to distal subungual onychomycosis but affects the nail in the vicinity of the cuticle first and extends distally. It usually occurs in individuals with a severely compromised immune system (Figure 193-5).
- White superficial onychomycosis appears as dull white spots on the surface of the nail plate (Figure 193-4). Eventually the whole nail plate may be involved. The white areas may be soft and can be lightly scraped to yield a chalky scale that may be examined or cultured.

TYPICAL DISTRIBUTION

- Nail infection may occur in a single digit but most often occurs simultaneously in multiple digits of the foot. Toenails and fingernails may be affected at the same time especially in patients that are immunocompromised (Figures 193-5 and 193-6).

LABORATORY TESTING

- KOH and culture—Clippings of nail plate and scrapings of subungual keratosis can be examined with KOH and microscopy and/or sent to the laboratory in a sterile container to be inoculated onto Sabouraud medium to culture.
- Dermatophyte test medium (DTM) culture is an alternative to Sabouraud medium culture. DTM is less expensive and can be

FIGURE 193-3 Severe toenail onychomycosis demonstrating subungual keratosis in the first nail and onychogryphosis (ram's horn nail) in the second nail because of the fungal infection. The culture grew *Trichophyton rubrum*. (Courtesy of Richard P. Usatine, MD.)

FIGURE 193-4 White superficial onychomycosis of the thumb nail. The culture was positive for *Trichophyton mentagrophytes*. (Courtesy of Richard P. Usatine, MD.)

performed in the physician's office, with results becoming available within 3 to 7 days. Dermatophyte growth is indicated by a change in the medium's color from yellow to red. It is important that DTM cultures be read in a timely fashion, as saprophytic organisms may grow over several weeks and cause a false-positive result. DTM does not identify the specific causative organism, but such identification is unnecessary as all dermatophyte infections are treated the same way. DTM cultures had good positive and negative correlation with culture on Sabouraud medium.⁷

- Clippings—Nail clippings may be sent to pathology in formalin to be examined with periodic acid-Schiff (PAS) stain for fungal elements. This can be more sensitive than KOH and culture.
- Comparison of diagnostic methods:
 - In a 2003 study by Weinberg et al, the sensitivities for onychomycosis detection were KOH 80%, Bx/PAS 92%, and culture 59%. The specificities were KOH 72%, Bx/PAS 72%, and culture 82%. The positive predictive values were KOH 88%, Bx/PAS 89.7%, and culture 90%. The negative predictive values were KOH 58%, Bx/PAS 77%, and culture 43%.⁸
 - In a 2007 study of the diagnosis of onychomycosis by Hsiao et al, the sensitivities of KOH, PAS, and culture were 87%, 81%, and 67%, respectively, and the negative predictive values of KOH, PAS, and culture were 50%, 40%, and 28%, respectively. One reason that the KOH may have done so well is that the nail specimen was immersed in 20% KOH in a test tube for 30 minutes or longer before looking under the microscope.⁹
 - KOH may be equivalent to PAS if done and read properly. It is less expensive and the results are available while the patient is in the office. PAS is a good second line if the KOH is negative and the suspicion for onychomycosis is still present.

DIFFERENTIAL DIAGNOSIS

- Nail trauma can cause a dysmorphic nail that is discolored and thickened. It is especially seen in the big toenail in runners. Ask about nail trauma before diagnosing onychomycosis. Although onychomycosis often starts in the big toenail, it usually spreads to other nails. Traumatic changes often present with only one nail involved.
- Psoriatic and lichen planus nail changes may easily be confused with onychomycosis, especially when the nail becomes thickened and discolored. Pitting of the nail plate surface, which is common in psoriasis, is not a feature of fungal infection. It is possible for a patient with psoriasis to get onychomycosis. Fungal studies can help determine if the changes are truly secondary to onychomycosis (see Chapter 195, Psoriatic Nails).
- Pseudomonal nail infection—Produces a blue-green tint to the nail plate (**Figure 193-8**).
- Leukonychia—White spots or bands that appear proximally and proceed out with the nail may be confused with white superficial onychomycosis (see Chapter 190, Normal Nail Variants).
- Habitual picking of the proximal nail fold—Induces the nail plate to be wavy and ridged, although its substance remains intact and hard (see Chapter 190, Normal Nail Variants).

FIGURE 193-5 Extensive onychomycosis involving all toenails in an HIV-positive man. His second toenail shows onychogryphosis (ram's horn nail) secondary to the fungal infection. (Courtesy of Richard P. Usatine, MD.)

FIGURE 193-6 Fungal infection involving 4 of 10 nails on the hands of the same HIV-positive man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 193-7 Onychomycosis involving both thumbnails. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

- Treating onychomycosis can be discouraging. Most topical creams and lotions do not penetrate the nail plate well and are of little value except in controlling inflammation at the nail folds.
- Surgical avulsion may be used to decrease pain caused by pressure on an elevated nail plate because of a dermatophytoma (a collection of dermatophytes and cellular debris under the nail plate). Recurrences are common in the absence of additional systemic or topical therapy with ciclopirox, as the infection typically involves the nail matrix and bed. **SOR** 
- There has been a resurgence of interest in phototherapy modalities for the treatment of onychomycosis. UV light therapy, near-infrared photoinactivation therapy, photodynamic therapy, and photothermal ablative therapy are being studied for treatment of onychomycosis.¹⁰ Further studies are required to determine the clinical role of laser and light therapy in the treatment of onychomycosis. The Pinpointe FootLaser was approved for use to treat onychomycosis in February 2011. **SOR** 

FIGURE 193-8 *Pseudomonas* of the nail showing a blue-green discoloration. (Courtesy of Richard P. Usatine, MD.)

MEDICATIONS

- Oral therapy (**Table 193-1**) is no longer expensive now that terbinafine is generic and on many discounted drug lists.

TABLE 193-1 Common Treatments for Onychomycosis

Drug	Pediatric Dose	Adult Dose	Course	Toenail Cure Rate
Griseofulvin (Grifulvin V)	Microsize 15 to 20 mg/kg per day	500 mg po qd	4 to 9 months (f), 6 to 12 months (t)	60% ± 6%
Terbinafine (Lamisil)	10 to 20 kg: 62.5 mg/day 20 to 40 kg: 125 mg/day	250 mg po qd	6 weeks (f), 12 weeks (t)	76% ± 3%
Terbinafine (Lamisil) pulse*	—	250 mg bid 1 wk/mo	2 months (f), 3 months (t)	NR
Itraconazole (Sporanox)	—	200 mg daily	6 weeks (f), 12 weeks (t)	59% ± 5%
Itraconazole (Sporanox) pulse	<20 kg: 5 mg/kg per day for 1 wk/mo 20 to 40 kg: 100 mg daily for 1 wk/mo	200 mg bid or 5 mg/kg per day capsules for 1 wk/mo	2 months (f), 3 months (t)	63% ± 7%
Fluconazole (Diflucan)	3 to 6 mg/kg once a wk	150 mg once a wk	12 to 16 weeks (f), 18 to 26 weeks (t)	48% ± 5%
Ciclopirox 8% nail lacquer (Penlac)	—	Apply daily to nail and surrounding 5-mm skin	Up to 48 weeks	Approximately 7%

NR, Not recorded.

*Not indicated for treating onychomycosis by the FDA.

From: Harrell TK, Necomb WW, Replogle WH, et al. Onychomycosis: improved cure rates with itraconazole and terbinafine.

J Am Board Fam Pract. 2000;13(4):268-273; Bell-Syer S, Porthouse J, Bigby M. Oral treatments for toenail onychomycosis.

Cochrane Database Syst Rev. 2004;(2):CD004766. DOI: 10.1002/14651858. CD004766; Crawford F, Hart R, Bell-Syer S, et al. Topical

treatments for fungal infections of the skin and nails of the foot. *Cochrane Database Syst Rev.* 1999;(3):CD001434. DOI: 10.1002/

14651858. CD001434; Havu V, Heikkila H, Kuokkanen K, et al. A double-blind, randomized study to compare the efficacy and safety of

terbinafine (Lamisil) with fluconazole (Diflucan) in the treatment of onychomycosis. *Br J Dermatol.* 2000;142(1):97-102.

- A Cochrane review found that the evidence suggests that terbinafine is more effective than griseofulvin and that terbinafine and itraconazole are more effective than no treatment.¹¹ **SOR A**
- Terbinafine dosing is 250 mg daily for 3 months for toenail onychomycosis and 2 months to treat fingernail involvement only.¹¹ **SOR A**
- Another Cochrane review found two trials of nail infections that did not provide any evidence of benefit for topical treatments (ciclopirox not included) compared with placebo.¹² **SOR A**
- Terbinafine has a preferable drug interaction profile, may have better long-term cure rates, and daily dosing may be the most effective treatment.^{6,11} **SOR A**
- Itraconazole (Sporanox) has more drug interactions. Pulse dosing is as effective as daily dosing, but even with pulse dosing, therapy is more costly than terbinafine. Consider itraconazole if terbinafine does not effectively treat onychomycosis caused by fungus other than dermatophytes. **SOR C**
- Fluconazole (Diflucan) is not currently FDA approved for nail therapy and is not as effective as other oral therapies.^{6,13} **SOR B**
- Ciclopirox 8% nail lacquer (Penlac) used daily (with weekly nail cleaning and filing) is an FDA-approved topical treatment for mild to moderate onychomycosis. A metaanalysis of 2 randomized controlled trials showed a clinical cure rate of 8% versus 1% for vehicle alone.¹⁴ Such a low cure rate is disappointing, but a larger group of patients had some improvement without cure. This is one option for persons able to afford this topical treatment but who are not able to take oral antifungals.
- Amorolfine is a topical antifungal agent with activity against dermatophytes, yeasts, and fungi that is available over the counter in Australia and the United Kingdom, but is not approved for use in the United States. Amorolfine 5% nail lacquer has been used as monotherapy for the treatment of onychomycosis. It is applied once weekly after the surface of the nail is filed with a disposable file and wiped with alcohol. Once weekly application of amorolfine 5% nail lacquer for 6 months led to both clinical and mycologic cure in 38% and 46% of patients. It may also be used to increase cure rates when used in combination with oral antifungals.¹⁵

COMPLEMENTARY AND ALTERNATIVE THERAPY

- There are numerous complementary and alternative medicine (CAM) therapies described on the Internet, most of which have minimal or no evidence of clinical efficacy.
- Mentholated chest rub—There is minimal data on the efficacy of a mentholated chest rub (Vicks VapoRub) in the treatment of onychomycosis. In a series of 18 patients who applied the medication to affected nails daily for 48 weeks, 4 patients (22%) achieved both clinical and mycologic cure.¹⁶ Although these products are unlikely to be harmful, additional studies that support their efficacy in onychomycosis are necessary before widespread use can be recommended.

PREVENTION

Patients should be educated about the use of appropriate footwear, especially in high-exposure areas such as communal bathing facilities and health clubs.

PROGNOSIS

The condition may persist indefinitely if left untreated.

In patients with diabetes or other immunocompromised states, onychomycosis may increase the risk of secondary bacterial infections.¹⁷

FOLLOW-UP

Routine monitoring of liver function tests during therapy is probably not necessary in patients without underlying liver disease. However, because the manufacturer of terbinafine recommends checking pretreatment serum aminotransferases and monitoring for potential symptoms of hepatotoxicity during treatment, many clinicians routinely obtain pretreatment and mid-therapy values.

PATIENT EDUCATION

Patients should be advised that with treatment, nails may not appear normal for up to 1 year. The normal nail must grow out as treatment progresses. The appearance of normal appearing nails at the proximal edge of the nail is an encouraging sign at the completion of therapy.

194 PARONYCHIA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 41-year-old woman presented with a 3-day history of localized pain, redness, and tenderness of the lateral nailfold of the index finger. A small abscess had developed in the last 24 hours at the nail margin (**Figure 194-1**). After informed consent was given, a digital block was performed. This acute paronychia was treated with incision and drainage using a #11 scalpel (**Figure 194-2**). A significant amount of pus was drained. She soaked her finger four times daily as directed. Two days later the patient's finger was much better and the culture grew out *Staphylococcus aureus*. Draining the abscess was sufficient treatment.

INTRODUCTION

Paronychia is a localized, superficial infection or abscess of the nailfolds. It is one of the most common infections of the hand. Paronychia can be acute or chronic. Acute paronychia usually presents as an acutely painful abscess in the nailfold. Chronic paronychia is defined as being present for longer than 6 weeks' duration. It is a generalized red, tender, swelling of the proximal or lateral nailfolds. It is usually nonsuppurative and is more difficult to treat.

EPIDEMIOLOGY

Paronychia is the most common infection of the hand, representing 35% of all hand infections in the United States.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Paronychial infections develop when a disruption occurs between the seal of the nailfold and the nail plate or the skin of a nailfold is disrupted and allows a portal of entry for invading organisms.²
- Acute paronychia is most commonly caused by *S. aureus*, followed by streptococci and *Pseudomonas* (**Figures 194-1 to 194-5**).¹
- Chronic paronychia more likely results from chronic *Candida albicans* (95%) (**Figures 194-6 and 194-7**). Other rare causes include atypical *Mycobacteria* and Gram-negative rods. There is some evidence that chronic paronychia is at least partially an eczematous process and that *Candida* infection is a secondary phenomenon.³
- Untreated persistent chronic paronychia may cause horizontal ridging, undulations, and other changes to the nail plate (**Figures 194-6 and 194-7**).

FIGURE 194-1 Painful acute paronychia around the fingernail of a 41-year-old woman. Note the swelling and erythema with a small white-yellow area suggesting underlying purulence. (Courtesy of Richard P. Usatine, MD.)

FIGURE 194-2 Incision and drainage of the acute paronychia in the previous figure with a #11 scalpel. Note the exuberant pus draining from the incision. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Acute paronychia commonly results from nail biting (**Figure 194-3**), finger sucking, aggressive manicuring (**Figure 194-6**), hang nails (**Figure 194-5**), trauma, and artificial nails.²
- Children are prone to acute paronychia through direct infection of fingers with mouth flora from finger sucking and nail biting.
- People at risk of developing chronic paronychia include those who are repeatedly exposed to liquid irritants or alkali, and those whose hands are chronically wet. People with occupations such as baker, bartender, housekeepers, and dishwashers are predisposed to developing chronic paronychia.
- Patients with diabetes mellitus, compromised immune systems, or a history of oral steroid use are at increased risk for paronychia. Retroviral therapy use, especially indinavir and lamivudine, may be associated with an increased incidence of paronychia.⁴

Sculptured (artificial) nail placement is associated with the development of paronychia.¹

DIAGNOSIS

CLINICAL FEATURES

- Acute paronychia presents with localized pain and tenderness. The nailfold appears erythematous and inflamed, and a collection of pus usually develops (**Figures 194-1 to 194-5**). Granulation tissue may develop along the nailfold, and cellulitis may develop (**Figure 194-5**).
- Chronic paronychia is a red, tender, painful swelling of the proximal or lateral nailfolds. A small collection of pus or abscess may form but typically only redness and swelling are present. Eventually, the nail plates may become thickened and discolored, with pronounced horizontal ridges (**Figures 194-6 and 194-7**).⁵

DIFFERENTIAL DIAGNOSIS

- Mucus cyst, which presents as a painless swelling lateral and proximal to the nail plate (**Figure 194-8**). This can also cause changes in the nail morphology.
- Ingrown nail (onychocryptosis) is a condition in which the nail plate is too large for the nail bed. The pressure applied to the lateral nailfold causes a painful inflammation. Although this is sometimes called paronychia, it is different from the type of paronychia caused by an infection of the nailfold (see Chapter 192, Ingrown Toenail).
- Glomus tumor, which presents with constant severe pain, nail plate elevation, bluish-discoloration of the nail plate, and blurring of the lunula.
- Herpetic whitlow, which results from herpes simplex virus (HSV) infection presents with acute onset of vesicles or pustules, severe edema, erythema, and pain. Tzanck staining of vesicles will demonstrate multinucleated giant cells and viral culture will grow HSV (see Chapter 129, Herpes Simplex).

FIGURE 194-3 Acute paronychia from nail biting. Note abscess formation in the lateral nailfold that is extending into the proximal fold. (Courtesy of E.J. Mayeaux, Jr., MD.)

FIGURE 194-4 Acute paronychia of the great toe. Note extensive manicure of the nails, which may predispose to paronychia if the cuticle or nailfolds are disrupted. (Courtesy of Jennifer P. Pierce, MD.)

FIGURE 194-5 Acute paronychia with cellulitis of the skin of the fingertip and granulation tissue formation. This all started when the patient began manipulating a hang nail. (Courtesy of Richard P. Usatine, MD.)

- Felon—Paronychia must be distinguished from a felon, which is an infection of the digital pulp. It is characterized by severe pain, swelling, and erythema in the pad of the fingertip.
- Benign and malignant neoplasms, which may present early with redness and swelling should always be ruled out when chronic paronychia does not respond to conventional treatment.

MANAGEMENT

NONPHARMACOLOGIC

- Milder cases of acute paronychia without abscess formation may be treated with warm soaks for 20 minutes 3 to 4 times a day.² **SOR C**
- When an abscess or fluctuance is present, drainage is necessary.⁷ **SOR C** It is performed with digital block anesthesia. The affected nailfold is incised with a scalpel with the blade parallel to the edge of the nail plate and the pus expressed (**Figure 194-2**). Warm soaks 4 times a day are initiated to keep the incision from sealing until all of the pus is gone.⁸ Between soaks, an adhesive bandage can protect the nailfold. Antibiotic therapy is usually not necessary unless there is accompanying cellulitis. **SOR C**

MEDICATIONS

- Although antibiotics are not necessary for simple paronychia, addition of an oral antistaphylococcal agent (dicloxacillin 500 mg 3 times daily, cephalexin 500 mg 2 to 3 times daily for 7 to 10 days, erythromycin 333 to 500 mg 3 times daily, or azithromycin 500 mg on day 1 followed by 250 mg daily for 4 days) may be added for cases with coexisting cellulitis or that are unresponsive. **SOR C**
- Both children who suck their fingers and patients who bite their nails and who require antibiotics should be covered against anaerobes. Clindamycin and amoxicillin-clavulanate potassium are effective against most pathogens isolated from infections originating in the mouth.⁶
- Long-term treatment of chronic paronychia primarily involves avoiding predisposing factors such as prolonged exposure to water, nail trauma, and finger sucking. Treatment with topical antifungals (topical miconazole or ketoconazole) or a combination of topical steroids and an antifungal agent has been shown to be successful.^{2,3} **SOR B** Oral antifungal therapy is usually not necessary.²

PREVENTION

- Trim hangnails to a semilunar smooth edge with a clean sharp nail plate trimmer. Trim toenails flush with the toe tip.
- Do not bite the nail plate or lateral nailfolds.
- Avoid prolonged hand exposure to moisture. If hand washing must be frequent, use antibacterial soap, thoroughly dry hands with a clean towel, and apply an antibacterial moisturizer. Use cotton glove liners under waterproof gloves to keep hands dry from sweat and condensation.
- Wear rubber or latex-free gloves when there is potential exposure to pathogens.
- Control diabetes mellitus.
- Keep fingernails clean.
- Moisturize the skin, don't let it become chafed and cracked.

FIGURE 194-6 Chronic paronychia. Note horizontal ridges on one side of the nail plate as a result of chronic inflammation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 194-7 Chronic *Candida* paronychia causing a dysmorphic fingernail with horizontal ridging. (Courtesy of Richard P. Usatine, MD.)

PROGNOSIS

Although the nailfold should improve with treatment, some chronic nail plate changes may not resolve.

FOLLOW-UP

Patients can perform warm soaks 3 to 4 times per day and should have a follow-up examination several days after incision and drainage to assure the infection is resolving appropriately.

PATIENT EDUCATION

Educate patients on measures that may prevent or improve paronychia (above.)

195 PSORIATIC NAILS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 19-year-old man with a 4-year history of plaque psoriasis presents with nail abnormalities in several fingers (**Figure 195-1**). He is particularly concerned about the recently acquired greenish discoloration of his fifth digit.

INTRODUCTION

Psoriasis is a hereditary disorder of skin with numerous clinical expressions. It affects millions of people throughout the world.¹ Nail involvement is common and can have a significant cosmetic impact.

EPIDEMIOLOGY

- Nails are involved in 30% to 50% of psoriasis patients at any given time, and up to 90% develop nail changes over their lifetime.¹ In most cases, nail involvement coexists with cutaneous psoriasis, although the skin surrounding the affected nails need not be involved. Psoriatic nail disease without overt cutaneous disease occurs in 1% to 5% of psoriasis. Patients with nail involvement are thought to have a higher incidence of associated arthritis.²
- The most common nail change seen with psoriasis is nail plate pitting (**Figures 195-1** and **195-2**).

ETIOLOGY AND PATHOPHYSIOLOGY

- In psoriasis, parakeratotic cells within the stratum corneum of the nail matrix alters normal keratinization.³ The proximal nail matrix forms the superficial portion of the nail plate, so that involvement in this part of the matrix results in pitting of the nail plate (**Figures 195-1** and **195-2**.) The pits may range in size from pinpoint depressions to large punched-out lesions. People without psoriasis can have nail pitting.
- Longitudinal matrix involvement produces longitudinal nail ridging or splitting (**Figure 195-2**). When transverse matrix involvement occurs, solitary or multiple “growth arrest” lines (Beau lines) may occur (see Chapter 190, Normal Nail Variants). Psoriatic involvement of the intermediate portion of the nail matrix leads to leukonychia and diminished nail plate integrity.
- Parakeratosis of the nail bed with thickening of the stratum corneum causes discoloration of the nail bed, producing the “salmon spot” or “oil drop” signs.³
- Desquamation of parakeratotic cells at the hyponychium leads to onycholysis, which may allow for bacteria and fungi infection.⁴

FIGURE 195-1 Patient with nail psoriasis demonstrating the oil drop sign (second digit), nail pitting (second and third digit), onycholysis (second, fourth and fifth digit), and secondary pseudomonas infection (fifth digit). (Courtesy of E.J. Mayeaux, Jr., MD.)

FIGURE 195-2 Nail psoriasis demonstrating nail pitting, onycholysis, oil drop sign, and longitudinal ridging. Nails held over the silvery plaque on the knee. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS

- Psoriasis of the skin.
- Psoriatic arthritis.
- Nail unit trauma.
- Generalized psoriasis flair.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of nail psoriasis is usually straightforward when characteristic nail findings coexist with cutaneous psoriasis. Nail pitting and onycholysis are the most common findings (**Figure 195-3**).
- Nail psoriasis and onychomycosis are often indistinguishable by clinical examination alone. Psoriasis at the hyponychium produces subungual hyperkeratosis and distal onycholysis (**Figures 195-4** and **195-5**). Trauma may accentuate this process. Secondary microbial colonization by *Candida* or *Pseudomonas* organisms may occur (**Figures 195-1** and **195-5**).
- Nail bed psoriasis produces localized onycholysis which often appears like a drop of oil on a piece of paper (oil drop sign) (**Figures 195-2, 195-4, and 195-5**). This same condition is also called the salmon patch sign.
- Extensive germinal matrix involvement may result in loss of nail integrity and transverse (horizontal) ridging (**Figure 195-6**).
- Psoriasis causes dermal vascular dilation and tortuosity, and in the nails is associated with splinter hemorrhages of the nail bed caused by foci of capillary bleeding. Extravasated blood becomes trapped between the longitudinal troughs of the nail bed and the overlying nail plate grows out distally along with the plate (**Figure 195-7**). The splinter hemorrhages of the psoriatic nail are analogous to the cutaneous Auspitz sign.

LABORATORY TESTING

- KOH preparation and fungal culture will usually provide an answer. However, it may be necessary to clip a portion of the nail plate and send it for fungal staining (periodic acid-Schiff [PAS] stain) if the first test results are not consistent with the clinical picture.⁵ Psoriasis and onychomycosis can occur concomitantly.

BIOPSY

- Biopsy of the nail unit is rarely necessary unless a malignancy is suspected.

DIFFERENTIAL DIAGNOSIS

- Onychomycosis produces distal onycholysis and hyperkeratosis that appear identical to psoriasis and may coexist with it (see Chapter 193, Onychomycosis).
- Darier disease (keratosis follicularis) is an autosomal dominant disorder that results in abnormal keratinization and loss of adhesion

FIGURE 195-3 Nail pitting and onycholysis in a patient with psoriasis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 195-4 Nail psoriasis with onycholysis and oil drop sign in a young woman. Note that end of the nail plates are no longer attached to the nail bed and there is a light brown discoloration where the nail loses its attachment. (Courtesy of Richard P. Usatine, MD.)

between epidermal cells. It typically presents in the second decade of life with hyperkeratotic, yellow-brown, greasy-appearing papules that coalesce into verrucous-like plaques in a seborrheic distribution. Nails may demonstrate red/white longitudinal stripes, subungual hyperkeratosis, and notching of the distal nail margins (**Figure 195-8**). The course of the illness is chronic and persistent.

- Alopecia areata also can produce pitting of the nails. As a general rule, pitting in psoriasis is more irregular and broader based; pitting in alopecia areata is more regular, shallow, and geometric and produces fine pits (see Chapter 187, Alopecia Areata).
- Neoplastic and dysplastic diseases may produce psoriasiform nail changes in a single nail. Bowen disease, squamous cell carcinoma, and verruca vulgaris may appear as an isolated subungual or periungual plaque, possibly with accompanying nail plate destruction. A biopsy can establish a definitive diagnosis.

MANAGEMENT

NONPHARMACOLOGIC

- Psoriatic nail disease is often persistent and refractory to treatment. There is insufficient evidence to recommend a standard treatment.
- The nails should be kept short, to avoid traumatic exacerbation of onycholysis and to avoid the accumulation of exogenous material under the nail.³ **SOR C**
- Nail polish may be very helpful in concealing a range of nail unit changes.⁶ **SOR C**
- Nail plate buffing may diminish surface imperfections.⁶ **SOR C**

MEDICATIONS

- Unfortunately, specific evidence for systemic therapy in nail psoriasis is generally lacking. It should be considered in those with significant cutaneous involvement in addition to nail disease.
- One treatment option for nail psoriasis, especially with matrix involvement, is intralesional corticosteroid injection. Triamcinolone acetonide (0.4 mL, 10 mg/mL) is injected into the nail bed, matrix, or proximal fold following digital block, and then at 3-month intervals.^{3,7} **SOR A** Subungual hyperkeratosis, ridging, and thickening respond better than pitting and onycholysis, with benefit sustained for at least 9 months.⁷ Pain, periungual hypopigmentation, subungual hemorrhage and atrophy have been reported.³
- Nail bed disease, including subungual hyperkeratosis, distal onycholysis, and “oil drop” changes may also need the lateral nail folds injected close to the nail bed. Direct injection into the nail bed is prevented by the nail plate and extreme pain sensitivity of the hyponychial region. Atrophy and subungual hematoma formation are potential complications.
- One study found that topical 1% 5-fluorouracil solution or 5% cream applied twice daily to the matrix area for 6 months improved pitting and hyperkeratosis but worsened onycholysis.³ **SOR B**
- Topical calcipotriol may be effective in reducing subungual hyperkeratosis.^{3,8} **SOR B**

FIGURE 195-5 Nail psoriasis with the oil drop sign proximal to the lighter onycholysis at the distal nail. (Courtesy of Richard P. Usatine, MD.)

FIGURE 195-6 Nail psoriasis demonstrating onycholysis, pits, and transverse (horizontal) ridging. (Courtesy of Richard P. Usatine, MD.)

- Topical tazarotene improves onycholysis and nail pitting (if applied under occlusion) in those treated for 24 weeks.³ **SOR A**
- In a single-blinded study, Feliciani et al found that combination therapy (oral cyclosporine and topical calcipotriol) was more effective than monotherapy (cyclosporine alone) on nail psoriasis.⁹
- Anthralin ointment 0.4% to 2.0%, applied and washed off after 30 minutes, is effective for onycholysis, subungual hyperkeratosis, and possibly pitting.³ **SOR B**
- Narrow-band UVB and psoralen UVA (PUVA) phototherapy for 3 to 6 months is effective for cutaneous psoriasis but its efficacy for nail psoriasis is poorly defined.³
- Acitretin, methotrexate, and cyclosporine are helpful for nail psoriasis.^{3,10} **SOR B**
- Systemic retinoid therapy is often effective for pustular psoriasis, and early intervention is most likely to prevent chronic nail-associated scarring.

PREVENTION¹¹

- Wearing gloves during wet work and during exposure to harsh materials may minimize trauma to the skin and nail unit.
- Trimming the nail short to minimize leverage at the free edge and resulting trauma.
- If dry skin or scaling develop, application of emollients may be helpful.
- Cosmetic manipulations of the nail risk exacerbating the disease due to minor trauma. Discretion and care should be exercised when trimming the cuticle and clearing subungual debris.

PROGNOSIS

- Psoriatic nail changes may be reversible because scarring typically does not occur. An exception to this may develop in severe cases of generalized pustular psoriasis.

FOLLOW-UP

- Follow-up can be combined with regular follow-ups for cutaneous psoriasis.

PATIENT EDUCATION

- Nail psoriasis is mainly a cosmetic problem. Nail polish or artificial nails can be used in some patients to conceal psoriatic pitting and onycholysis. When subungual hyperkeratosis becomes uncomfortable because of pressure exerted by footwear, the nail can be pared down to relieve the pressure.
- Patients should be instructed to trim nails back to the point of firm attachment with the nail bed to minimize further nail-bed and nail-plate disassociation. Wearing gloves while working may minimize trauma to the nails. Tell patients to avoid vigorous cleaning and scraping under the nails as this may break the skin where the nail is attached and lead to an infection.

196 SUBUNGUAL HEMATOMA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 22-year-old woman dropped an iron on her toe the day before she visited our free clinic. Her toe was painful at rest and worse when walking (**Figure 196-1**). This subungual hematoma needed to be drained and we did not have an electrocautery unit. A paperclip was bent open and held in a hemostat and heated with a torch. With some pressure it pierced the patient's nail plate and the blood spontaneously drained (**Figures 196-2 and 196-3**). This relieved the pressure and gave the patient immediate pain relief. The remaining old blood was drained with a little pressure on the proximal nail fold (**Figure 196-4**). Although we were concerned about a possible underlying fracture, the patient did not have health insurance and chose to postpone an x-ray. Her toe healed well and no radiographs were ever taken. (Story by Richard P. Usatine, MD.)

INTRODUCTION

Subungual hematoma (blood under the fingernail or toenail) is a common injury. It is typically caused by a blow to the distal phalanx (e.g., smashing with a tool, crush in a door jamb, stubbing one's toe). The blow causes bleeding of the nail matrix or bed with resultant subungual hematoma formation. Patients usually present because of throbbing pain associated with blue-black discoloration under the nail plate. Subungual hematomas may be simple (i.e., the nail and nail fold are intact) or accompanied by significant injuries to the nail fold and digit.¹ The patient may not be aware of the precipitating trauma, because it may have been minor and/or chronic (e.g., rubbing in a tight shoe).

EPIDEMIOLOGY

Subungual hematoma is a common childhood and adult injury.

ETIOLOGY AND PATHOPHYSIOLOGY

- The injury causes bleeding of the nail matrix and nail bed, which results in subungual hematoma formation (**Figures 196-1 to 196-5**).
- In most cases it grows out with the nail plate, exhibiting a proximal border that reproduces the shape of the lunula. Occasionally, a hematoma does not migrate because of repeated daily trauma. An extended, nonmigrating hematoma should be considered suspicious. Nail plate punch biopsy will often reveal the dark streak to be a subungual hematoma as the color lifts off with nail plate (**Figure 196-5**).
- Potential complications of subungual hematoma include onycholysis, nail deformity (usually splitting as in **Figure 196-6**), and infection. Complications are more likely to occur when presentation is delayed or there is an underlying fracture.²

FIGURE 196-1 Acute subungual hematoma 1 day after dropping an iron on her toe. It was painful at rest and worse when walking. (Courtesy of Richard P. Usatine, MD.)

FIGURE 196-2 A paperclip was held in a hemostat and heated with a torch to pierce the patient's nail plate in order to relieve the subungual hematoma. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS**CLINICAL FEATURES**

- Patients complain of throbbing pain and blue-black discoloration under the nail as the hematoma progresses. Pain is relieved immediately in most patients with simple nail trephination (**Figure 196-3**).

IMAGING

- If the mechanism of injury and clinical picture suggest a possible distal phalanx or distal interphalangeal (DIP) fracture, obtain a radiograph. **SOR C**

DIFFERENTIAL DIAGNOSIS

- Nail bed nevus—Appears as a stable or slowly growing painless dark spot in the nail bed or matrix.
- Longitudinal melanonychia—Appears as painless pigmented bands that start in the matrix and extend the length of the nail (see Chapter 191, Pigmented Nail Disorders).
- Subungual melanoma—May start as a painless darkly pigmented band in the matrix and extend the length of the nail. It may be associated with pigment deposition in the proximal nail fold (Hutchinson sign) (see Chapter 191, Pigmented Nail Disorders).
- Splinter hemorrhages—Appears as reddish streaks in the nail bed and are seen in psoriasis more commonly than endocarditis (see Chapter 195, Psoriatic Nails).
- The diagnosis of child abuse must be considered in cases of chronic or frequently recurrent subungual hematomas in children.³

MANAGEMENT**NONPHARMACOLOGIC**

- Subungual hematomas are treated with nail trephination, which removes the extravasated blood and relieves the pressure and resulting pain. Beyond 48 hours, most subungual hematomas have clotted and pain has decreased, so trephination is ineffective. **SOR C**

SURGERY

- Nail trephination is a painless procedure because there are no nerve endings in the nail plate that is perforated. The nail is perforated with a hot metal wire or steel paper clip (**Figures 196-2 to 196-4**), an electrocautery device, or by spinning a large-bore needle against the nail plate like a mechanical spade bit. This allows the collected blood to drain out (**Figures 196-3 and 196-4**). The hole must be large enough for continued drainage, which can continue for 24 to 36 hours. The puncture site should be kept covered with sterile gauze dressing while the wound drains, and the gauze should be changed daily.

MEDICATIONS

- The use of prophylactic antibiotics does not appear to improve outcomes in patients with subungual hematomas and intact nail folds.⁴ **SOR B**

FIGURE 196-3 The hot paper clip formed a nice hole in the nail plate and the blood drained out spontaneously. This relieved the pressure and gave the patient immediate pain relief. (Courtesy of Richard P. Usatine, MD.)

FIGURE 196-4 After the nail plate is pierced, the blood drains easily with a little pressure on the proximal nail fold. (Courtesy of Richard P. Usatine, MD.)

- Oral analgesia such as ibuprofen 10 mg/kg (maximum dose: 800 mg) every 6-8 hours may be used with more painful digits. **SOR C**

REFERRAL

- Some authors recommend removal of the nail with inspection instead of nail trephination when the hematoma involves more than 25% to 50% of the nail because of the increased likelihood of significant nail bed injury and fracture of the distal phalanx.^{5,6} **SOR C**
- When deeper injuries are involved, nail plate removal after a digital block allows for nail bed repair.⁷ **SOR C**

PROGNOSIS

The potential complications of a subungual hematoma include onycholysis (separation of the nail plate from the nail bed), nail deformity, nail loss, and infection. Complications are more likely to occur when care is delayed.

A retrospective analysis of 123 patients treated with simple trephination found that 85% of patients reported an excellent or very good outcome, 2% reported a poor outcome (nail splitting), and no correlation was found between outcome and size of the hematoma or the presence of fracture or infection.²

FOLLOW-UP

After trephination, instruct the patient to soak the affected digit in warm water several times per day for 2 days, and to keep the area dressed between soaks. Follow-up with any signs of reaccumulation of blood or infection.

PATIENT EDUCATION

- Potential complications of subungual hematoma and nail trephination should be discussed with the patient and/or the patient's parents or guardian.
- Inform the patient that residual discoloration usually slowly grows out with the nail.

SECTION 18 PIGMENTARY AND LIGHT-RELATED CONDITIONS

197 MELASMA

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A young Hispanic woman delivers a healthy baby boy. On the first postpartum day, she is sitting in the rocking chair after breastfeeding her son. Her doctor notes that she has melasma and asks her about it. She states that the hyperpigmented areas on her face have become darker during this pregnancy (**Figure 197-1**). She noted the dark spots started with her first pregnancy but they are worse this time. On physical examination, hyperpigmented patches are noted on the cheeks and upper lip (**Figure 197-2**). Although the patient hopes the pigment will fade, she does not want to treat the melasma at this time.

INTRODUCTION

Melasma is an acquired hyperpigmentary disorder characterized by light- to dark-brown macules and patches occurring in the sun-exposed areas of the face and neck. It is most commonly caused by pregnancy or the use of sex steroid hormones, such as oral contraceptive pills.

SYNONYMS

Chloasma, mask of pregnancy.

EPIDEMIOLOGY

- It is a relatively common disorder that affects sun-exposed areas of skin, most commonly the face. It is believed to affect up to 75% of pregnant women.¹
- It affects predominantly women (**Figures 197-1 to 197-3**), with men accounting for only 10% of all cases. It is particularly prevalent in women of Hispanic, East Asian, and Southeast Asian origin (skin types IV to VI) and who live in areas of intense UV radiation exposure.¹
- Melasma caused by pregnancy usually regresses within a year, but areas of hyperpigmentation may never completely resolve.² It may increase with each subsequent pregnancy becoming more obvious.

ETIOLOGY AND PATHOPHYSIOLOGY

The major etiologic factors include genetic influences, exposure to UV radiation, and sex hormones.

FIGURE 197-1 Melasma (chloasma) in the typical distribution in a woman that just gave birth to her second child. This is sometimes called the mask of pregnancy. (Courtesy of Richard P. Usatine, MD.)

- The precise cause of melasma has not been determined. Multiple factors have been implicated, including pregnancy, oral contraceptives, genetics, sun exposure, cosmetic use, thyroid dysfunction, and antiepileptic medications.^{3,4}
- Women with melasma not related to pregnancy or oral contraceptive use may have hormonal alterations that are consistent with mild ovarian dysfunction.
- Melasma in men (**Figure 197-4**) shares the same clinical features as in women, but it is not known if hormonal factors play a role.⁵

Other factors associated with melasma include certain cosmetic ingredients (oxidized linoleic acid, salicylate, citral, preservatives) and certain antiepileptic drug. Some medications or topical preparations in combination with sun exposure worsen melasma.¹

RISK FACTORS

A recent global survey of 324 women with melasma demonstrated that a combination of the known triggers, including pregnancy, hormonal birth control, family history, and sun exposure, affects onset of melasma.⁶

DIAGNOSIS

CLINICAL FEATURES

The diagnosis of melasma is based upon clinical appearance. Affected patients exhibit splotchy areas of hyperpigmented macules on the face (**Figures 197-1 to 197-4**). In natural light, epidermal melasma appears light to dark brown, and the dermal pattern is blue or gray.

Melasma is divided into four clinical types:

1. Epidermal type—The hyperpigmentation is usually light brown, and Wood's light enhances the color contrast between hyperpigmented areas and normal skin. It is the most common type, and it best responds to the use of depigmenting agents.
2. Dermal type—The hyperpigmentation is ashen or bluish-gray and exhibits no accentuation of color contrast under Wood's light. Depigmenting agents are generally not effective for this type.
3. Mixed type—The hyperpigmentation is usually dark brown, and Wood's light enhances the color contrast in some areas but not in others.
4. Indeterminate type—Presents in patients with darker complexions (skin types V to VI) and cannot be categorized under Wood's light.¹

TYPICAL DISTRIBUTION

The lesion is found typically on sun-exposed areas. The three typical patterns of involvement are:

1. Centrofacial involving the cheeks, forehead, upper lip, nose, and chin.
2. Malar involving the cheeks and nose.
3. Mandibular involving the ramus of the mandible.

IMAGING

A Wood's light may be used to determine the type of melasma.¹ This does not change the choices of standard topical therapies.

FIGURE 197-2 Close-up of the melasma showing the hyperpigmented patches on cheeks and upper lip. (Courtesy of Richard P. Usatine, MD.)

FIGURE 197-3 A 39-year-old Hispanic woman with melasma seeking treatment. She is disturbed by this dark color on her face. Note the hyperpigmentation reaches the eyebrows but does not cover the upper lip. She has not been pregnant for years and is not taking hormonal contraceptives. (Courtesy of Richard P. Usatine, MD.)

BIOPSY

Histologically, there are an increased number of melanocytes, with the deposition of additional melanin and a background of solar elastosis. The two main histologic patterns are epidermal and dermal, depending on the skin layers involved.

DIFFERENTIAL DIAGNOSIS

- The facial rash of systemic lupus may be confused with melasma as they both can have a butterfly pattern. Melasma is hyperpigmented, whereas the lupus facial rash is usually inflammatory. An antinuclear antibody (ANA) test should be positive in systemic lupus erythematosus (SLE) and negative in melasma. False-positive antinuclear antibodies are usually low titer and the patient does not have other criteria for lupus (see Chapter 180, Lupus Erythematosus).
- Discoid lupus or cutaneous lupus can occur across the face but is usually seen with scarring. In this condition, the ANA is often negative (see Chapter 180, Lupus: Systemic and Cutaneous).
- Contact dermatitis will be inflamed in the acute stage but the postinflammatory hyperpigmentation could be confused with melasma (see Chapter 146, Contact Dermatitis).

MANAGEMENT

The treatment of melasma is challenging because treatment for melasma is generally unsatisfactory.⁷ Numerous less-than-adequate treatment options exist, including topical agents and chemical peels. Melasma treatment is started only when the patient is disturbed by the hyperpigmentation. All patients can benefit from sun protection and this is always a good place to start.

It is important to give the patient realistic treatment goals. The treatments that follow may lighten the hyperpigmentation but do not generally remove all the hyperpigmentation.

Side effects of all topical treatments include contact dermatitis, depigmentation of surrounding normal skin, and postinflammatory hyperpigmentation. Tretinoin should not be used during pregnancy. Discontinue oral contraceptives or other estrogen/progesterone agents, if possible.

MEDICATIONS

- Hydroquinone is the main bleaching agent used to treat melasma.⁷
SOR A It is available over the counter in 2% or 3% formulations (some including sunscreens). The prescription strength is 4% and is available with or without a sunscreen. Generic 4% hydroquinone comes in many sizes and formulations, so write the prescription to be flexible to avoid hassles for you and the patient. Although hydroquinone with sunscreen may be somewhat better than hydroquinone alone, a combination product has not been shown to be better than using these two topical agents together as two separate products. **SOR C**
- Hydroquinone is applied twice daily for up to 3 months with subsequent tapering to once daily. If the patient has not noticed a benefit by 3 months, the treatment should be stopped. **SOR C**

FIGURE 197-4 Melasma in a man. (Courtesy of Richard P. Usatine, MD.)

- Ochronosis—If the skin becomes darker with treatment, then the hydroquinone should be discontinued as there is a known side effect of hydroquinone, called ochronosis, that causes hyperpigmentation. Ochronosis only occurs in the treated area, but the hyperpigmentation can be permanent.⁸
- Hydroquinone can also cause a contact dermatitis, so it is a good idea for the patient to try it on a small area of skin before applying it to large areas of the face. Hydroquinone should be avoided on inflamed skin to avoid additional postinflammatory hyperpigmentation.
- Tretinoin 0.1% (Retin-A) cream is applied once daily at bedtime to lighten melasma. In two studies where tretinoin was compared to placebo, participants rated their melasma as significantly improved in one but not the other. In both studies, by other objective measures, tretinoin treatment significantly reduced the severity of melasma.⁷ **SOR A**
- Combining tretinoin and hydroquinone is believed to potentiate their effects. **SOR C**
- There is a triple combination cream (Tri-Luma) containing 4% hydroquinone, retinoic acid, and fluocinolone (corticosteroid). It is used once daily before bed for a duration of 8 weeks. Studies show that it has a superior efficacy than hydroquinone monotherapy for melasma.^{9,10} **SOR A** However, the side effect of skin irritation is very common and it is not recommended for long-term use.^{9,10} Triple-combination cream was significantly more effective at lightening melasma than hydroquinone alone (relative risk [RR] 1.58) or when compared to the dual combinations of tretinoin and hydroquinone (RR 2.75).⁷ **SOR A**
- Note that Tri-Luma is very expensive. Individual prescriptions for 4% hydroquinone, tretinoin cream, and a mild topical steroid cream can be given to keep the cost down. Desonide or 1% hydrocortisone are good options for the topical steroid. The steroid should not be used daily for longer than 8 weeks to avoid adverse effects.
- Azelaic acid (20%) was significantly more effective than 2% hydroquinone at lightening melasma but not better than 4% hydroquinone.⁷ **SOR A**
- Kojic acid formulations, and α -hydroxy acids (such as glycolic acid) also have been used in the treatment of melasma. **SOR C**
- The adverse events most commonly reported with topical agents were mild and transient such as skin irritation, itching, burning, and stinging.⁷ **SOR A**

SURGICAL PROCEDURES

- Chemical peels are one option for patients with moderate to severe melasma that has not responded to bleaching agents and are seeking further treatment. **SOR C**
- Dermabrasion treatment is one aggressive option.¹¹ **SOR C**
- Q-switched pigmentary lasers, intense pulsed light, and fractional laser treatments have some efficacy but can cause postinflammatory hyperpigmentation and relapses may occur so are usually not recommended.¹² **SOR C**

PREVENTION

Strict avoidance of sun exposure is important to prevent further hyperpigmentation. **SOR C** Broad-spectrum, high-protection-factor sunscreens (with UVB and UVA protection), such as titanium dioxide, micronized zinc oxide, Mexoryl, or avobenzene/Parsol, are essential.¹³

FOLLOW-UP

Follow-up is advisable when using bleaching agents. Long-term follow-up and reinforcement of limiting sun exposure can be accomplished during routine prevention visits.

PATIENT EDUCATION

- Provide the patient with realistic treatment goals.
- If the topical medications are irritating the skin, stop them and return for further evaluation.
- If after 3 months hydroquinone has not worked, stop it.
- If the skin is darkening rather than lightening, stop the medications and return for further evaluation.
- Bleaching agents are often not covered by insurance. The price of hydroquinone formulations can vary widely, so it helps to shop around when cost is a major concern.

198 VITILIGO AND HYPOPIGMENTATION

Karen A. Hughes, MD, FAAFP
Richard P. Usatine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

An 8-year-old Hispanic boy is brought in to the clinic by his mother, who is concerned about his pigment loss (**Figure 198-1**). He is starting to develop this vitiligo around the eyes, and his mother wants him to be treated. The child was started on a topical steroid, and the use of narrow band UVB was discussed if the steroid does not prove helpful. Realistic expectations of the treatments were provided to the mother and her son.

INTRODUCTION

Vitiligo is an acquired, progressive loss of pigmentation of the epidermis. The Vitiligo European Task Force defines nonsegmental vitiligo as “an acquired chronic pigmentation disorder characterized by white patches, often symmetrical, which usually increase in size with time, corresponding to a substantial loss of functioning epidermal and sometimes hair follicle melanocytes.”¹ Segmental vitiligo is defined similarly except for a unilateral distribution that may totally or partially match a dermatome; occasionally more than one segment is involved.¹

SYNONYMS

Vitiligo vulgaris.

EPIDEMIOLOGY

- Vitiligo occurs in approximately 0.5% to 2% of the worldwide population.^{2,3}
- It can occur at any age but typically develops between the ages of 10 and 30 years.²
- Vitiligo has equal rates in men and women.²
- It occurs in all races but is more prominent in those with darker skin.

ETIOLOGY AND PATHOPHYSIOLOGY

- Autoimmune disease with destruction of melanocytes.
- Genetic component in approximately 30% of cases. Toll-like receptor genes were found to be associated with vitiligo in a population of Turkish patients.⁴
- Can trigger or worsen with illness, emotional stress, and/or skin trauma (Koebner phenomenon).

FIGURE 198-1 Vitiligo on the neck of an 8-year-old Hispanic boy. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

CLINICAL FEATURES

- Macular regions of depigmentation with scalloped, well-defined borders (**Figures 198-1 to 198-3**).
- Depigmented areas often coalesce over time to form larger areas (**Figures 198-4 and 198-5**).
- Depigmented areas are more susceptible to sunburn. Tanning of the normal surrounding skin makes the depigmented areas more obvious.
- There is no standardized method for assessing vitiligo; strategies include subjective clinical assessment, semiobjective assessment (e.g., Vitiligo Area Scoring Index [VASI] and point-counting methods), macroscopic morphologic assessment (e.g., visual, photographic in natural or UV light, computerized image analysis), micromorphologic assessment (e.g., confocal laser microscopy), and objective assessment (e.g., software-based image analysis, tristimulus colorimetry, spectrophotometry).⁵ Authors of a literature review concluded that the VASI, the rule of 9, and Wood's lamp were the best techniques for assessing the degree of pigmentary lesions and measuring the extent and progression of vitiligo.⁵
- Conditions associated with vitiligo include thyroid disease and the presence of thyroid antibodies,^{6,7} congenital nevi (in one study, 6.2% vs. 2.8% in those without vitiligo),⁴ and halo nevi,¹ and possibly primary open-angle glaucoma (57% of patients in one case series).⁸

TYPICAL DISTRIBUTION

- Widespread, but generally seen first on the face, hands, arms, and genitalia (**Figure 198-6**).
- Depigmentation around body openings such as eyes, mouth, umbilicus, and anus is common (**Figure 198-7**). When the eyelashes are involved it is called *leukotrichia*.
- Vitiligo can be unilateral or bilateral; in one study, patients with unilateral vitiligo were younger and had an earlier age at onset while those with bilateral vitiligo were more likely to have light skin types and more commonly had associated autoimmune disease.⁹

LABORATORY AND IMAGING

- Evaluation for endocrine disorders such as hyper- or hypothyroidism (e.g., thyroid-stimulating hormone [TSH]) and diabetes mellitus (e.g., fasting blood sugar) is indicated, as vitiligo can be associated with these disorders.¹⁰
- Pernicious anemia and lupus erythematosus should be considered; obtain complete blood count (CBC) with indices and an antinuclear antibody (ANA).

BIOPSY

Not indicated unless the diagnosis is not clear and then a 4-mm punch biopsy will suffice.

DIFFERENTIAL DIAGNOSIS

- Pityriasis alba—Areas of decreased pigmentation with scaling and mild itching. Seen in young children and usually associated

FIGURE 198-2 Vitiligo on the hands of a Hispanic man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-3 Vitiligo on the hands, knees, and feet of a black woman. (Courtesy of Dan Stulberg, MD.)

FIGURE 198-4 Vitiligo covering more than 50% of this young Hispanic woman's body. The patient is starting topical monobenzone to attempt to bleach the unaffected skin so that she has one matching skin color. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-5 This previously dark-skinned woman has only a few spots of pigment remaining on her arm because of the extensive vitiligo. Her father has the same condition. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-6 Vitiligo on the penis of a 72-year-old man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-7 Vitiligo occurs commonly around the eye. **A.** Vitiligo with normal eyelashes. **B.** Vitiligo with leukotrichia. The loss of melanocytes has turned some of the eyelashes white. (Courtesy of Richard P. Usatine, MD.)

with eczema and improves with age (see Chapter 145, Atopic Dermatitis).

- Ash leaf spots—Lance-shaped macules of hypopigmentation, which remain stable in size and shape over time (**Figure 198-8**). Often the earliest sign of tuberous sclerosis. More concerning if there are 3 or more present in one child.
- Halo nevus—Hypopigmentation confined to areas surrounding pigmented nevi that typically appear in adolescents and young adults (see Chapter 162, Nevus).
- Idiopathic guttate hypomelanosis—Confetti-like 2- to 5-mm areas of depigmentation predominantly on sun-exposed areas (**Figure 198-9**).
- Nevus depigmentosus is usually present at birth or starts in early childhood. There is a decreased number of melanosomes within a normal number of melanocytes. It typically has a serrated or jagged edge. Its presence at birth or early in childhood helps to differentiate it from vitiligo (**Figure 198-10**).
- Nevus anemicus—A congenital hypopigmented macule or patch that is stable in relative size and distribution. It occurs as a result of localized hypersensitivity to catecholamines and not a decrease in melanocytes. On diascopy (pressure with a glass slide) the skin is indistinguishable from the surrounding skin. Its presence from birth helps distinguish it from vitiligo (**Figure 198-11**).
- Hypomelanosis of Ito is a rare syndrome with hypopigmented whorls of skin present at birth along the Blaschko lines of development. This pattern may be accompanied by congenital abnormalities involving the eyes, or neurologic or renal systems. Its presence at birth helps distinguish it from vitiligo (**Figure 198-12**).

MANAGEMENT

For assessing outcomes to treatment, the Vitiligo European Task Force suggests a system combining analysis of extent using percentage of body area involved (rule of 9), stage of disease based on cutaneous and hair pigmentation in **vitiligo** patches and staged 0 to 4 (with 0 representing normal pigment and 4 complete hair whitening) on the largest macule in each body region except hands and feet, and disease progression (spreading) assessed with Wood's lamp examination of the same largest macule in each body area.¹ An evaluation sheet can be found in the citation.¹

NONPHARMACOLOGIC

- Addressing the psychological distress that this disfiguring skin disorder causes should be a primary focus as the clinical course is unpredictable and, in some cases, little can be done to modify the condition itself.
- Management of inciting factors such as illness, stress, and skin trauma may be useful. **SOR C**

MEDICATIONS

Topical treatments used for vitiligo include corticosteroids, immunomodulators, vitamin D analogs, and psoralens; these treatments had mixed outcomes based on a systematic review, with topical steroids having the highest rate of adverse events.¹¹ **SOR B** Ineffective topical agents include melagenina, topical phenylalanine, topical L-DOPA (levodopa), coal tar, anacarcin forte oil, and minoxidil.¹²

FIGURE 198-8 A hypopigmented patch on the abdomen of an infant in a shape that suggests an ash leaf. The child is otherwise healthy with no seizures or developmental delay but should be monitored for signs of tuberous sclerosis. This may be nothing more than a nevus depigmentosus (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-9 Idiopathic guttate hypomelanosis on the arm. This is usually seen in sun-exposed areas especially of the arms and legs. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-10 Nevus depigmentosus, present since birth, on the chest of this 4-month-old infant. Note the serrated or jagged edge. Vitiligo is not present at birth. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-12 Hypomelanosis of Ito is a rare syndrome with hypopigmented whorls of skin present at birth along the Blaschko lines of development. It is typically unilateral and extends down an extremity such as an arm. Note the whorls on the chest and upper arm. (Courtesy of Richard P. Usatine, MD.)

FIGURE 198-11 Nevus anemicus on the back of this woman, which has been there since birth. This is a congenital hypersensitivity to localized catecholamines. On diascopy the skin was indistinguishable from the surrounding skin. The irregular broken-up outline is seen in nevus anemicus and nevus depigmentosus. (Courtesy of University of Texas Health Science Center Division of Dermatology.)

FIGURE 198-13 Vitiligo, which spared the area under a ring; the patient has spotty return of pigment on hand with narrowband UVB treatment. (Courtesy of Richard P. Usatine, MD.)

- In a retrospective study of 101 children with vitiligo treated with moderate- to high-potency topical corticosteroids 64% (45/70) had repigmentation of the lesions, 24% (17/70) showed no change, and 11% (8/70) were worse than at the initial presentation.¹³ **SOR B** Local steroid side effects were noted in 26% of patients at 81.7 ± 44 days of follow-up. Two children were given the diagnosis of steroid-induced adrenal suppression. Children with head and/or neck affected areas were eight times more likely to have an abnormal cortisol level compared with children who were affected in other body areas.¹³ Therefore, a trial of topical steroids may be useful for patients with localized vitiligo that does not predominantly involve the head and neck. **SOR C**
- Based on several reviews, topical corticosteroids (potent or very potent) are the preferred drugs for localized vitiligo (<20% of skin area)^{11,12}; a less-than-2-month trial is recommended.¹² **SOR B**
- Topical immunomodulators (tacrolimus, pimecrolimus) are an alternative for localized vitiligo and display comparable effectiveness with fewer side effects.¹⁴ **SOR B**
- In a small case series (N = 6), various antitumor necrosis factor α agents (infliximab, etanercept, and adalimumab given according to treatment regimens used for psoriasis) were not effective for widespread nonsegmental vitiligo.¹⁵

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Antioxidants may be useful adjunctive therapy.¹¹

OTHER TREATMENT

- Use sunscreen to prevent burns to the depigmented areas and further trauma to unaffected skin, and to minimize contrast between these areas.¹⁴ **SOR A**
- Bleaching the unaffected skin in patients with widespread depigmentation to reduce contrast with depigmented areas can improve cosmetic appearance.¹⁴ **SOR B** A monobenzyloether of hydroquinone 20% cream (Benoquin) is available by prescription to produce a permanent bleaching of the skin around the vitiligo. It is irreversible and makes the skin at higher risk for sunburn.

PROCEDURES

- Combination therapies are likely to be more effective than monotherapy, and most combinations include a form of phototherapy; narrow-band UVB appears to be the most effective with the fewest adverse effects (**Figure 198-13**).^{11,14} **SOR B** Psoralen UVA (PUVA) is the second-best choice. Authors of a Cochrane review concurred that majority of analyses showing statistically significant differences in treatment outcomes were from studies that assessed combination interventions including some form of light treatment.¹⁶
- Excimer laser is an alternative to UVB therapy, achieving good responses especially in localized vitiligo of the face, where the excimer laser may be superior to UVB therapy. By combining with topical immunomodulators, treatment response can be accelerated.¹⁴ **SOR B** In one prospective study of 14 patients, repigmentation rates for once, twice, and thrice weekly treatment approached each other (60%, 79%, and 82%, respectively) at 12 weeks.¹⁷ Although repigmentation occurred fastest with thrice weekly

treatment, the final repigmentation depends on the total number of treatments, not their frequency. **SOR B**

- No single therapy for vitiligo can be regarded as the most effective as the success of each treatment modality depends on the type and location of vitiligo. **SOR B**

PROGNOSIS

The course of vitiligo varies, but is usually progressive with periods of activity interspersed with times of inactivity.¹⁸ Spontaneous repigmentation can occur but is rare.

- The face and neck respond best to all therapeutic approaches, while the acral areas are least responsive.¹⁴ **SOR B**
- Vitiligo does not appear to be associated with adverse outcomes in pregnancy.¹⁹

FOLLOW-UP

- Counseling and emotional support are a mainstay of follow-up treatment.
- Trials of various combination therapies may be needed.

PATIENT EDUCATION

- Reassurance that this is a benign condition while acknowledging any psychological distress.
- Advise patients about the highly variable course of vitiligo with usually progressive periods of activity interspersed with times of inactivity.
- Inform patients about the multiple treatment options and possible need for prolonged or repeat treatment.

199 PHOTSENSITIVITY

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 50-year-old woman presented to the clinic with an abrupt onset of an intensely pruritic rash that extended over the dorsal aspect of both arms (**Figure 199-1**). The patient notes no new medicines and no recent exposures to any new chemicals. She acknowledged recent time spent outside in the sun. The plaques were photodistributed, with sparing of her watch area. A clinical diagnosis of polymorphous light eruption (PMLE) was made, and the patient was started on oral antihistamines and topical steroids. It was recommended that she minimize her sun exposure.

INTRODUCTION

Photosensitivity is an abnormal skin response to ultraviolet light that occurs on sun-exposed areas of the skin. There are three common types of photodermatitis:

- PMLE (**Figures 199-1** and **199-2**).
- Phototoxic eruptions (**Figures 199-3** to **199-7**).
- Photoallergic eruptions (**Figure 199-8**). **Table 199-1** compares key characteristics of phototoxic and photoallergic reactions.

UV light radiating from the sun may be categorized into UVA (wavelength 320 to 400 nm), UVB (290 to 320 nm), and UVC (200 to 290 nm). UVC is completely absorbed by the earth's ozone layer and thus does not play a role in photosensitivity. Photosensitivity may be induced by UVA, UVB, or visible light (400 to 760 nm). Longer wavelength light penetrates deeper into the skin. UVA penetrates through to the dermis, but UVB mainly penetrates and affects the epidermis.

Ultraviolet light has multiple effects on the skin. Notably, it causes DNA damage and has immunosuppressive effects on skin inflammatory cells increasing the risk of carcinogenesis. In patients with photosensitivity, it elicits an inflammatory response in the skin, leading to the development of a photodermatosis.

EPIDEMIOLOGY

- PMLE (**Figures 199-1** and **199-2**) may affect up to 10% of the population, with a predilection for females.¹ The prevalence increases in northern latitudes. Onset typically occurs within the first three decades of life, but may appear spontaneously at any age.
- The incidence of drug- and plant-induced phototoxic reactions in the United States is unknown. Phototoxic reactions are much more common than photoallergic reactions.

ETIOLOGY AND PATHOPHYSIOLOGY

PMLE is an idiopathic, delayed-type hypersensitivity reaction to UVA light and, to a lesser extent, UVB light (**Figures 199-1** and **199-2**). PMLE

FIGURE 199-1 Polymorphous light eruption noted over dorsum of left forearm. Note absence of the lesion where the patient had been wearing her watch. (From Wenner C, Lee A. A bright red pruritic rash on the forearms. *J Fam Pract.* 2007;56(8):627-629. Reproduced with permission from Frontline Medical Communications.)

FIGURE 199-3 Severe phototoxic drug reaction secondary to hydrochlorothiazide use. (Courtesy of Richard P. Usatine, MD.)

FIGURE 199-4 Phototoxic drug reaction secondary to ibuprofen. (Courtesy of Richard P. Usatine, MD.)

FIGURE 199-5 Phototoxic drug reaction secondary to treatment of vitiligo with oral psoralen and ultraviolet light (phytophotodermatitis). Note the bullae. (Courtesy of Richard P. Usatine, MD.)

FIGURE 199-6 Phytophotodermatitis in a woman, caused by lime juice and sun exposure on the beach. Note the hand print of her fiancé who had been squeezing limes into their tropical drinks. This contact occurred when they posed for a photograph. (From Darby-Stewart AL, Edwards FD, Perry KJ. Hyperpigmentation and vesicles after beach vacation. *Phytophotodermatitis*. *J Fam Pract*. 2006;55(12):1050-1053. Reproduced with permission from Frontline Medical Communications.)

FIGURE 199-7 Phytophotodermatitis visible on the arm, trunk, and leg caused by lime juice and sun exposure on the beach. Note the hyperpigmentation that occurs in conjunction with the erythema. (From Darby-Stewart AL, Edwards FD, Perry KJ. Hyperpigmentation and vesicles after beach vacation. *Phytophotodermatitis*. *J Fam Pract*. 2006;55(12):1050-1053. Reproduced with permission from Frontline Medical Communications.)

is the most common photoeruption encountered in clinical practice. The reaction will remit spontaneously with time and absence of sun exposure, but occasionally it will last as long as sun exposure occurs. PMLE usually begins in the first three decades of life and occurs more commonly in women. The rash develops within hours to days after exposure to sunlight and lasts for several days to a week.

There is a broad range of degrees of photosensitivity with PMLE. Extremely sensitive individuals can tolerate only minutes of exposure, whereas many people have a low sensitivity and require prolonged exposure to sunlight before developing a reaction. It is a recurrent condition that persists for many years in most patients.²

Phototoxic reactions are the most common drug-induced photoeruptions (Figures 199-3 to 199-7). They are caused by absorption of ultraviolet rays by the causative drug, which releases energy and damages cell membranes, or, in the case of psoralens, DNA. The drugs that most frequently cause phototoxic reactions are NSAIDs, quinolones, tetracyclines, amiodarone, and the phenothiazines³ (Table 199-2). Most of these drugs have at least one resonating double bond or an aromatic ring that can absorb radiant energy. Most compounds are activated by wavelengths within the UVA (320 to 400 nm) range, although some compounds have a peak absorption within the UVB or visible range.

Phytophotodermatitis are phototoxic reactions to psoralens, which are plant compounds found in limes, celery, figs, and certain drugs. They can cause dramatic inflammation and bullae where the psoralen comes into contact with the skin (Figures 199-5 to 199-7). The inflammation is frequently followed by hyperpigmentation.

Photoallergic eruptions are a lymphocyte-mediated reaction. Photoactivation of a drug or agent results in the development of a metabolite that can bind to proteins in the skin to form a complete antigen. The antigen is presented to lymphocytes by Langerhans cells, causing an inflammatory response and spongiotic dermatitis (eczema). The eruption is characterized by widespread eczema in the photodistribution areas such as the face, upper chest, arms, and back of hands (Figure 199-8). Most photoallergic reactions are caused by topical agents such as antibiotics and halogenated phenolic compounds added to soaps and fragrances.⁴ Systemic photoallergens such as the phenothiazines, chlorpromazine, sulfa products, and NSAIDs can produce photoallergic reactions, although most of their photosensitive reactions are phototoxic (Table 199-3).

RISK FACTORS

Unprotected exposure to sunlight and the use of drugs associated with phototoxic and photoallergic eruptions are the main risk factors.

DIAGNOSIS

CLINICAL FEATURES

Most cases of photodermatitis can be diagnosed on the basis of the patient's history. Be sure to review the patient's medications for possible sources.

- The appearance of the PMLE varies from person to person but is consistent in a given patient. Erythematous pruritic papules, sometimes with vesicles, are most common (Figures 199-1 and 199-2).

FIGURE 199-8 A photoallergic drug reaction characterized by widespread eczema in the photodistribution areas such as the face, upper chest, arms, and back of hands. A punch biopsy showed a spongiotic dermatitis (eczema). The exact photoallergen was not found. (Courtesy of Richard P. Usatine, MD.)

TABLE 199-1 Characteristics of Phototoxic and Photoallergic Reactions

Feature	Phototoxic Reaction	Photoallergic Reaction
Incidence	High	Low
Amount of agent required for photosensitivity	Large	Small
Onset of reaction after exposure	Minutes to hours	24 to 72 hours
More than 1 exposure to agent required	No	Yes
Examination findings	Exaggerated sunburn	Dermatitis
Immunologically mediated	No	Yes

TABLE 199-2 Common Medications That Cause Phototoxic Reactions

Class	Medication
Antibiotics	Tetracyclines Fluoroquinolones Sulfonamides Griseofulvin
NSAIDs	Ketoprofen Ibuprofen Naproxen
Diuretics	Furosemide Hydrochlorothiazide
Retinoids	Isotretinoin Acitretin
Photodynamic therapy prophotosensitizers	5-Aminolevulinic acid Methyl-5-aminolevulinic acid Verteporfin Photofrin
Neuroleptic drugs	Phenothiazines Thioxanthenes (chlorprothix- ene and thiothixene) Other drugs Itraconazole 5-Fluorouracil (5-FU) Amiodarone Diltiazem Quinidine Coal tar
Sunscreens	Paraaminobenzoic acid (PABA)

Lesions may coalesce to form plaques. The rash typically involves the V of the neck and the arms, legs, or both. The face, which is exposed to sunlight in both summer and winter, tends to be spared.

It tends to present in spring/summer, with the first significant UV exposure of the year. The rash typically develops 1 to 4 days after sun exposure.

- Phototoxic reaction occurs 2 to 6 hours after exposure to sunlight. The eruption typically appears as an exaggerated sunburn, with mild cases causing slight erythema and severe cases causing vesicles or bullae (**Figures 199-3 to 199-7**).
- Phytophotodermatitis reactions are asymmetric and localized to the area in which the plant psoralen was in contact with the skin. Accompanying hyperpigmentation is a good clue to a phytophotodermatitis reaction (**Figures 199-5 to 199-7**). Ask the patient if he or she had any contact with limes, celery, or figs. Squeezing lime juice into drinks is a particularly common cause of this reaction.
- Photoonycholysis phototoxicity reactions (sun-induced separation of the nail plate from the nail bed) have been reported with the use of tetracycline, psoralen, chloramphenicol, fluoroquinolones, oral contraceptives, quinine, and mercaptopurine. Photoonycholysis may be the only manifestation of phototoxicity in individuals with heavily pigmented skin.

TABLE 199-3 Common Substances That Cause Photoallergic Reactions

5-Fluorouracil (5-FU)
6-Methylcoumarin
Fragrances (6-methylcoumarin, musk, sandalwood oil)
NSAIDs (e.g., ketoprofen, diclofenac, piroxicam, celecoxib)
Sunscreens (benzophenones, cinnamates, dibenzoylmethanes)
Dapsone
Hormonal contraceptives
Hydrochlorothiazide
Antimicrobial agents (bithionol, chlorhexidine, hexachlorophene, fenticlor, Itraconazole)
Phenothiazines
Salicylates
Sulfonyleureas (glipizide and glyburide)
Quinidine

- Photoallergic eruptions are characterized by widespread eczema in the photodistribution areas such as the face, upper chest, arms, and back of hands. They resemble allergic contact dermatitis, but the distribution is mostly limited to sun-exposed areas of the body (**Figure 199-8**).

TYPICAL DISTRIBUTION

- All photodermatitis reactions occur in sun-exposed areas, such as the face, ears, dorsal forearms, and V-area of the neck and upper chest.

LABORATORY TESTING

- Laboratory studies that may be helpful include antinuclear antibody (ANA), anti-Ro (SSA), and anti-La (SSB) titers to rule out lupus and porphyrin studies to exclude porphyria.
- Phototesting can be used to determine a patient's minimal erythema dose to light exposure and help to define the inciting spectrum of a photodermatosis (UVA versus UVB versus visible light). Phototesting involves irradiating the skin with varying doses of UVA, UVB, and visible light through an opaque screen with multiple openings.⁵ Usually the test is performed on the back. The presence or absence of solar urticaria is recorded within the first hour and the minimal erythema dose is determined after 24 hours.
- Provocative phototesting involves irradiating normal-appearing previously affected skin with the suspected causative light, either by higher doses of UV light or by natural sunlight exposure.⁵ Provocative phototesting is primarily used for suspected PMLE.

- Photopatch testing is useful when a topical photoallergen is suspected. It is performed by placing two identical sets of potential photoallergens on the patient's back and covering them. After 24 hours, one set is removed and that site is irradiated with UVA. The site is covered again. Twenty-four hours later, both the irradiated and control test sites are assessed for reactions. A reaction to a specific photoallergen in the irradiated site, but not the control site, indicates a photoallergy. A similar reaction in both sites suggests a contact dermatitis.⁵

BIOPSY

- Punch biopsy of PMLE demonstrates extensive spongiosis and edema of the dermis with a deep lymphohistiocytic infiltrate. In acute phototoxic reactions, necrotic keratinocytes are observed.

DIFFERENTIAL DIAGNOSIS

- Systemic lupus erythematosus (SLE)—Sunlight can precipitate a lupus rash. Serum ANA is usually positive (see Chapter 180, Lupus: Systemic and Cutaneous).
- Porphyria cutanea tarda reactions can also be precipitated by sunlight. It tends to present with vesicles or bullae in sun-exposed areas such as the back of the hands. The bullae generally do not have any surrounding erythema, and urine for porphyrins should be positive (see Chapter 186, Other Bullous Disease).
- Dermatomyositis may cause an erythematous or violaceous eruption in sun-exposed areas. If these cutaneous findings precede the muscle weakness it can appear to be a photosensitivity reaction such as PMLE or a phototoxic drug reaction. Therefore, it is essential in the management and follow-up of patients with suspected PMLE or other photosensitivity to inquire about muscle weakness and to look for other signs of dermatomyositis on the hands and/or through laboratory tests for muscle enzyme elevations (see Chapter 181, Dermatomyositis). The dermatomyositis patient story in Chapter 181 is one in which the initial rash was thought to be a photosensitivity reaction to a new hydrochlorothiazide (HCTZ) prescription.
- Contact dermatitis appears the same as photoallergic dermatitis but is usually not limited to sun-exposed areas (see Chapter 146, Contact Dermatitis).

MANAGEMENT

NONPHARMACOLOGIC

- The management of PMLE is aimed mainly at prevention. Patients who have mild disease should adopt a program of sun avoidance (see "Prevention" below). Broad spectrum (UVA and UVB blocking) sunscreen with a minimum sun protection factor (SPF) of 30 should be used whenever out of doors (Table 199-4).⁶ However, the SPF value of a sunscreen describes its protection factor against sunburn, which is primarily caused by UVB. The SPF does not provide sufficient information on UVA protection.⁷ **SOR C** Patients must use sunscreen liberally and frequently (reapply every 2 hours and after swimming) as an insufficiently thick application may reduce its effectiveness.⁸ **SOR B**

TABLE 199-4 UV Blocking Characteristics of Sunscreens

Sunscreen	Blocks UVB	Blocks UVA
Aminobenzoic acid	X	
Avobenzene		X
Cinoxate	X	
Dioxybenzone	X	X

Drometrizole trisiloxane (Mexoryl XL)*	X	X
Methylene-bis-benzotriazolyl tetramethylbutylphenol (Tinosorb M)*	X	X
Bis-ethylhexyloxyphenol methoxyphenyl triazine (Tinosorb S)*		X

*Not available in the United States in 2012.

- Patients with severe PMLE can be desensitized in the spring with the use of phototherapy and maintained in the nonreactive state with weekly 1 hour unprotected exposure to sunlight. **SOR C** A course of psoralen and UVA radiation, or a course of narrow-band UVB, 3 times a week for 4 weeks provides protection.⁹ **SOR B** These treatments may induce a typical rash or erythema but otherwise have no major adverse effects.
- Avoid tobacco products since they may make PMLE worse.¹⁰ **SOR B**

MEDICATIONS

- Acute episodes of photodermatitis respond rapidly to topical and/or oral corticosteroids. Topical steroids should provide symptomatic relief and decrease the inflammation. For more severe reactions, a course of prednisone 30 mg daily for 5 to 7 days may be used.¹¹ **SOR B**

- Patients with acute drug-induced photodermatitis need to practice sun avoidance until well after the drug is discontinued. Topical and systemic corticosteroids may be used, especially with photoallergic reactions, but their efficacy is unproven. **SOR C**
- Nicotinamide was successful in 60% of 42 patients treated with 3 g/day orally for 2 weeks.¹² **SOR B**

PREVENTION

Sun protection is the primary preventative measure for patients with photosensitivity. Patients should avoid exposure to midday sun (between 10:00 AM and 3:00 PM). Protective clothing such as long sleeve shirts and broad rim hats should be worn while outdoors. Fabrics that are tightly woven, thick, and/or dark-colored are useful for protection.¹⁴ Clothing treated with broad-spectrum UV absorbers is also helpful. Window film that blocks UV and some visible light can be applied to cars or homes.¹⁵

Sunscreen is important for daily use for patients with photosensitivity. Sunscreens are divided into chemical (organic) and physical (inorganic) products. Physical sunscreens block both UV and some visible light (see **Table 199-4**). Products containing avobenzone or ecamsule offer improved protection against UVA.

Physical blocker (inorganic) sunscreens, such as titanium dioxide and zinc oxide, work by reflecting and scattering UV and visible light. Older formulations were opaque making them cosmetically less acceptable to patients. Newer nonopaque, micronized formulations of titanium and zinc oxide have been developed but are less capable of scattering visible light and the longer wavelengths of UVA.

Chemical sunscreens may cause allergic contact dermatitis or photoallergic reactions in some patients. These patients should use titanium dioxide or zinc oxide sunscreens for protection.

PROGNOSIS

- Some patients with PMLE experience less-severe reactions with successive years, but they may also worsen over time without appropriate treatment.
- The prognosis is excellent with patients when the offending agent is removed. Complete resolution of the photosensitivity may take weeks to months. Patients with persistent light reactivity beyond this have a poorer prognosis.

FOLLOW-UP

- Follow-up is needed if the photosensitivity persists.

PATIENT EDUCATION

- Patients with any type of photodermatitis should apply strong broad-spectrum sunscreens daily and use protective clothing (hats and shirts that cover the arms and V-neck). The sunscreen should be water resistant and applied to exposed areas before sun

exposure.¹⁶ Sunscreens should be reapplied every 2 hours if there is continued sun exposure. Some of the most effective sunscreens contain stabilized avobenzone, Mexoryl, and/or titanium dioxide or zinc oxide to block UVA and UVB.

- Tell your patients that if they develop an allergy to one sunscreen, they should find another with different ingredients.
- It is important to avoid sunlight during the midday whenever possible.
- Explain to patients that phototoxic reactions may cause hyperpigmentation, which can take weeks to months to resolve. There is no guarantee that all the hyperpigmentation will go away.
- Avoid repeated rubbing and scratching, which can lead to skin thickening and chronic lichenification. Use the topical medications prescribed to treat the itching and to avoid lichenification.

200 ERYTHEMA Ab IGNE

Amor Khachemoune, MD
Yoon-Soo Cindy Bae-Harboe, MD
Khashayar Sarabi, MD

PATIENT STORY

A 50-year-old woman presented to the office with bilateral erythematous lesions on the inner aspects of both of her lower extremities (**Figures 200-1** and **200-2**). The lesions started developing for the past 6 months. They became progressively more noticeable but stayed localized in the inner aspects of the lower extremities. She mentioned that she was using a hot-water bottle in the area involved to keep her warm at night when she was sleeping in bed. Although our working clinical diagnosis was erythema ab igne, clinical entities such as livedo reticularis, poikiloderma atrophicans vasculare, and acanthosis nigricans were also considered in the differential diagnosis. A skin biopsy was performed and confirmed the diagnosis of erythema ab igne. The patient was advised to abandon the hot-water bottle application to the skin. Over the course of 4 months her skin lesions started to clear with no further intervention.

INTRODUCTION

Erythema ab igne is a rare condition caused by chronic exposure to heat (below the threshold for a thermal burn) from external heat sources. More specifically, prolonged use of hot-water bottles, heating pads, electric blankets, car seat warmers as well as exposure to open fires and laptops placed on the users' thighs or propped legs have all been reported to cause erythema ab igne. Affected skin is characterized by reticular pink colored and hyperpigmented mottled patches. Patients may complain of associated pruritus, paresthesias, or may be asymptomatic. Treatment is limited and patients are instructed to avoid triggers.

SYNONYMS

Chronic moderate heat dermatitis, chronic radiant heat dermatitis, toasted skin syndrome, fire stains, hot-water bottle rash, laptop thigh.

EPIDEMIOLOGY

- Rare disease.
- Women, in particular those who are overweight, are affected more often than men.

ETIOLOGY AND PATHOPHYSIOLOGY

- The skin findings form as a result of multiple exposures to an intense source of heat.

FIGURE 200-1 Mottled or mesh-like pigmentary changes on the legs of a 50-year-old woman who slept with a hot-water bottle between her legs. (From El-Ghandour A, Selim A, Khachemoune A. Bilateral lesions on the legs. *J Fam Pract.* 2007;56(1):37-39. Reproduced with permission from Frontline Medical Communications.)

FIGURE 200-2 Close-up of legs in **Figure 200-1**. (From El-Ghandour A, Selim A, Khachemoune A. Bilateral lesions on the legs. *J Fam Pract.* 2007; 56(1):37-39. Reproduced with permission from Frontline Medical Communications.)

- Erythema ab igne has been noted for many years, and the sources of heat have changed over time. It used to be reported in women who stay for long periods of time in front of open fires, fireplaces, or furnaces to cook.¹⁻⁴ Most of the lesions were appearing on the medial side of the thigh and the lower leg in general.
- Currently, erythema ab igne is seen on different parts of the body, depending on what source of heat initiated the pathology, the angle of the heat radiation, the morphology of the skin, and the layers of clothing. Some of the modern-day examples are repeated application of hot-water bottles or heating pads to treat chronic pain, exposure to car heaters and furniture with internal heaters, the use of a laptop computer for long periods, and cooks and chefs who stand for long periods in the range of heat. Other causes include hot bricks, infrared lamps, and even microwave popcorn. Ultrasound physiotherapy was also reported as a cause of erythema ab igne. Recently, there was a reported case of frequent prolonged hot baths that caused the disease.⁵

RISK FACTORS

- Persistent exposure to heat.
- Occupations that involve chronic exposure to external heat sources (e.g., kitchen workers, silversmiths, jewelers, foundry workers).⁶

DIAGNOSIS

CLINICAL FEATURES

- Some patients have mild pruritus or burning sensation, but the majority of patients are asymptomatic.
- Skin lesions may not appear immediately after the exposure; it might take a period of 1 month to show up. Skin changes start as a reddish-brown pigmentation distributed as a mottled rash and are followed by skin atrophy (**Figures 200-1 to 200-3**).
- Telangiectasias with diffuse hyperpigmentation and subepidermal bullae may also develop.
- The rash appears mesh-like or net-like in the area exposed to the heat. The heat can be from fireplaces, heating pads, laptop computers, open fires, place heaters, and hot-water bottles (**Figures 200-1 to 200-7**).
- Malignant melanoma and various sarcomas are reported to arise in burn scars; however, those arising in areas of erythema ab igne have not been reported to date.

TYPICAL DISTRIBUTION

At the area of heat exposure, which is most often the legs or back (**Figure 200-4**).

LABORATORY STUDIES

None recommended.

SKIN BIOPSY

- In almost all cases, the diagnosis is based on the history and physical exam. Once the typical skin pattern is seen by the clinician, a few questions often will prompt the patient to recall the heat source.

FIGURE 200-3 Mottled hyperpigmentation and hint of blistering and crusting on the anterior leg area in a 23-year-old woman who spent significant time close to a fireplace. (Courtesy of Amor Khachemoune, MD.)

FIGURE 200-4 Erythema ab igne from the use of a heating pad in a woman with back pain. (Courtesy of Richard P. Usatine, MD.)

- In some rare cases, Merkel cell carcinoma and squamous cell carcinomas have developed in areas of erythema ab igne.⁷⁻⁹
- If clinically warranted, a biopsy is performed to exclude the possibility of malignant transformation.
- Histopathology shows epidermal atrophy, subepidermal separation, and haziness of the dermoepidermal junction. Dilation of capillaries and connective tissue disintegration, elastosis, hemosiderin deposition, melanocytosis, and abundance of inflammatory cells are all seen in the dermis. Some of these lesions might progress to actinic keratosis, which could be a precursor for squamous cell carcinoma of the skin.

DIFFERENTIAL DIAGNOSIS

Erythema ab igne should be differentiated from other diseases with skin changes that mimic its presentation.

LIVEDO RETICULARIS

- Reticular cyanotic cutaneous discoloration surrounding pale central areas caused by dilation of capillary blood vessels and stagnation of blood (**Figure 200-8**).
- Occurs mostly on the legs, arms, and trunk and appears to be a purplish mottling of the skin.
- More pronounced in cold weather.
- Idiopathic condition that may be associated with systemic diseases such as systemic lupus erythematosus (SLE).

POIKILODERMA ATROPHICANS VASCULARE

- A variant of mycosis fungoides (cutaneous T-cell lymphoma) (see Chapter 176, Mycosis Fungoides).
- Circumscribed violaceous erythema.
- Occurs mostly in posterior shoulders, back, buttocks, V-shaped area of anterior neck and chest.
- May be asymptomatic or mildly pruritic.
- May remain stable in size or gradually increase.
- Numerous atypical lymphocytes are observed around dermal blood vessels, and some epidermotropism is observed.

CUTIS MARMORATA

- Net-like reticulated pink patches seen early usually seen in premature newborns.
- Improves with rewarming of the skin, worsens with cooling.

CUTIS MARMORATA TELANGIECTASIA CONGENITA

- Net-like reticulated pink patches.
- Persists despite rewarming.
- Genodermatosis usually associated with underlying limb atrophy.

ACANTHOSIS NIGRICANS

- Velvety, light-brown-to-black markings usually on the neck, under the arms, or in the groin (see Chapter 220, Acanthosis Nigricans).
- Most often associated with being overweight.

FIGURE 200-5 Erythema ab igne on the legs of a woman who was straddling a place heater to keep warm during the winter. (Courtesy of Richard P. Usatine, MD.)

FIGURE 200-6 Close-up of leg in Figure 200-5 showing the net-like pattern on the medial leg. (Courtesy of Richard P. Usatine, MD.)

- More common in people with darker skin pigmentation.
- A disorder that may begin at any age and that may be inherited as a primary condition or associated with various underlying syndromes.
- Should be able to distinguish from erythema ab igne by the typical location around the neck and in the axilla.

MANAGEMENT

- The first goal of treatment is to identify the source of heat radiation to avoid further exposure. For mild lesions, no intervention is needed after the heat source is removed and the probability of full resolution is good.
- Topical retinoids, vitamin A derivatives, hydroquinone, and 5-fluorouracil have been prescribed to treat the abnormal skin pigmentation.¹⁰ Laser therapy has been used to even out the skin color.^{4,10} **SOR** 

PROGNOSIS

Prognosis is excellent for full resolution if the external heat source is removed or discontinued. However, the hyperpigmentation may remain and various treatments may not succeed in returning the skin to its normal pigmentation.

FOLLOW-UP

Follow-up visits are recommended if there are new changes to the skin after removing the source of heat. This is to diagnose and manage any malignant transformation.

PATIENT EDUCATION

Patients should avoid excessive and prolonged localized heat exposures (i.e., fireplaces, heating pads, laptop computers, and hot-water bottle applications).

There are many ways to shield the thighs from the heat of a laptop computer, from the use of pillows and blankets to the purchase of special devices manufactured for this purpose.

SECTION 19 VASCULAR

201 ACQUIRED VASCULAR SKIN LESIONS

Nathan Hitzeman, MD

PATIENT STORY

A 31-year-old woman presented with a new swelling on her lower lip. This was clinically recognized as a venous lake (**Figure 201-1**). The patient was bothered by its appearance and wanted it removed. She chose to have cryotherapy, which eradicated the venous lake. A closed-probe was used on a Cryogun for lesion compression while the freeze was applied using liquid nitrogen.

INTRODUCTION

Acquired vascular lesions are common skin findings. They appear “vascular,” or filled with blood. Acquired vascular lesions differ from congenital or hereditary vascular lesions in that they manifest months to years after birth.

EPIDEMIOLOGY

- Venous lakes are acquired vascular lesions of the face and ears.¹
- Cherry angiomas are common vascular malformations that occur in many adults after the age of 30 years (**Figure 201-2**). Cherry angiomas sometimes proliferate during pregnancy.¹
- Angiokeratomas, the most common form being angiokeratomas of the scrotum (Fordyce) or vulva, develop during adult years (**Figures 201-3 and 201-4**).¹
- Glomangiomas, also known as glomuvenous malformations or glomus tumors, are a type of rare venous malformation (**Figure 201-5**). Most patients with glomangiomas are of Northern European descent and have a family history of similar lesions.²
- Cutaneous angiosarcomas are malignant vascular tumors most commonly found on the head and neck areas of elderly white men. These are rare but deadly (**Figure 201-6**).³

ETIOLOGY AND PATHOPHYSIOLOGY

- Venous lakes are benign dilated vascular channels (**Figure 201-1**).
- Cherry angiomas are common benign vascular malformations (see **Figure 201-2**). They may increase during pregnancy. Several case reports have cited increased cherry angiomas after exposure to toxins.⁴
- Angiokeratomas are dilated superficial blood vessels that may be associated with increased venous pressure (such as in pregnant patients and patients with hemorrhoids)¹ (**Figures 201-3 and 201-4**).

FIGURE 201-1 Venous lake on the lip of a young woman. This was eradicated with cryotherapy. (Courtesy of Richard P. Usatine, MD.)

FIGURE 201-2 Large cherry angioma treated with shave excision and electrodesiccation of the base. (Courtesy of Richard P. Usatine, MD.)

- Glomangiomas are a distinct type of venous malformation caused by abnormal synthesis of the protein glomulin² (Figure 201-5). Lesions may be acquired or congenital.
- Cutaneous angiosarcomas are rare malignant vascular tumors thought to arise from vascular endothelium. Most arise spontaneously, but risk factors include radiation, chronic lymphedema, toxins, and certain familial syndromes. Elevation of several growth factors and cytokines has been associated with this malignancy (Figures 201-6 and 201-7).³

DIAGNOSIS

CLINICAL FEATURES

- Venous lakes are dark blue, slightly raised, and less than a centimeter in size. The lesions empty with firm compression. They may bleed with trauma.
- Cherry angiomas are deep red papules with a distinct cherry color.
- Angiokeratomas are multiple red-to-purple papules with associated hyperkeratosis. They may bleed easily with trauma.
- Glomangiomas are typically tender, blue-purple, partially compressible nodules with a cobblestone appearance.
- Cutaneous angiosarcomas present as progressively enlarging erythematous plaques.

TYPICAL DISTRIBUTION

- Venous lakes are found on the face and ears, particularly the vermilion border of the lips (Figure 201-1).
- Cherry angiomas favor the trunk but may occur on other parts of the body. Number of lesions ranges from several to hundreds.
- Angiokeratomas typically occur on the scrotum or vulva (Figures 201-3 and 201-4).
- Glomangiomas tend to occur on the extremities (Figure 201-5). Solitary glomangiomas often occur in the nail bed, especially in women. The number of lesions ranges from solitary to more than 100.⁵
- Cutaneous angiosarcomas often present on the head and neck areas (Figures 201-6 and 201-7).

LABORATORY STUDIES AND BIOPSY

- Diagnosis of venous lakes, cherry angiomas, and angiokeratomas is usually by history and physical examination alone. If these are removed surgically, it is still best to send them to pathology for confirmation of diagnosis. If the diagnosis is not clear clinically, a biopsy is warranted to rule out malignancy.
- Diascopy is a technique in which a microscope slide is used to compress a vascular lesion, allowing the clinician the ability to see the red or purple color of a vascular lesion blanch under pressure (Figure 201-8).
- Skin biopsy of glomangioma reveals distinct rows of glomus cells that surround distorted vascular channels.²
- Skin biopsy of cutaneous angiosarcoma reveals irregular vascular channels and atypical endothelial cells.³

DIFFERENTIAL DIAGNOSIS

- Melanoma lesions are irregularly shaped, usually pigmented lesions identified by the ABCDE guidelines discussed in Chapter 172, Melanoma. Unlike venous lakes, they do not change consistency with firm compression.

FIGURE 201-3 Angiokeratosis on the scrotum. Fordyce spots. (Courtesy of Lewis Rose, MD.)

FIGURE 201-4 Angiokeratosis on the vulva. This might be mistaken for a melanoma. (Courtesy of Eric Kraus, MD.)

FIGURE 201-5 Glomangiomas can be multiple or solitary. **A.** Large glomangiomas of the arm. (Courtesy of Jack Resneck, Sr., MD.) **B.** Solitary painful glomangioma on the leg of a young man. **C.** Small solitary painful glomangioma on the arm. These solitary glomangiomas were surgically resected. (Courtesy of Richard P. Usatine, MD.)

FIGURE 201-6 Angiosarcoma on the nose. A lesion like this requires an urgent biopsy. (Courtesy of Amor Khachemoune, MD.)

FIGURE 201-7 Angiosarcoma behind the ear and on the scalp of this 64-year-old man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 201-8 Diascopy in which a microscope slide is being used to compress a vascular lesion. The red color of this vascular hemangioma is blanching under pressure. (Courtesy of Richard P. Usatine, MD.)

- Angiokeratomas typically occur on the scrotum or vulva and have a distinct appearance. They may bleed easily with trauma.
- Glomangiomas have a cobblestone appearance and are tender. Unlike venous lakes, these anomalies do not empty with compression.
- Cutaneous angiosarcomas present as progressively enlarging erythematous plaques that may resemble bruising, cellulitis, rosacea, or erysipelas. The head-tilt maneuver has been described to aid in its detection.⁵ Having a patient lower his or her head below the level of the heart for 5 to 10 seconds will make the lesion more engorged and violaceous, thus confirming its vascular nature.

MANAGEMENT

OBSERVATION

- Patients can be reassured that venous lakes and most other acquired vascular lesions (with the exception of angiosarcomas) are benign lesions that develop during adult years.

SURGICAL

- Venous lakes, cherry angiomas, and other acquired vascular lesions can be eradicated by cryotherapy, electrodesiccation, sclerotherapy, intralesional bleomycin, intense pulsed light, and other laser modalities.^{1,6-10} **SOR C** Compared with intense pulsed light, the Nd:YAG (neodymium:yttrium-aluminum-garnet) laser system may yield superior results in the treatment of benign vascular lesions.¹¹ **SOR B** Hyperpigmentation is the most common complication of treatment.
- When using cryotherapy to treat vascular lesions, it helps to compress the lesion at the same time as it is frozen. This can be done with a Cryogun that has a solid probe for compression. **SOR C**
- Cherry angiomas can be treated with light electrodesiccation using an electrosurgical instrument on a low setting without anesthesia. The tip of the instrument is lightly applied to the apex of the lesion while electrical current is engaged. The desired end point is “charring” of the lesion with minimal surrounding tissue destruction. **SOR C**
- Larger cherry angiomas can be removed with a shave excision after injecting with lidocaine and epinephrine. The base can be treated with electrodesiccation if needed. **SOR C**
- Isolated glomangiomas may be surgically excised. Sclerotherapy may be useful for multiple lesions or large segmental lesions.¹² **SOR C**
- Cutaneous angiosarcoma is best treated with excision and wide surgical margins, as the primary tumor is often more extensive than appears on examination. Postoperative radiotherapy is then used at the primary site and regional lymphatics. If inoperable, palliative chemotherapy may be considered.³ **SOR C**

PATIENT EDUCATION

- When discussing any new lesions in sun-exposed areas, the clinician should take the opportunity to counsel patients on sunscreen use, avoiding direct sun during peak hours, and performing periodic skin examination.
- Patients should be fully informed about the risk of pigmentary changes and chance of recurrence if they elect for cosmetic removal of benign lesions. Avoidance of sunlight to the healing skin helps prevent a hyperpigmented scar.

FOLLOW-UP

None typically needed for benign lesions unless lesions recur or the patient is concerned about growth or changes to the lesions.

202 HEREDITARY AND CONGENITAL VASCULAR LESIONS

Nathan Hitzeman, MD

PATIENT STORY

A 56-year-old woman has had recurrent nosebleeds starting in childhood and has visible telangiectasias on her lips and tongue (**Figure 202-1**). In early adulthood, she was diagnosed with hereditary hemorrhagic telangiectasias (HHTs) (Osler-Weber-Rendu syndrome) and was found to have an arteriovenous malformation (AVM) in the lung requiring surgical resection. She has led a normal productive life and has two children who have not inherited this condition. Her mom had recurrent epistaxis, but never had an AVM.

INTRODUCTION

Hereditary and congenital vascular lesions range from the very common and benign stork bite (a variation of nevus flammeus) to rare but serious neurocutaneous syndromes. Childhood hemangiomas are covered separately in Chapter 109, Childhood Hemangiomas and Vascular Malformations.

EPIDEMIOLOGY

- HHT is an autosomal-dominant vascular disorder that affects one in several thousands of people (**Figure 202-1**). Certain populations in Europe and the United States have a higher prevalence of this disease.¹
- Nevus flammeus, or port-wine stains, are congenital vascular malformations that occur in 0.1% to 0.3% of infants as developmental anomalies. They persist into adulthood (**Figure 202-2**).² They may be associated with rare syndromes such as Klippel-Trenaunay and Sturge-Weber syndromes (**Figure 202-3**).
- Maffucci syndrome is a rare, nonhereditary condition characterized by hemangiomas and enchondromas involving the hands, feet, and long bones (**Figure 202-4**).³

ETIOLOGY AND PATHOPHYSIOLOGY

- HHT is associated with mutations in two genes: endoglin on chromosome 9 (HHT type 1) and activin receptor-like kinase-1 on chromosome 12 (HHT type 2). These genes are involved in vascular development and repair. With the mutations, arterioles become dilated and connect directly with venules without a capillary in between. Although manifestations are not present at birth, telangiectasias later develop on the skin, mucous membranes, and GI tract. In addition, AVMs often develop in the hepatic (up to 70% of patients), pulmonary (5% to 300%), and cerebral circulations

FIGURE 202-1 Hereditary hemorrhagic telangiectasias (Osler-Weber-Rendu syndrome) in a 56-year-old woman with recurrent nosebleeds and an arteriovenous malformation in the lung. (Courtesy of Richard P. Usatine, MD.)

FIGURE 202-2 Large nevus flammeus or port-wine stain over the trunk of a 55-year-old man since birth. (Courtesy of Casey Pollard, MD.)

(10% to 15%). Any of these lesions may become fragile and prone to bleeding.¹

- Port-wine stains are vascular ectasias or dilations thought to arise from a deficiency of sympathetic nervous innervation to the blood vessels. Dilated capillaries are present throughout the dermis layer of the skin.
- The bone and vascular lesions of Maffucci syndrome exist at birth or develop during childhood. Progression usually does not occur after completion of puberty.

DIAGNOSIS

CLINICAL FEATURES

- HHT is diagnosed if three of the following four Curaçao criteria are met (and suspected if two are present):
 1. Recurrent spontaneous nosebleeds (the presenting sign in more than 90% of patients, often during childhood);
 2. Mucocutaneous telangiectasia (typically develops in the third decade of life);
 3. Visceral involvement (lungs, brain, liver, and colon); and/or
 4. An affected first-degree relative.⁴
- Port-wine stains are irregular red-to-purple patches that start out smooth in infancy but may hypertrophy and develop a cobblestone texture with age. Nuchal port-wine stains are associated with alopecia areata.⁵ Klippel-Trenaunay syndrome is characterized by vascular malformations, venous varicosities, and soft-tissue hyperplasia. Patients with Sturge-Weber syndrome often have mental retardation, epilepsy, and eye problems.²
- The cobblestone deformity of the hands and feet in Maffucci syndrome is striking (**Figure 202-4**).

TYPICAL DISTRIBUTION

- HHT skin manifestations are few to numerous lesions on the tongue, lips, nasal mucosa, hands, and feet. However, any skin area or internal organ may be involved.
- Port-wine stains tend to affect the face and neck, although lesions may affect any body surface, including mucous membranes. Lesions of Klippel-Trenaunay syndrome tend to affect the lower extremities. A diagnosis of Sturge-Weber syndrome requires that a port-wine stain be present in the V1 trigeminal nerve distribution (aka ophthalmic branch). Patients with port-wine stains of the eyelids, bilateral trigeminal lesions (40% of patients with Sturge-Weber syndrome), and unilateral lesions involving all three divisions of the trigeminal nerve are particularly at risk of Sturge-Weber syndrome.²

LABORATORY STUDIES

- Check an annual complete blood count (CBC) and fecal occult blood in patients with HHT. They are at higher risk for iron-deficiency anemia because of recurrent nosebleeds and/or GI bleeding.
- Patients with benign-appearing port-wine stains, who lack other concerning symptoms, do not require laboratory testing (**Figure 202-5**).
- If Sturge-Weber syndrome is suspected, perform neuroimaging and glaucoma testing. Neuroimaging may reveal leptomeningeal malformations ipsilateral to the port-wine stain. An electroencephalogram

FIGURE 202-3 Port-wine stain, since birth, on the face of a man. Its distribution puts this patient at risk of Sturge-Weber syndrome. (Courtesy of Richard P. Usatine, MD.)

FIGURE 202-4 Hereditary hemangiomas, also called Maffucci syndrome. Note the cobblestone deformity of the foot. (Courtesy of Tran Shellenberger, MD.)

may reveal epilepsy. Elevated ocular pressures or visual field deficits may indicate glaucoma.

- Investigate the musculoskeletal system in persons with Maffucci syndrome. It is associated with various benign and malignant tumors of the bone and cartilage.³

DIFFERENTIAL DIAGNOSIS

- CREST (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) syndrome and scleroderma usually have multiple telangiectasias as in HHT. Other clinical features and laboratory tests such as the antinuclear antibody (ANA) and skin biopsies can differentiate between these rheumatologic conditions and HHT (see Chapter 182, Scleroderma and Morphea).
- Port-wine stains are often isolated findings but may indicate underlying Klippel-Trenaunay or Sturge-Weber syndrome. Further investigations may be necessary when these syndromes are suspected.
- Glomangiomas are blue-purple, partially compressible nodules with a cobblestone appearance. These glomuvenous malformations may appear similar to Maffucci syndrome but lack the rheumatologic component (see Chapter 201, Acquired Vascular Skin Lesions).
- Salmon patches, also known as “stork bites” or “angel kisses” (present in 40% to 70% of newborns), are a type of nevus flammeus or port-wine stain. Salmon patches are pinker than purple but are true congenital vascular malformations, not hemangiomas. The angel kisses over the face tend to fade with time but the stork bites on the nape of the neck often persist, as seen in **Figure 202-6** (see Chapter 109, Childhood Hemangiomas and Vascular Malformations).²

MANAGEMENT

- HHT has no cure. Oral iron supplementation and transfusions are sometimes needed as a result of bleeding. Few randomized controlled trials exist regarding treatment of bleeding. Estrogen/progesterone supplementation for heavily transfusion-dependent patients decreases recurrent bleeding.⁶ **SOR B** Case reports and uncontrolled studies regarding epistaxis treatment show some benefit from laser treatment, surgery, embolization, and topical therapy. **SOR C** Caution is not recommended because of complications from local tissue damage. Embolization procedures have been described for AVMs in the liver, lungs, and brain. Surgical resection of AVMs is sometimes done as a last resort when other measures fail.¹ In short, it is often best to do as little intervention as possible with HHT and, if any intervention is done, it is done with input from specialists experienced with this disease, as complications and recurrence are frequently encountered.
- Port-wine stains may be treated with makeup (see “Patient Resources” below). Pulsed-dye laser treatment is another option, albeit expensive. Laser treatments blanch most port-wine lesions to some degree, but complete resolution is difficult to achieve and the recurrence rate is high.⁷ **SOR C**

FIGURE 202-5 Nevus flammeus or port-wine stain, since birth, on the arm of a 34-year-old woman. She has had no problems with this benign capillary malformation. (Courtesy of Richard P. Usatine, MD.)

FIGURE 202-6 Stork bite (salmon patch) that has persisted since birth in this 72-year-old woman. This benign capillary malformation is more visible now, caused by the hair loss from chemotherapy. (Courtesy of Richard P. Usatine, MD.)

- Patients with Maffucci syndrome often require multiple orthopedic surgeries for their enchondromatous deformities and for cosmetic purposes.^{3,8}

PATIENT EDUCATION

- Whatever the vascular condition is, patients can benefit from reliable information about the current and future outlook for their condition.

FOLLOW-UP

- Patients with port-wine stains should have periodic skin checks, as other lesions may develop within the port-wine stains. Several case reports of basal cell cancers developing within port-wine stains have been described.⁹
- Patients with Sturge-Weber syndrome should have yearly eye examinations that include testing of intraocular pressures. **SOR** 
- Patients with Maffucci syndrome should be monitored closely for both skeletal and nonskeletal tumors, particularly of the brain and abdomen.⁸ **SOR** 

PATIENT RESOURCES

- HHT Foundation International. Excellent patient information on HHT can be found at the Foundation's website—<http://www.hht.org>.
- Covermark. Port-wine stains are often psychologically detrimental. Cosmetic makeup may be purchased through Covermark—<http://www.covermark.com>.
- Dermablend is another effective cosmetic product for port-wine stains—<http://www.dermablend.com>.

PROVIDER RESOURCES

SECTION 20 OTHER SKIN DISORDERS

203 CUTANEOUS DRUG REACTIONS

Richard P. Usatine, MD
Anna Allred, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 20-year-old college student was seen for fatigue and an upper respiratory infection and started on amoxicillin for a sore throat. Six days later she broke out with a red rash all over her body (**Figure 203-1**). She went to see her family physician back home with the rash and lymphadenopathy. A monospot was drawn and found to be positive. This morbilliform rash (like measles) is typical of an amoxicillin drug eruption in a person with mononucleosis. Amoxicillin was stopped, and diphenhydramine was used for the itching.

INTRODUCTION

Cutaneous drug reactions are skin manifestations of drug hypersensitivity. Drug hypersensitivity may be defined as symptoms or signs initiated by a drug exposure at a dose normally tolerated by nonhypersensitive persons.¹ Drug-induced adverse reactions are often classified as type A and type B. Type A reactions are common (80%) predictable side effects caused by a pharmacologic action of the drug, and type B reactions are uncommon (10% to 15%) and considered idiosyncratic, a result of individual predisposition (e.g., an enzyme defect).² Cutaneous drug reactions range from mild skin eruptions (e.g., exanthem, urticaria, and angioedema) to severe cutaneous drug reactions (SCARs), the latter category including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS) or drug-induced hypersensitivity syndrome (DIHS).³

SYNONYMS

Cutaneous adverse reactions, drug reactions, medication reactions, adverse effects to drugs, hypersensitivity reactions.

EPIDEMIOLOGY

- Cutaneous drug reactions are common complications of drug therapy occurring in 2% to 3% of hospitalized patients.⁴
- One study found that 45% of all adverse drug reactions were manifested in the skin.⁴

FIGURE 203-1 Amoxicillin rash in a young woman with mononucleosis. This is a morbilliform eruption. (Courtesy of Richard P. Usatine, MD.)

FIGURE 203-2 Maculopapular drug eruption in a 5-year-old boy with an upper respiratory infection started on amoxicillin for a questionable otitis media. Four days later he broke out with a red rash all over his face and body. This morbilliform rash (like measles) is typical of an amoxicillin drug eruption. (Courtesy of Robert Tunks, MD.)

- Approximately 1 in 6 adverse drug reactions represents drug hypersensitivity, and are allergic or non-immune-mediated (pseudoallergic) reactions.²
- Maculopapular eruptions, also known as exanthematous drug eruptions, are the most frequent of all cutaneous drug reactions, representing 95% of skin reactions.⁵ They are often confused with viral exanthems. This occurs most commonly with β -lactams such as amoxicillin, but also with barbiturates, gentamicin, isoniazid, phenytoin, sulfonamides, thiazides, and trimethoprim-sulfamethoxazole (**Figures 203-1** and **203-2**).
- Urticarial drug reactions are the second most common skin eruptions, representing approximately 5% of cutaneous drug reactions.⁵ This reaction can result from any drug but commonly occurs with aspirin, penicillin, sulfa, angiotensin-converting enzyme (ACE) inhibitors, aminoglycosides, and blood products. Urticaria results from immunoglobulin (Ig) E reactions within minutes to hours of drug administration (**Figures 203-3** and **203-4**).
- Drug-induced hyperpigmentation occurs with antiarrhythmics (amiodarone), antibiotics (minocycline), NSAIDs, and chemotherapy agents (Adriamycin) (**Figure 203-5**).
- Warfarin-induced skin necrosis (WISN) is a rare but serious side effect predominantly seen in obese women and presents between days 3 and 6 of warfarin treatment. WISN is more common in those with thrombophilic abnormalities, given large loading doses (**Figure 203-6**).
- Fixed drug eruptions (FDEs) can occur with many medications, including phenolphthalein, doxycycline, ibuprofen, sulfonamide antibiotics, and barbiturates. FDEs are more commonly observed in men (**Figures 203-7** to **203-13**).
- Erythema multiforme (EM) and SJS can occur secondary to drug reactions (**Figures 203-14** to **203-16**). Incidence of SJS is estimated at 1.2 per 6 million people.³
- DRESS is also a severe adverse drug-induced reaction characterized by eosinophilia with liver involvement, fever, and lymphadenopathy. In a case series (N = 172), 44 drugs were associated with DRESS.⁶ Also called DIHS, this syndrome is estimated to occur in 1 per 1000 to 1 per 10,000 exposures to antiepileptic drugs.⁷
- **Tables 203-1** and **203-2** list the most common medications associated with allergic cutaneous drug reactions and the rates of reactions found.⁸
- **Table 203-3** lists the frequency of various classes of drugs associated with an eruption (in cases with <4 suspected drugs) based on a 5-year study.⁹

ETIOLOGY AND PATHOPHYSIOLOGY

- Two mechanisms are responsible for cutaneous drug reactions— Immunologic, including all four types of hypersensitivity reactions, and, more commonly, nonimmunologic (pseudoallergic). Although the precise mechanism of immune stimulation is unknown, it may be triggered by drug-protein (hapten-carrier) complexes or through direct interaction with immune receptors (p-i concept).² The mechanism for pseudoallergic reactions is pathogenetically poorly defined.²

TABLE 203-1 Allergic Cutaneous Reactions to Drugs Received by at Least 1000 Patients (Boston Collaborative Drug Surveillance Program)

Drug	Reactions, No.	Recipients, No.	Rate, %	95% Confidence Interval
Amoxicillin	63	1225	5.1	3.9 to 6.4
Ampicillin	215	4763	4.5	3.9 to 5.1
Cotrimoxazole (trimethoprim-sulfamethoxazole)	46	1235	3.7	2.7 to 4.8
Semisynthetic penicillins	41	1436	2.9	2.0 to 3.7
Red blood cells	67	3386	2.0	1.5 to 2.4
Penicillin G	68	4204	1.6	1.2 to 2.0
Cephalosporins	27	1781	1.5	0.9 to 2.1
Gentamicin	13	1277	1.0	0.5 to 1.6

- Hypersensitivity to NSAIDs is a nonimmunologic reaction that can be immediate (within hours after exposure) or delayed (more than 24 hours after administration).¹
- WISN develops during the hypercoagulable state as a result of a more rapid fall in concentration of protein C compared to the other vitamin-K–dependent procoagulant factors. Thrombophilic abnormalities such as familial or acquired deficiency of protein C or S and antiphospholipid antibodies have been implicated in WISN (**Figure 203-6**).
- SJS/TEN is most commonly associated with penicillins and sulfonamide antibiotics but can also occur with anticonvulsants, NSAIDs, allopurinol, and corticosteroids. It is hypothesized that a specific human leukocyte antigen (HLA)-B molecule may present the drug or its metabolites to naïve CD8 cells resulting in clonal expansion of CD8 cytotoxic lymphocytes and induction of cytotoxic effector responses, resulting in apoptosis of keratinocytes.¹⁰ This pathway is not likely to be specific to SJS.

RISK FACTORS

- Drug hypersensitivity reactions increase with the drug dose, duration, route of administration (topical > subcutaneous > intramuscular > oral > intravenous),¹¹ immune activation of the individual, and immunogenetic predisposition; they are also more frequent in women.² Multiple drug therapy may also increase risk.¹¹
- Patients with the following HLAs are at higher risk for cutaneous drug reactions: HLA-B*1502 (confers a very high risk of carbamazepine-induced and other antiepileptic drug-induced SJS among people of southeastern Asian ethnicity); HLA-B*5801 (higher risk of allopurinol-induced severe cutaneous reactions); HLA-B*5701 (higher risk of abacavir [an antiretroviral drug] hypersensitivity reactions); HLA-B*3501, HLA-B*3505, HLA-B*1402, and HLA-Cw8 (nevirapine [an antiretroviral drug] sensitivity with rash; the latter two found in a Sardinian population); HLA-DRB1*0101 (nevirapine hypersensitivity rash with hepatitis).^{2,6}

TABLE 203-2 Allergic Cutaneous Reactions to Drugs Received by at Least 1000 Patients

Drug	Reactions, No.	Recipients, No.	Rate, %	95% Confidence Interval
Fluoroquinolones	16	1015	1.6	0.8 to 2.3
Amoxicillin	40	3233	1.2	0.9 to 1.6
Augmentin	12	1000	1.2	0.5 to 1.9
Penicillins	63	5914	1.1	0.8 to 1.3
Nitrofurantoin	7	1085	0.6	0.2 to 1.1
Tetracycline	23	4981	0.5	0.3 to 0.7
Macrolides	5	1435	0.3	0.0 to 0.7

- Prior drug reaction may result in a faster recurrence on reexposure.¹¹
- Concomitant illness, especially viral infections and autoimmune disorders.¹¹

DIAGNOSIS

CLINICAL FEATURES AND TYPICAL DISTRIBUTION (THE MOST COMMON AND IMPORTANT DRUG ERUPTIONS)

- *Maculopapular*—These eruptions, red macules with papules, can occur any time after drug therapy is initiated (often 7 to 10 days) and last 1 to 2 weeks. The reaction usually starts on the upper trunk or head and neck then spreads symmetrically downward to limbs. The eruptions may become confluent in a symmetric, generalized distribution that spares the face (**Figure 203-1**). Mild desquamation is normal as the exanthematous eruption resolves.
- *Urticaria and angioedema*—Urticaria reactions present as circumscribed areas of blanching-raised erythema and edema of the superficial dermis (**Figures 203-3 and 203-4**). They may occur on any skin area and are usually transient, migratory, and pruritic. Angioedema represents a deeper reaction, with swelling usually around the lips and eyes (see Chapter 150, Urticaria and Angioedema).
- *Hyperpigmentation*—Drug-induced hyperpigmentation presents in many ways. Amiodarone causes a dusky red coloration that turns blue-gray with time in photo-exposed areas. Minocycline can cause a blue-gray color in acne lesions, on the gingiva and on the teeth. Phenytoin (Dilantin) and other hydantoins may cause melasma-like brown pigmentation on the face. Bleomycin can cause a streaking hyperpigmentation on the trunk and extremities. Adriamycin, as evident in the case above, can cause hyperpigmentation of the face and nails (**Figure 203-5**).
- *NSAIDs*—The cutaneous reactions to NSAID-associated drug hypersensitivity are urticaria, angioedema, or anaphylaxis.¹ These reactions can be caused by a single NSAID or multiple NSAIDs. There is also an NSAID-exacerbated urticaria and angioedema that occurs in patients with chronic idiopathic urticaria.
- *Warfarin-induced skin necrosis (WISN)*—It presents with sudden onset of painful localized skin lesion that is initially erythematous and/or hemorrhagic that becomes bullous, culminating in gangrenous necrosis (**Figure 203-6**). It develops more often in obese women in their 50s in areas with high subcutaneous fat content such as breasts, thighs, and buttocks. This is different from a warfarin bleed secondary to too much anticoagulation (**Figure 203-14**).
- *Fixed drug eruption (FDE)*—Presents with single or multiple sharply demarcated circular, violaceous or hyperpigmented plaques that may include a central blister (**Figures 203-8 to 203-13 and 203-17**). The lesion(s) appear after drug exposure and reappear exactly at the same site each time the drug is taken. The site resolves, leaving an area of macular hyperpigmentation (**Figure 203-8**). Lesions can occur anywhere including the hands and feet, but are commonly found on the penis (**Figures 203-10 and 203-11**). The eruption presents 30 minutes to 8 hours after drug administration. Bullous

FIGURE 203-17 Bullous fixed drug eruption with a dusky color and an annular pink border on the ankle. (Courtesy of Richard P. Usatine, MD.)

fixed drug eruptions occur when the lesion blisters and erodes, followed by desquamation and crusting (**Figures 203-7, 203-11, and 203-17**).

- *EM*—It presents with typical target or raised edematous papules distributed acraly. Most importantly, there should be some type of epidermal disruption with bullae or erosions within the target lesions (**Figures 203-14 and 203-15**). Severe EM becomes and more widespread epidermal detachment may occur involving less than 10% of total body surface area (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- *SJS*—It presents with erythematous or pruritic macules, widespread blisters on the trunk and face, and erosions of one or more mucous membranes (**Figure 203-16**). Atypical target lesions or widespread erythema, particularly in the upper chest and back, are potential early signs of both SJS and TEN.¹¹ Burning or painful skin can be a sign of increased severity. Epidermal detachment occurs and involves less than 30% of total body surface area.
- *Toxic epidermal necrolysis (TEN)*—It is on the most severe side of the SJS spectrum. EM is diagnosed when less than 10% of the body surface area is involved, SJS/TEN when 10% to 30% is involved, and toxic epidermal necrolysis when more than 30% is involved.
- *Drug reaction with eosinophilia and systemic symptoms (DRESS) or drug-induced hypersensitivity syndrome (DIHS)*—Infiltrated, palpable lesions are potential heralds of this disorder.¹¹ Central facial edema and erythema (**Figure 203-18**) and a maculopapular rash are seen along with high fever, generalized lymphadenopathy, and arthralgias. *Drug reaction with eosinophilia and systemic symptoms* can also cause an erythroderma (**Figure 203-19**). Latency between starting a drug and first signs of drug reaction with eosinophilia and systemic symptoms can be up to 12 weeks.¹¹
- Drugs most commonly known to cause SJS and TEN are sulfonamide antibiotics, allopurinol, nonsteroidal antiinflammatory agents, amine antiepileptic drugs (phenytoin and carbamazepine), and lamotrigine (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).¹² Fifty percent of SJS/TEN cases have no identifiable cause.

LESS COMMON DRUG REACTIONS

- Acute generalized exanthematous pustulosis (AGEP)—is a type of drug eruption that results in clusters of small pustules along with erythematous skin (**Figure 203-20**). The patients are often febrile and the pustules are primarily non-follicular and sterile.
- Systemic drug-related intertriginous and flexural exanthema (SDRIFE)—is a type of drug eruption that causes erythema around the buttocks and genitalia along with intertriginous and flexural areas. If the pattern of erythema creates a red buttocks then it may also be called the baboon syndrome (**Figure 203-21**).

LABORATORY STUDIES

The diagnosis of drug eruptions is usually made based on history and physical examination.

- An FDE may be diagnosed by “provoking” the appearance of the lesion with an oral rechallenge with the suspected drug; however, this can be dangerous in bullous cases.

FIGURE 203-18 Drug reaction with eosinophilia and systemic symptoms on the face with facial swelling and erythema. This 40-year-old woman developed. *Drug reaction with eosinophilia and systemic symptoms* as a reaction to a new Dilantin prescription. (Courtesy of Robert T. Gilson, MD.)

FIGURE 203-19 Drug reaction with eosinophilia and systemic symptoms syndrome (drug reaction, eosinophilia, systemic symptoms). Erythroderma has persisted but the patient is feeling better after treatment and discharge from the hospital. (Courtesy of Richard P. Usatine, MD.)

- Severe reactions may need a complete blood count (CBC) with differential and comprehensive serum chemistry panel to look for systemic involvement and check hydration status.
- In more challenging cases, a skin biopsy may be helpful to confirm the diagnosis.
- Intradermal skin testing may be hazardous to patients, and patch tests are not useful.
- Skin biopsies are usually not required for diagnosis of WISN, but may aid in the diagnosis.
- Testing for thrombophilia (high platelet count) may also be done in WISN.
- Laboratory tests in patients with DRESS/DIHS may show atypical lymphocytes, eosinophilia, lymphocytopenia, and thrombocytopenia; liver abnormalities are often seen.

DIFFERENTIAL DIAGNOSIS

- Viral exanthems look just like generalized maculopapular drug eruptions. Sometimes when a patient is given an antibiotic for an upper respiratory infection, the rash that ensues may be the viral exanthem rather than a drug eruption. The best way to avoid this confusion is only to use antibiotics when the evidence for bacterial infection is sufficient to justify the risks of a drug reaction. (See Section 4: Viral [Chapters 123 to 134] for more information on viral exanthems.)
- Urticarial reactions present as transient migratory circumscribed areas of blanching-raised erythema and edema of the superficial dermis. Patients experience itching. Identifying urticaria is easy compared with finding the precipitating factors. If there is a temporal association with starting a new drug, it is best to stop the drug (in most cases) and see if the urticaria resolves. (See Chapter 150, Urticaria and Angioedema.)
- EM presents with sudden onset of rapidly progressive, symmetrical, and cutaneous lesions with centripetal spread. The patient may have a burning sensation in affected areas but usually has no pruritus. EM is most often caused by a reaction to an infection such as herpes simplex virus (HSV) or mycoplasma but may be caused by a drug reaction. Careful history and physical examination can help differentiate between the possible causes (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- SJS and TEN present with generalized cutaneous lesion with blisters, fever, malaise, arthralgias, headache, sore throat, nausea, vomiting, and diarrhea. The patient may also have difficulty in eating, drinking, or opening his or her mouth secondary to erosion of oral mucous membranes (**Figure 203-16**). Not all SJS or TEN is secondary to drug exposure, but it is the job of the clinician to investigate this cause and stop any suspicious medications. SJS and TEN can be life-threatening (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- DRESS/DIHS can be distinguished by involvement of organs other than skin including liver (hepatitis in 50% to 70%), kidney (nephritis in 10%), and, more rarely, pneumonitis, colitis, myocarditis,

FIGURE 203-20 Acute generalized exanthematous pustulosis caused by a drug eruption. The clusters of small pustules with erythematous skin are seen on the buttocks. In this case the pustules and erythema covered major portions of the back and buttocks. (Courtesy of Robert T. Gilson, MD.)

FIGURE 203-21 Systemic drug-related intertriginous and flexural exanthema. Because the pattern of erythema creates a red buttocks it may also be called the baboon syndrome. (Courtesy of Robert T. Gilson, MD.)

parotitis, meningitis, encephalitis, and pancreatitis; the pattern of organ involvement appears to depend on the drug trigger.^{7,13} Some of the sequelae from DRESS/DHIS are strongly related to herpes virus reactivation.⁷ A recurrence of symptoms at the third week is common. Diagnostic criteria have been proposed to include all of the following: maculopapular rash developing more than 3 weeks after drug exposure, prolonged clinical symptoms after drug discontinuation, fever ($>38^{\circ}\text{C}$ [100.4°F]), liver abnormalities or other organ involvement, leukocyte abnormalities (atypical lymphocytosis, leukocytosis, eosinophilia), lymphadenopathy, and human herpesvirus-6 reactivation.¹³

- Pityriasis rosea (PR) is a mysterious eruption of unknown etiology that could easily mimic a maculopapular drug eruption. Look and ask for the herald patch to help make the diagnosis of PR. In PR, look for the collarette scale and observe whether the eruption follows the skin lines (causing a Christmas tree pattern on the back). These features should help positively identify PR because there are no laboratory tests that are specific to PR or most drug eruptions (see Chapter 153, Pityriasis Rosea).
- Syphilis is the great imitator. Any generalized rash without a known etiology may be caused by secondary syphilis. A rapid plasma reagin (RPR) will always be positive in secondary syphilis and is easy to run (see Chapter 216, Syphilis).
- Bullous pemphigoid and pemphigus vulgaris can resemble a bullous drug eruption. Biopsies are the best way to diagnose these bullous diseases. Their clinical pictures are described in detail in Chapter 184, Bullous Pemphigoid, and Chapter 185, Pemphigus.
- Hematoma is a much more common complication of warfarin therapy and must be distinguished from WISN early to decrease permanent tissue damage; a high index of suspicion is needed and a very elevated international normalized ratio (INR) will confirm that bleeding is a result of overcoagulation (Figure 203-22).

FIGURE 203-22 Large bleed in the arm secondary to overcoagulation with Coumadin. The large hematoma was surgically evacuated to prevent neurovascular compromise to the arm. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

NONPHARMACOLOGIC

- Discontinue the offending medication for all types of drug reactions whenever possible. Older patients with drug eruptions may be on multiple medications and may be very ill; however, efforts should be made to discontinue all nonessential medications.⁵ **SOR C**
- Patients with maculopapular reactions may continue to be treated with the offending agent if it is essential for treating a serious underlying condition.⁵
- Maculopapular drug eruptions are not a precursor to severe reactions such as TEN.⁵
- Hyperpigmentation—Stop the drug if possible. In the case of Adriamycin-induced skin hyperpigmentation, the Adriamycin may be continued if it is the best chemotherapy for a life-threatening malignancy (Figure 203-5).
- Local wound care, debridement, and skin grafting may need to be performed to repair resultant disfigurement from necrosis.^{14,15}

MEDICATIONS

- Maculopapular- and urticarial/angioedema-type drug reactions are treated with antihistamines. If the angioedema is causing airway compromise, epinephrine (10 mcg/kg intramuscular) and other treatments will be necessary.^{5,13} **SOR C** Usually an H₁-blocker is started. In some cases of urticaria/angioedema, an H₂-blocker is added on for broader antihistamine effects (see Chapter 150, Urticaria and Angioedema).
- Diphenhydramine (Benadryl)—Adult dosing is 25 to 50 mg orally every 4 to 6 hours (nonprescription).
- Hydroxyzine (Atarax)—Adults receive 25 mg orally every 6 hours. Pediatric dose 0.5 to 1.0 mg/kg per day orally 4 times daily.⁵
- Loratadine (Claritin)—10 to 20 mg orally 1 time daily⁵ (nonprescription).
- Any H₂-blocker can be used by prescription or nonprescription.
- Topical steroids such as triamcinolone or desonide may be used for symptomatic relief of pruritus.⁵ **SOR C**
- Oral steroids have been used, but little benefit has been shown.⁵ **SOR C** These are used in DRESS/DHIS.¹³
- FDEs are treated by discontinuing the drug and applying topical corticosteroids to the affected area.⁴ **SOR C**

REFERRAL OR HOSPITALIZATION

Patients with WISN, SJS, TEN, and DRESS/DIHS are usually hospitalized.

- WISN treatment is generally supportive, including discontinuing the warfarin, admission to the hospital, and administration of vitamin K and fresh-frozen plasma.^{14,15}
- Many clinicians recommend resuming heparin therapy if needed for the patient's underlying pathology that prompted the use of initial anticoagulation therapy.^{14,15}
- SJS, TEN, DRESS/DIHS—Start with early diagnosis, rapid discontinuing of offending agent, intravenous fluid replacement, and placement in an intensive care unit (ICU) or burn unit (see Chapter 177, Erythema Multiforme, Steven-Johnson Syndrome, and Toxic Epidermal Necrolysis).^{4,5} Liver transplant has been used in patients with DRESS.¹³
- Most experts and studies now agree that systemic corticosteroids should not be used.⁴ **SOR B**
- Nutritional support, careful wound care, temperature control, and anticoagulation are recommended.⁴ **SOR C**
- Daily skin samples should be sent for bacterial Gram stain and culture to monitor for developing infection.⁴ **SOR C**

PREVENTION

- In the future, prevention may occur through screening for HLA associations and drug avoidance.¹
- Avoid reexposure to the drug.

- Screening for HLA-B*1502 is advised by the U.S. FDA and Health Canada for patients of southeastern Asian ethnicity before carbamazepine therapy.¹

PROGNOSIS

- Most cutaneous drug reactions resolve with discontinuation of the causative agent.
- Mortality, however, is high at 10% for SJS and DRESS/DHIS and 30% to 50% for TEN.^{5,16} In a case series of patients with possible or probably DRESS, case fatality rate was 5% (9/172).⁶
- Some studies show the occurrence of autoimmune diseases, including type 1 diabetes mellitus, autoimmune thyroid disease, sclerodermoid graft-versus-host disease (GVHD)-like lesions, and lupus erythematosus months to years after resolution of DIHS/DRESS.⁷ Because of the long symptom-free interval in some patients, this relationship is questioned.

FOLLOW-UP

- Follow-up is most important when the case is severe or the diagnosis is uncertain. Clear-cut mild drug reactions may not need scheduled follow-up.
- Continued surveillance for autoimmune disorders may be warranted in patients following DRESS/DHIS.

PATIENT EDUCATION

- Most patients with drug eruptions recover fully without any complications. The patient should be warned that even after the responsible medication is stopped the eruptions may clear slowly or even worsen at first; the patient should be advised that the reaction may not resolve for 1 to 2 weeks.
- The patient should also be counseled that mild desquamation is normal as the exanthematous eruption resolves. Confirming the diagnosis of an FDE, especially lesions presenting on the glans, with a drug challenge may allay the patient anxiety about the venereal origin of the disease.
- The family should be counseled as to the genetic predisposition of some drug-induced eruptions.
- The patient should be advised to enroll in a medic alert program and to wear a bracelet detailing the allergy.

204 KELOIDS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 64-year-old black woman presents to the office with itching keloids on her chest (**Figure 204-1**). The horizontal keloid started during childhood when she was scratched by a branch of a tree. The vertical keloid is the result of bypass surgery 1 year ago. The lower portion of this area could be called a hypertrophic scar as it does not advance beyond the borders of the original surgery. The patient was happy to receive intralesional steroids to decrease her symptoms. Intralesional triamcinolone did, in fact, decrease the itching and flatten the vertical keloid.

INTRODUCTION

Keloids are benign dermal fibroproliferative tumors that form in scar because of altered wound healing. They form as a result of overproduction of extracellular matrix and dermal fibroblasts that have a high mitotic rate.

SYNONYMS

Cheloid

EPIDEMIOLOGY

- Individuals with darker pigmentation are more likely to develop keloids. Sixteen percent of black persons reported having keloids in a random sampling.¹
- Men and women are generally affected equally except that keloids are more common in young adult women—probably secondary to a higher rate of piercing the ears (**Figure 204-2**).²
- Highest incidence is in individuals ages 10 to 20 years.^{2,3}

ETIOLOGY AND PATHOPHYSIOLOGY

- Keloids are dermal fibrotic lesions that are a variation of the normal wound-healing process in the spectrum of fibroproliferative disorders.
- Keloids are more likely to develop in areas of the body that are subjected to high skin tension such as over the sternum (**Figure 204-1**).
- These can occur even up to a year after the injury and will enlarge beyond the scar margin. Burns and other injuries can heal with a keloid in just one portion of the area injured (**Figure 204-3**).
- Wounds subjected to prolonged inflammation (acne cysts) are more likely to develop keloids.

FIGURE 204-1 Two keloids that cross the chest of a 64-year-old black woman. The horizontal keloid came from a scratch during childhood, and the vertical keloid is a result of open heart surgery. (Courtesy of Richard P. Usatine, MD.)

FIGURE 204-2 A keloid on the earlobe that started from piercing the ear. (Courtesy of Richard P. Usatine, MD.)

RISK FACTORS³

- Darker skin pigmentation (African, Hispanic, or Asian ethnicity).
- A family history of keloids.
- Wound healing by secondary intention.
- Wounds subjected to prolonged inflammation.
- Sites of repeated trauma.
- Pregnancy.
- Body piercings (**Figure 204-4**).

DIAGNOSIS

CLINICAL FEATURES

- Some keloids present with pruritic pain or a burning sensation around the scar.
- Initially manifest as erythematous lesions devoid of hair follicles or other glandular tissue.
- Papules to nodules to large tuberous lesions (**Figure 204-5**).
- Range in consistency from soft and doughy to rubbery and hard. Most often, the lesions are the color of normal skin but can become brownish red or bluish and then pale as they age.⁴
- May extend in a claw-like fashion far beyond any slight injury.
- Lesions on neck, ears, and abdomen tend to become pedunculated.

TYPICAL DISTRIBUTION

- Anterior chest, shoulders, flexor surfaces of extremities, anterior neck, earlobes, and wounds that cross skin tension lines.

LABORATORY TESTING

- Biopsy is rarely needed to make a diagnosis because the clinical appearance is usually distinctive and clear.

DIFFERENTIAL DIAGNOSIS

- Hypertrophic scars can appear similar to keloids but are confined to the site of original injury.
- Acne keloidalis nuchae is an inflammatory disorder around hair follicles of the posterior neck that results in keloidal scarring (**Figure 204-6**). Although the scarring is similar to keloids the location and pathophysiology are unique. This process can also cause alopecia (Chapter 114, Pseudofolliculitis and Acne Keloidalis Nuchae).
- Dermatofibromas are common button-like dermal nodules usually found on the legs or arms. They may umbilicate when the surrounding skin is pinched. These often have a hyperpigmented halo around them and are less elevated than keloids (Chapter 160, Dermatofibroma).
- Dermatofibrosarcoma protuberans is a malignant version of the dermatofibroma. It usually presents as an atrophic, scar-like lesion developing into an enlarging firm and irregular nodular mass. If this is suspected, a biopsy is needed (Chapter 160, Dermatofibroma).

FIGURE 204-3 A keloid on the arm of a Hispanic woman burned accidentally by a hot iron at the age of 1 year. Most of the burn scar is not a keloid. The keloid is at the distal edge where the skin is raised nodular and pink. She has pruritus in that area. (Courtesy of Richard P. Usatine, MD.)

FIGURE 204-4 This keloid formed at the site of a belly button piercing in this young woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 204-5 Many keloids in a woman who develops keloids with even the most minor skin injuries. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

- Patients frequently want keloids treated because of symptoms (pain and pruritus) and concerns about appearance.
- A 2006 systematic review of 396 studies and an accompanying metaanalysis of 36 articles concluded that no optimal evidence-based therapy exists and recommended choosing treatment based on cost and adverse effect profile.⁵

NONPHARMACOLOGIC

- Silicone gel sheeting as a treatment for hypertrophic and keloid scarring is supported by poor-quality trials susceptible to bias. There is only weak evidence of a benefit of silicone gel sheeting as prevention for abnormal scarring in high-risk individuals.^{6,7} **SOR B**

MEDICATIONS

- Intralesional steroid injections—Intralesional injection of triamcinolone acetonide (10 to 40 mg/mL) may decrease pruritus, as well as decreasing size and flattening of keloids (**Figure 204-7**). **SOR C** This may be repeated monthly as needed.^{5,8}
- Earlobe keloids can be treated with imiquimod 5% cream following tangential shave excision on both sides of the earlobe.^{9,10} **SOR B** Patients were instructed to administer imiquimod 5% cream to the excision sites the night of the surgery and daily for 6 to 8 weeks postsurgery. Imiquimod 5% cream only temporarily prevented the recurrence of presternal keloids after excision.¹¹ **SOR C**
- Intralesional verapamil 2.5 mg/mL, bleomycin 1.5 IU/mL, and interferon α 2b injections 1.5 million IU twice daily for 4 days are less-studied alternatives to corticosteroid treatment.³ **SOR C**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- No available evidence supports using nonprescription products such as Mederma and other creams, gels, and oils, to treat scars.⁷ Limited clinical trials have failed to demonstrate lasting improvement of established keloids and hypertrophic scars with onion extract topical gel (e.g., Mederma) or topical vitamin E.³ **SOR B**

SURGICAL

- Cryosurgery and intralesional triamcinolone have been used to treat smaller keloids (e.g., secondary to acne) with similar success to other therapies.^{3,12} **SOR B**
- Combined cryosurgery and intralesional triamcinolone—The lesion is initially frozen with liquid nitrogen spray and allowed to thaw. Then it is injected with triamcinolone acetate (10 to 40 mg/mL). **SOR C**
- Earlobe keloids can be surgically excised with a shave or excisional technique and then injected with triamcinolone acetate (10 to 40 mg/mL) after hemostasis is obtained. The triamcinolone injection can be repeated in 1 month to decrease the chance of recurrence.⁸ **SOR B**
- Keloids on the upper ear can be excised and the skin closed with sutures (**Figure 204-8**). **SOR C**
- Pulsed-dye laser treatment can be beneficial for keloids.¹³ Combination treatment with pulsed-dye laser plus intralesional therapy

FIGURE 204-6 Acne keloidalis nuchae on the posterior neck of this young African-American man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 204-7 Triamcinolone injected into this symptomatic keloid on the chest. Note how the keloid is blanching white, demonstrating that the steroid is properly injected into the body of the keloid. A Luer lock syringe is used to avoid the needle popping off during the injection under pressure and a 27-gauge needle is used to minimize patient discomfort. (Courtesy of Richard P. Usatine, MD.)

with corticosteroids and/or fluorouracil 50 mg/mL 2 to 3 times per week may be superior to either approach alone.¹⁴ **SOR C**

- Keloids can be treated with cryosurgery alone or in combination with intralesional steroids. In one, small, controlled study, 10 patients with keloids were treated with intralesional steroid and cryosurgery vs. intralesional steroid or cryosurgery alone.¹⁵ **SOR B** Patients were treated at least 3 times 4 weeks apart. Based upon keloid thickness, the keloids responded significantly better to combined cryosurgery and triamcinolone versus triamcinolone alone or cryotherapy alone. Pain intensity was significantly lowered with all treatment modalities. Pruritus was lowered only with the combined treatment and intralesional corticosteroid alone.¹⁵
- In another study, 20 patients with hypertrophic and keloidal scars received two 15-second cycles (total 30 seconds) of cryosurgery treatments once monthly for 12 months with intralesional injections of 10 to 40 mg/mL triamcinolone once monthly for 3 months.¹⁶ **SOR B** Topical application of silicone gel was added 3 times daily for 12 months. The control group included 10 patients who received treatment with silicone sheeting only. After 1 year there was improvement in all the parameters, especially in terms of symptoms, cosmetic appearance, and associated signs, compared to baseline and compared to the control group.¹⁶ **SOR B**
- Layton et al. reported that the intralesional injection of a steroid is helpful but cryotherapy is more effective (85% improvement in terms of flattening) for recent acne keloids located on the back.¹⁷ Treatment with intralesional triamcinolone was beneficial, but the response to cryosurgery was significantly better in early, vascular lesions.¹⁷ **SOR B**
- If the keloid is older and/or firmer, it may not respond to injection therapy as well as softer and newer lesions. It may help to pretreat the keloid with cryotherapy. It is not necessary to freeze a margin of normal tissue. After liquid nitrogen or another freezing modality is applied to the keloid, it is allowed to thaw and develop edema. This generally takes 1 to 2 minutes, which allows an easier introduction of intralesional steroids into the lesions. **SOR C**
- In one double-blind, clinical trial, 40 patients were randomized to receive intralesional triamcinolone (TAC) or a combination of TAC and 5-fluorouracil (5-FU).¹⁸ Both groups received injections at weekly intervals for 8 weeks and lesions were assessed for erythema, pruritus, pliability, height, length, and width. Both groups showed an acceptable improvement in nearly all parameters, but these were more significant in the TAC plus 5-FU group ($P < 0.05$ for all except pruritus and percentage of itch reduction). Good-to-excellent improvement was reported by 20% of the patients receiving TAC alone and by 55% of the patients in the group receiving TAC plus 5-FU.¹⁸ **SOR B**
- Earlobe keloids may be excised with a shave excision and injection of the base with steroid. It is hard to get much volume of steroid into the base of these keloids, so 40 mg/mL triamcinolone is preferred as the concentration for injection. **SOR C** Another option is to use radiofrequency electrosurgery technique with a pure cutting setting (and using steroid in the anesthetic).
- According to one article, simple excision of earlobe keloids can result in recurrence rates approaching 80%.¹⁹ A randomized, prospective trial comparing steroid injections versus radiation therapy

FIGURE 204-8 A. A large keloid has been present on the upper ear of this 14-year-old boy for more than 2 years, since he experienced trauma to this area. B. The keloid was excised in the office with local anesthetic and the defect sutured using 5-0 Prolene. The cosmetic result was excellent. (Courtesy of Richard P. Usatine, MD.)

found that 2 of 16 keloids (12.5%) recurred after surgery and radiation therapy, whereas 4 of 12 (33%) recurred after surgery and steroid injections. These results did not produce a statistically significant difference. No alteration of skin pigmentation, wound dehiscence, or chronic dermatitis was observed in any patient in either group.¹⁹ Although radiation therapy was considered easy to obtain in this study, it is reasonable to use steroid injections in office practice.

PREVENTION

- Avoiding trauma, including surgical trauma, whenever possible may decrease keloids in susceptible individuals.

PROGNOSIS

- A 2006 systematic review of 396 studies and an accompanying metaanalysis of 36 articles concluded that any treatment gave patients an overall 70% (95% confidence interval, 49% to 91%) chance of improvement.⁵

FOLLOW-UP

- Follow-up is based on the chosen treatment. Follow-up for intralesional steroid injections is usually in 1 month.

PATIENT EDUCATION

- Advise patients to avoid local skin trauma, for example, ear piercing, body piercing, and tattoos, and to control inflammatory acne.

205 GENODERMATOSES

Michael J. Babcock, MD
Richard P. Usatine, MD

PATIENT STORY

A 45-year-old black man presents with greasy scale over his face and large parts of his chest and back (**Figure 205-1**). A previous biopsy was diagnostic for Darier disease. His mother has the same condition. His sister has the full-blown disease. His brother has similar nail findings, but his skin is affected only behind the ears (**Figure 205-2**). The patient has suffered with this condition for his entire life and believes that he has been ostracized from normal social life because of his appearance and bad body odor. He suffers from depression and has used various substances to treat his pain. Topical steroids provide some help for the itching and scaling, but the patient is looking for a more effective treatment. The cost of oral retinoids is currently prohibitive, but an application has been put in for patient assistance to receive acitretin.

INTRODUCTION

There are more than 100 genetic syndromes with cutaneous manifestations that are referred to as genodermatoses. For example, there are disorders of pigmentation (albinism), cornification (the ichthyoses and Darier disease), vascularization (Sturge-Weber syndrome), connective tissue (Ehlers-Danlos syndrome), porphyrin metabolism, other errors of metabolism (phenylketonuria), the immune system (Wiskott-Aldrich syndrome), and DNA repair (ataxia-telangiectasia and xeroderma pigmentosa), to name a few. Some textbooks are dedicated to the topic of genodermatoses alone.¹ This chapter introduces the topic and illustrates a couple of genodermatoses. We have chosen two disorders of cornification as an introduction to the genodermatoses: Darier disease and X-linked ichthyosis.

EPIDEMIOLOGY

- Darier disease (keratosis follicularis)—1:30,000 to 1:100,000. Males and females are equally affected. Clinically becomes apparent near puberty.
- X-linked ichthyosis—1:2000 to 1:6000 males. Clinical lesions present typically during the first 1 to 2 months of life.

ETIOLOGY AND PATHOPHYSIOLOGY

- Darier disease—An abnormal calcium pump in the sarco-/endoplasmic reticulum, SERCA2, results from a gene mutation in the ATP2A2 gene. It is inherited in an autosomal-dominant fashion and results in abnormal epidermal differentiation.
- X-linked ichthyosis—A deletion of the steroid sulfatase gene results in keratinocyte retention by inhibiting degradation of the desmosome. It is inherited in an X-linked recessive manner.

FIGURE 205-1 Darier disease with greasy scales, hyperkeratotic and hyperpigmented papules and plaques in a seborrheic distribution involving the (A) face, neck, and chest, and (B) back, neck, ears, and scalp. Sunlight and heat make his disease worse. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

DARIER DISEASE

- Clinical features—Greasy, hyperkeratotic, yellowish-brown papules in a seborrheic distribution (**Figures 205-1 to 205-3**). The feet can be covered with hyperkeratotic plaques (**Figure 205-4**). The palms may have pits or keratotic papules, and the nails can have V-shaped nicking and alternating longitudinal red and white bands (**Figure 205-5**). The keratotic papules can be intensely malodorous such that it can interfere with normal social situations.
- Typical distribution—The clinical lesions involve skin in the seborrheic distribution (face, ears, scalp, upper chest, upper back, and groin) (**Figures 205-1 to 205-4**). The axilla and inframammary areas may be involved (**Figure 205-6**). In early, mild, or partially treated disease, only the skin behind the ears may be affected (**Figure 205-7**).² The nails are characteristically involved.
- Laboratories—Skin biopsy reveals the characteristic histopathology. A test for the ATP2A2 gene mutation can be performed.

X-LINKED ICHTHYOSIS

- Clinical features—Firm, adherent, fish-like brown scale noted early in the life of young affected boys whose mothers were carriers of the gene on their X chromosome (**Figures 205-8 and 205-9**). These boys have an increased incidence of cryptorchidism and are at an increased risk of testicular cancer, independent of the risk from cryptorchidism alone.^{2,3} Often they are delivered by cesarian section because a placental sulfatase deficiency results in failure of labor progression. These patients can have corneal opacities on the Descemet membrane of the posterior capsule, which does not affect their vision.
- Typical distribution—Most of the body is involved, except for the typical sparing of the flexures, face, palms, and soles. The antecubital fossae are notably spared (**Figure 205-9**). There is an accentuation noted on the neck, giving these patients a characteristic “dirty neck” appearance.
- Tight skin over the fingers can be as a manifestation of X-linked ichthyosis (**Figure 205-10**).
- Laboratories—Increased levels of serum cholesterol sulfate levels (steroid sulfatase hydrolyses cholesterol sulfate). Steroid sulfatase activity can also be measured directly.

DIFFERENTIAL DIAGNOSIS

DARIER DISEASE⁴

- Hailey-Hailey disease (aka benign familial pemphigus)—Another genodermatosis with crusted erosions and flaccid vesicles distributed in the intertriginous areas as opposed to the greasy keratotic papules in the seborrheic distribution (**Figure 205-11**). A 4-mm punch biopsy is adequate to make this diagnosis.
- Grover disease—This presents sporadically as many small, pruritic, erythematous to reddish-brown hyperkeratotic papules on the trunk of older adults. These typically result from conditions that cause sweating or occlusion (like lying in a hospital bed) (Chapter 117, Folliculitis).

FIGURE 205-2 Darier disease present in three siblings. The brother on the left and the sister have the full blown disease. The sister's face cleared after 3 months of acitretin. The brother on the right has similar nail findings, but his skin is affected only behind the ears. As a family physician, I take care of all three siblings and their mother who also has the disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-4 Thick hyperkeratotic plaque on the heel of the woman with Darier disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-5 A. Typical nail findings in Darier disease showing longitudinal bands and longitudinal splitting. B. V-shaped nick at the free margin of the fingernail—the most pathognomonic nail finding in Darier disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-3 A. Darier disease with greasy, hyperkeratotic scaling plaques on the face of the 44-year-old woman (sister of the patient in Figure 205-1) with Darier disease prior to her use of acitretin. She is wearing a wig to cover the alopecia and plaques on her scalp. B. Close-up of the hyperkeratotic scaling plaques on the forehead, scalp, and ears. Note the seborrheic distribution. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-6 Darier disease with axillary and inframammary involvement in this 64-year-old woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-8 Heavy fish scale of X-linked ichthyosis on the legs of two affected brothers. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-7 Darier disease with hyperkeratotic papules behind the ear of this middle-aged white man. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-9 X-linked ichthyosis in two brothers showing sparing of the antecubital fossae of the arms amidst the heavy scales. (Courtesy of Richard P. Usatine, MD.)

- Seborrheic dermatitis—Erythematous patches and thin plaques with yellow greasy scale on the scalp, central face, and chest. This is rarely as severe as Darier disease (Chapter 151, Seborrheic Dermatitis).

X-LINKED ICHTHYOSIS

- Ichthyosis vulgaris—A relatively common condition that is inherited in an autosomal dominant manner (approximately 1 in 250 people affected). It presents in childhood with a fine adherent scale in similar distribution to X-linked ichthyosis (**Figure 205-12**). These patients frequently have hyperlinear palms, keratosis pilaris, and atopic dermatitis, which are not commonly associated with X-linked ichthyosis.
- Acquired ichthyosis does not occur until adulthood. It is not inherited and may be associated with some systemic disease. The time of onset is the key to diagnosis. The legs are often most involved and the skin appears similar to fish-scales (**Figure 205-13**).
- Lamellar ichthyosis—A more severe and rare disorder that has a plate-like scale, which involves most of the body, including the face and flexures (**Figure 205-14**). These patients are typically born as a collodion baby (they have a thin translucent membrane that surrounds the baby at birth).
- Asteatotic eczema—Dry skin that has a “dried riverbed” or “cracked porcelain” appearance, which usually involves the lower extremities. There may be erythema and serous exudate associated with the cracks. It typically presents in the winter, improves during the rest of the year, and is also known as winter itch or eczema craquelé (Chapter 145, Atopic Dermatitis).
- Xerosis—Dry scaly skin most notably on legs without significant inflammation. This is very common compared with any ichthyosis.

MANAGEMENT

- Darier disease is so rare that there are no randomized controlled trials to guide treatment.
- The intense malodor that accompanies the disease, as well as the facial involvement, often adversely affects the patient’s quality of life; thus, treatment is often warranted. Mild-to-moderate disease can be treated by avoiding exacerbating factors (sunlight, heat, and occlusion) and with topical medications, **SOR C** but severe disease is best treated with oral retinoids. **SOR C**
- Topical retinoids (adapalene, tretinoin, or tazarotene) are effective in some patients, but their main limitation is irritation. Adapalene use may be effective in localized variants.⁵ **SOR C** All retinoids are contraindicated in pregnancy.
- Topical corticosteroids may be of some help. Lower-potency topical corticosteroids should be used on the face, groin, and axillae to minimize side effects in these areas. **SOR C**
- Topical calcineurin inhibitors (pimecrolimus and tacrolimus) may also be helpful as noted in some case reports.^{6,7} **SOR C** These do not have a risk of skin atrophy like steroids, but are generally more expensive and have a controversial black box warning.

FIGURE 205-10 This man has tight skin over the fingers as a manifestation of his X-linked ichthyosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-11 Hailey-Hailey disease, also known as benign familial pemphigus, on the back of a 54-year-old man. This genodermatosis has a similar appearance to Darier disease and also occurs in a seborrheic distribution. (Courtesy of Richard P. Usatine, MD.)

- Systemic retinoids (acitretin or isotretinoin) are the most potent treatment and treatment of choice for severe disease.⁸ **SOR C** They should only be prescribed by physicians who have experience with these medications. Patients on systemic retinoids require close monitoring and careful selection, as they are teratogenic (category X) and can cause hyperlipidemia, hypertriglyceridemia, mucous membrane dryness, alopecia, hepatotoxicity, and possible mood disturbances. Females must not get pregnant for at least 1 month after stopping isotretinoin and at least 3 years after stopping acitretin.
- Cyclosporine can be used for acute flares but should also only be prescribed by a physician who has experience with this medication. It should only be used temporarily and requires close follow-up for monitoring hypertension and nephrotoxicity. It is metabolized by the common cytochrome P450 3A4 system and has many medication interactions.
- Topical or oral antibiotics may be necessary for flares as they often are secondarily infected with bacteria. **SOR C**
- Laser, radiation, photodynamic, and gene therapy are newer treatment modalities that are being investigated.
- X-linked ichthyosis is rare and treatments are based on the clinical experience of experts rather than large studies.
- Frequent application of emollients, humectants, and keratinolytics are the mainstay of therapy. **SOR C** There are many effective non-prescription and prescription products that contain propylene glycol, urea, or lactic acid. Salicylic acid products should be used only on a limited body surface area, as systemic absorption has led to salicylate toxicity in some patients.
- Topical retinoids can be used, **SOR C** but systemic retinoids are rarely used.
- Refer to a urologist or ophthalmologist if testicular abnormality or corneal opacities are detected. **SOR C**
- Gene therapy has also been studied but has not yet become a viable treatment option.

FOLLOW-UP

- Darier disease—Follow-up is needed if patients are on oral retinoids to monitor patients' lipid panel and liver function tests approximately every 3 months. They should also be monitored for signs of secondary bacterial infection.
- X-linked ichthyosis—Monitoring for corneal opacities and for testicular cancer in men should be performed at follow-up visits.

PATIENT EDUCATION

DARIER DISEASE

- Avoid direct sunlight, heat, occlusion, and people acutely infected with herpes simplex virus (HSV) or varicella-zoster virus.
- Watch for signs of secondary cutaneous bacterial or viral infections.

X-LINKED ICHTHYOSIS

- Use daily moisturizers, especially in dry climates and in the winter.

FIGURE 205-12 Ichthyosis vulgaris starts in childhood and has a fine scale. (Courtesy of Richard P. Usatine, MD.)

FIGURE 205-13 Acquired ichthyosis starts in adulthood and is especially prominent on the legs. (Courtesy of Richard P. Usatine, MD.)

PATIENT RESOURCES

- There are patient advocacy groups for several genetic skin conditions. A quick search online can obtain their websites and contact information.
- The American Academy of Dermatology has a summer camp that is free of charge for children with skin conditions called Camp Discovery. Information can be found at <http://www.campdiscovery.org/>.

PROVIDER RESOURCES

- A helpful free online resource for the genodermatoses, or any genetic disease for that matter, is the Online Mendelian Inheritance of Man website at <http://www.omim.org>.
- For information on laboratories that perform rare genetic tests and clinics that perform prenatal diagnostic testing for certain conditions, see <http://www.genetests.org>.
- Skin Advocate is a free application for mobile devices that is provided by the Society of Investigative Dermatology. It lists contact information for various patient advocacy groups.

206 ERYTHEMA ANNULARE CENTRIFUGUM

Shehnaz Zaman Sarmast, MD
Richard P. Usatine, MD

PATIENT STORY

A 57-year-old farm worker presents with itchy red rings on his body that have come and gone for more than 13 years (**Figures 206-1** and **206-2**). The erythematous annular eruption was visible on his abdomen, legs, and arms. **Figure 206-2** shows the typical “trailing scale” of erythema annular centrifugum (EAC). A KOH preparation was negative for fungal elements and the patient was given the diagnosis of EAC. He recently began using paint thinner to “dry out the rash” and decrease the itching. Because topical steroids did not provide any relief for him in the past, we offered the option of using calcipotriol ointment. He chose to try the calcipotriol and stop using paint thinner.

INTRODUCTION

EAC is an uncommon inflammatory skin disease characterized by slowly migrating annular or configurate erythematous lesions.

SYNONYMS

Erythema gyratum perstans, erythema exudativum perstans, erythema marginatum perstans, erythema perstans, erythema figuratum perstans, erythema microgyratum perstans, and erythema simplex gyratum.

EPIDEMIOLOGY

- It may begin at any age (mean age of onset: 39.7 years), with no predilection for either sex.¹
- The mean duration of skin condition is 2.8 years but may last between 4 weeks and 34 years.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Unknown etiology and pathogenesis, but EAC has been associated with other medical conditions, such as fungal infections (in 72% of cases),¹ malignancy, and other systemic illness. Few case reports have reported the diagnosis of cancer 2 years after presentation of EAC.²
- Other infections identified as triggers for EAC include bacterial infections such as cystitis, appendicitis, and tuberculosis (TB); viral infections such as Epstein-Barr virus (EBV), molluscum contagiosum, and herpes zoster; and parasites, such as *Ascaris*.²

FIGURE 206-1 Erythema annulare centrifugum with large erythematous rings on the trunk and legs of a 57-year-old man. (Courtesy of Richard P. Usatine, MD. Reproduced with permission from Brand ME, Usatine RP. Persistent itchy pink rings. *J Fam Pract.* 2005;54(2):131-133. Reproduced with permission from Frontline Medical Communications.)

FIGURE 206-2 Erythema annulare centrifugum with conjoined rings on the thigh. Arrow pointing to “trailing scale,” which appears as a white scaling line within the erythematous border. (Courtesy of Richard P. Usatine, MD. Reproduced with permission from Brand ME, Usatine RP. Persistent itchy pink rings. *J Fam Pract.* 2005;54(2):131-133. Reproduced with permission from Frontline Medical Communications.)

- Certain drugs, such as chloroquine, hydroxychloroquine, estrogen, cimetidine, penicillin, salicylates, piroxicam, hydrochlorothiazide, amitriptyline, lenalidomide, finasteride, and etizolam, can also trigger EAC.²⁻⁶
- Systemic diseases involving the liver, dysproteinemias, autoimmune disorders, HIV, and pregnancy are associated with EAC by various case reports.^{2,7,8}
- Because injections of *Trichophyton*, *Candida*, tuberculin, and tumor extracts have been reported to induce EAC, a type IV hypersensitivity reaction is thought to be one possible mechanism for its development.⁸

DIAGNOSIS

CLINICAL FEATURES

- Large, scaly, erythematous plaques, which begin as papules and spread peripherally with a central clearing forming a “trailing” scale. The margins are indurated and may vary in width from 4 to 6 mm^{1,2} (Figures 206-1 to 206-4).
- Pruritus is common but not always present.²
- Slowly progressing but may enlarge up to 2 to 5 mm/day.²
- Evaluation of a skin biopsy specimen by light microscopy reveals parakeratosis and spongiosis within the epidermis and a tightly cuffed lymphohistiocytic perivascular infiltrate with focal extravasation of erythrocytes in the papillary dermis.¹⁰

TYPICAL DISTRIBUTION

- Lesions typically found in lower extremities, particularly the thighs, but also can be found on trunk and face.^{1,2}

LABORATORY STUDIES

- No specific laboratory tests are necessary to diagnose EAC, but laboratory tests may be obtained to rule out other common conditions. Consider a KOH prep to search for tinea corporis or cutaneous candidiasis. If the patient has been in an area with Lyme disease, consider *Borrelia* titers to rule out Lyme disease.^{2,7}

BIOPSY

- If the diagnosis is uncertain, a punch biopsy can be performed to look for the typical histology of EAC, and a periodic acid-Schiff (PAS) stain can be performed on the specimen to look for fungal elements. Other diseases on the differential diagnosis, such as psoriasis, cutaneous lupus, and sarcoidosis, can be diagnosed with a punch biopsy.

DIFFERENTIAL DIAGNOSIS

- Pityriasis rosea has erythematous patch distributed on trunk and lower extremities, but these patches have distinctive collarette border and typically have a “herald patch” that appears first. Classically, the patches have a “Christmas tree” pattern in the back and, unlike EAC, last only 6 to 8 weeks² (see Chapter 153, Pityriasis Rosea).

FIGURE 206-3 Erythema annulare centrifugum on the arm with trailing scale. Note the largest ring is not a complete circle. (Courtesy of Richard P. Usatine, MD.)

FIGURE 206-4 Erythema annulare centrifugum in the axilla of a 28-year-old man, which had repeatedly been mistaken for tinea corporis. The trailing scale is visible and a punch biopsy confirmed the diagnosis of erythema annulare centrifugum. (Courtesy of Richard P. Usatine, MD.)

- Tinea corporis (ringworm) presents with one or multiple areas of annular plaques caused by a dermatophyte fungal infection. Tinea corporis often produces red scaling rings that resemble EAC. However, the scale in tinea corporis tends to lead with the erythema inside the ring and the scale on the outside (**Figure 206-5**). This is the opposite of the trailing scale seen with EAC (**Figure 206-6**). KOH prep shows branched hyphae with septae. Tinea corporis responds to antifungal treatment.² **Figure 206-4** shows a case of EAC that was mistaken for tinea corporis by a number of physicians (see Chapter 138, Tinea Corporis).
- Psoriatic plaques can be annular but do not have the trailing scale that is characteristic of EAC. Psoriasis will respond to steroid therapy² (see Chapter 152, Psoriasis).
- Erythema migrans seen in Lyme disease is a large annular rash with central clearing. The red ring in erythema migrans is usually smooth without the scale seen in EAC. Patients usually have other signs of infection, positive antibodies, and may have a history of tick bite (see Chapter 218, Lyme Disease).
- Erythema gyratum repens, which is typically seen in association with malignancies, has concentric rings but trailing scale is noted.
- Cutaneous lupus could present with annular or papulosquamous plaques, with or without scales, on sun-exposed areas. Patients with lupus generally have other systemic symptoms and positive antinuclear antibodies⁹ (see Chapter 180, Lupus: Systemic and Cutaneous).
- Sarcoidosis may present with annular indurated papules and plaques, but they are more commonly found on the face. Patients may have other systemic manifestations of sarcoidosis. Sarcoidosis can effectively be treated with systemic corticosteroids¹¹ (see Chapter 175, Sarcoidosis).
- Mycosis fungoides, a type of cutaneous T cell lymphoma, can mimic EAC (Chapter 176, Cutaneous T Cell lymphoma).¹²

MANAGEMENT

- There is no proven treatment for EAC. Identifying and treating underlying medical conditions may help resolve the skin condition. Because EAC is seen in association with certain drugs, discontinuing the offending medication may resolve the problem.
- Topical corticosteroids have been traditionally used but there is little evidence to support their use. **SOR C**
- Case reports have reported benefits of using calcipotriol (Dovonex) daily for EAC.¹³ Another case report described a good outcome for a patient with EAC being treated with calcipotriol and narrow-band UVB phototherapy.¹⁴ Case reports have shown etanercept and metronidazole to be beneficial as well.^{15,16}

PROGNOSIS

The prognosis is excellent if there is no underlying disease and may resolve in an average of 11 months.¹⁷ It often resolves with effective treatment of any underlying disorder. If EAC is associated with pregnancy, it should resolve soon after delivery. If EAC is associated with a malignancy, the prognosis depends on that of the malignancy. Even if it resolves, EAC may recur repeatedly over many years.

FIGURE 206-5 Tinea corporis with leading scale (arrows). The white scale is on the outside of the ring and the erythema is on the inside. KOH prep was positive. (Courtesy of Richard P. Usatine, MD.)

FIGURE 206-6 Erythema annulare centrifugum on the buttocks and upper thigh showing trailing scale (arrows) inside the ring of erythema. KOH prep was negative. (Courtesy of Richard P. Usatine, MD.)

FOLLOW-UP

Follow-up depends on the type of treatment provided and patient's preferences.

PATIENT EDUCATION

- EAC is not contagious or malignant.
- Although the treatment might not work and the condition may recur, it is not dangerous and is confined to the skin only.

207 CORN AND CALLUS

Naohiro Shibuya, DPM, MS
Javier La Fontaine, DPM, MS

PATIENT STORY

A 52-year-old man with diabetes and mild sensory neuropathy presented with callus under “the ball of his foot” for at least 5 years. He recently noticed that the callus had grown thicker as he gained weight. Sharp debridement of the callus was performed, and an offloading pad was placed (**Figure 207-1**). The patient walked out of the office with less pain and discomfort. He was encouraged to use a pumice stone gently after bathing. One important goal is to avoid an ulcer (**Figure 207-2**), which occurred in another patient who did not get care for his callus.

INTRODUCTION

Corns and calluses are localized, thickened epidermis, resulting from mechanical pressure or shearing force applied repeatedly on the same area. A callus is located on the plantar surface and “grows in.” A corn is located on the dorsal surface or between digits and “grows out.” An ulcer forms if the lesion penetrates the subcutaneous layer. Initial management includes removing the pressure by changing shoes or using pads followed by sharp debridement if needed.

SYNONYMS

Hyperkeratotic lesion, keratosis, heloma durum (hard corn) or heloma molle (soft corn), tyloma (callus), clavi (corns).

EPIDEMIOLOGY

In one population-based study, 20% of men and 40% of women reported corns or calluses.¹

ETIOLOGY AND PATHOPHYSIOLOGY

Calluses and corns are caused by multiple factors:

- Mechanical pressure from abnormal biomechanics, underlying spur/exostosis, ill-fitting shoes, physiologic repetitive activities, and foot surgery or amputation that result in increased focal pressure at the distance site.²
- Shearing force from ill-fitting shoes, foot deformities (e.g., hammer toe and bunion), and physiologic repetitive activities.
- A foreign body in the foot or shoe.

FIGURE 207-1 Typical callus under the first metatarsal head. An offloading device can alleviate pain caused by the callus. (Courtesy of Naohiro Shibuya, DPM.)

FIGURE 207-2 Callus resulting in an underlying ulceration in a person with diabetes. A neglected callus in a high-risk patient can result in ulceration and infection. (Courtesy of Naohiro Shibuya, DPM.)

RISK FACTORS

- Bunion (**Figure 207-3**), hammer toe (**Figure 207-4**), flatfoot, high-arched (cavus) foot.
- Older age, fat pad atrophy.
- Smoking.
- Female gender.
- Genodermatoses with abnormal keratin formation (**Figure 207-5**).

DIAGNOSIS

The diagnosis of callus or corn formation is made clinically. Radiographic examination is helpful in identifying underlying bony pathology.

CLINICAL FEATURES

- Pain at site, especially with pressure.
- Prominent underlying bony structure or deformity of the foot (high arch, flatfoot, or bunion).
- Hard, slightly hyperpigmented or skin colored, well demarcated (**Figure 207-6**).
- Hard or soft nucleus.

TYPICAL DISTRIBUTION

- Callus (weight-bearing surface)—Under the metatarsal heads, plantar-medial hallux interphalangeal joint, distal tip of the digits, plantar heel, fifth metatarsal base, dorsolateral fifth digit, and nail folds.
- Corns (non-weight-bearing surface)—Dorsal proximal interphalangeal joints in patients with hammer-toe deformity (**Figure 207-4**), interdigital spaces, most commonly the fourth space (**Figure 207-7**).

IMAGING

- Dorsoplantar, lateral, and medial oblique weight-bearing plain radiographs, with a metal marker on the lesion may detect an exostosis (spur). Underlying deformities can also be assessed with plain radiographs.

DIFFERENTIAL DIAGNOSIS

Other painful hyperkeratotic lesions in the foot can be caused by the following:

- Plantar warts are common painful human papillomavirus (HPV) skin infections found on the sole of the foot. Black dots (thrombosed capillaries) and disruption of skin lines differentiate these warts from callus or corns (see Chapter 134, Planter Warts).
- Acrolentiginous melanoma can occur on the foot and become painful over time. These are usually pigmented with irregular borders and variations in color. If these are amelanotic they may be harder

FIGURE 207-3 Bunion resulting in callus on the side of the big toe and a corn between the first and second digit because of abnormal biomechanical pressure. (Courtesy of Richard P. Usatine, MD.)

FIGURE 207-4 Dorsal hard corn formed secondary to a hammer-toe deformity. (Courtesy of Naohiro Shibuya, DPM.)

to diagnose. Any unusual growth on the foot should be biopsied (see Chapter 172, Melanoma).

- Nonmelanoma skin cancers rarely occur on the foot and are more likely to be on the dorsum of the foot where there is more sun exposure. These cancers are hyperkeratotic and may ulcerate. If suspicious, a shave biopsy should be adequate for diagnosis (see Chapters 170, Basal Cell Carcinoma and 171, Squamous Cell Carcinoma).
- Porokeratosis is a deep, seeded callus that has been described as a “plugged sweat duct” and is not necessarily located in a weight-bearing area.
- Diseases with abnormal keratin production can cause painful and thick callus on the feet in the same areas such as the heels and under the metatarsal heads. **Figure 207-5** is an example of severely painful and hypertrophic callus on the heel of a patient with the genodermatosis of pachyonychia congenita.
- Surgical physiologic/hypertrophic scar can be easily identified by the surgical orientation of the incision and patient history.

MANAGEMENT

First, consider the following conservative measures:

- Suggest that the patient change shoes to something that puts less pressure on the area involved.
- Pad the foot to limit shearing force from shoes (**Figure 207-1**).
- Use interdigital spacers to relieve pressure (**Figure 207-8**).
- Incorporate offloading devices or “cutoffs” in custom-made orthoses to realign an underlying deformity to minimize abnormal biomechanics.
- Suggest the patient reduce activity level on the feet.
- Encourage the patient to stop smoking and offer assistance.

If conservative measures fail to work, consider these surgical options:

- Sharp debridement of the lesion provides instant temporary relief from pain and discomfort. Infiltration of a local anesthetic may be necessary before debridement of an extremely painful lesion, but most calluses and corns can be debrided without anesthesia. Perform sharp debridement with a #10 or #15 surgical blade. The #10 blade is especially good for large callus. Debride the lesion down to soft, nonkeratotic tissue and remove the hard nucleus (**Figure 207-9**).
- In a patient with recurring lesions, consider a surgical referral to a foot specialist to correct an underlying deformity or spur.
- Exostectomy of the prominent underlying bone can be done with a minimal incision technique.
- Consider prophylactic correction of the deformity and/or removal of exostosis in a high-risk patient (e.g., patients with diabetes who are immunocompromised and neuropathic) to reduce the risk of future ulceration and infection.
- Plastic procedures (e.g., excisional biopsy with primary closure or local flap) may be necessary in patients with a chronic lesion of idiopathic origin.

FIGURE 207-5 Pachyonychia congenita causes hard callus on the feet and other abnormal keratin papules seen on the legs in this young man. This genetic disease causes such painful thick calluses that it hurts to walk. (Courtesy of Richard P. Usatine, MD.)

FIGURE 207-6 Hard corn in a typical location on the dorsum of the fifth digit. (Courtesy of Richard P. Usatine, MD.)

FIGURE 207-7 Soft corn in the fourth interspace at the base of the fifth digit. (Courtesy of Richard P. Usatine, MD.)

PREVENTION

- Well-padded shoes and/or padded insoles can prevent hyperkeratotic lesion formation.
- Insoles made by Spenco or Doctor Scholl's can be an inexpensive start before purchasing customized orthotics.
- People with severe underlying deformity may benefit from customized orthotic and shoe management to relieve localized pressure in the foot.

PROGNOSIS

In healthy, younger patients, both conservative and surgical treatments have good prognosis. Severe peripherally neuropathic patients neglect repetitive painful stimuli, and they are prone to ulceration from untreated hyperkeratotic lesions. Surgical management by changing the biomechanics of the foot is often successful, but it can cause a “transfer lesion”—a new lesion developing distance from the original lesion.

FOLLOW-UP

- A healthy patient can be seen in an “as-needed” basis.
- A high-risk patient requires periodic follow-up and sharp debridement of the lesion are necessary to prevent development of a neurotrophic ulcer.
- If the patient develops an open lesion, obtain plain radiographs to rule out osteomyelitis and gas gangrene. An irregular, hyperpigmented, fast-growing lesion must be biopsied.

PATIENT EDUCATION

Conservative measures are effective in mild lesions. If conservative measures fail, surgical management is indicated to correct the underlying cause of the problem. Surgical correction can result in a “transferred lesion” by shifting the pressure point away from the original site.³ Tell patients with neuropathy and/or their caregivers to examine the patient's feet daily for potential ulceration. An overlying hyperkeratotic lesion can mask an underlying ulcer. Drainage, maceration, and malodor are signs of underlying ulceration and infection.

208 BUNION DEFORMITY

Naohiro Shibuya, DPM, MS
Javier La Fontaine, DPM, MS

PATIENT HISTORY

A healthy 34-year-old woman has had “bunion pain” for 5 years. Her custom-made orthoses alleviate 50% of her pain. On examination, she has severe lateral deviation of the hallux (**Figure 208-1**), a mildly dorsiflexed second digit, tenderness at the medial prominence, painless first metatarsophalangeal (MTP) range of motion, and a callus under the second metatarsal head. Radiographs (**Figure 208-2**) show medial angulation of the first metatarsal and lateral deviation of the hallux.

The patient was referred to podiatry for surgical correction of the bunion deformity. After surgery, she was placed in a short-leg cast for 6 weeks. She progressed to a regular shoe over the next month and was encouraged to use the custom-made orthoses for her flatfoot to prevent recurrence of the bunion.

INTRODUCTION

Bunion deformity is characterized by the presence of a medial prominence at the first MTP joint, caused by an abducted hallux and adducted first metatarsal. The deformity causes irritation in a tight shoe and pain in the MTP joint. Initial therapy can be conservative with correction of footwear and padding. Surgical procedures correct the misalignment, rather than shave the medial prominence.

SYNONYMS

Hallux valgus, hallux abducto valgus, metatarsus adducto-varus.

EPIDEMIOLOGY

- The prevalence of bunions ranges from 2% to 50%.¹
- It is far more common in women.

ETIOLOGY AND PATHOPHYSIOLOGY

Bunion deformities are caused by multiple factors:

- Genetic and hereditary factors.
- Abnormal biomechanics (limb length discrepancy, hypermobility/ligament laxity, flatfoot deformity, malaligned skeletal structures, and ankle equinus).²
- Neuromuscular diseases.
- Ill-fitting shoes.
- Trauma.
- Iatrogenic causes.

FIGURE 208-1 Laterally deviated hallux resulting in a bunion (hallux abducto valgus deformity). (Courtesy of Naohiro Shibuya, DPM.)

FIGURE 208-2 A weight-bearing dorsoplantar plain radiograph helps in assessing severity of the deformity and determining treatment plan. (Courtesy of Naohiro Shibuya, DPM.)

RISK FACTORS

- Flatfoot.
- Family history.
- Ligamentous laxity.

DIAGNOSIS

The diagnosis of hallux abducto valgus deformity is made clinically and radiographically.

CLINICAL FEATURES

- Laterally deviated hallux, erythema, edema.
- Tenderness on the medial eminence at the first MTP joint and pain through the first MTP joint range of motion.
- Associated signs—Hypermobility, flatfoot deformity, second MTP joint pain, pain under the second metatarsal head, overlapped second digit, decreased ankle dorsiflexion, concurrent gout, decreased first MTP joint range of motion, sesamoiditis, hyperkeratosis, and hammer toe deformity (see Chapter 209, Hammer Toe, Figure 209-4).

TYPICAL DISTRIBUTION

- Often bilateral (**Figure 208-3**).
- A unilateral bunion deformity is often caused by a limb length discrepancy (**Figure 208-4**).

IMAGING

- Weight-bearing plain radiographs are obtained in dorsoplantar, lateral, and medial oblique views (**Figure 208-2**).
- Lateral deviation of the hallux and medial deviation of the first metatarsal bone are noted in the dorsoplantar view.
- The first MTP joint narrowing, osteophyte formation, subchondral cysts, and sclerosis are indicative of osteoarthritis.
- The lateral view is useful in assessing elevation of the first metatarsal, dorsal spur formation at the first MTP joint, and hammer-toe deformity.

DIFFERENTIAL DIAGNOSIS

Pain and swelling around the first MTP joint may be caused by the following:

- Gout or pseudogout presents with acute pain with signs of inflammation and prior history of gout/pseudogout. Joint aspiration may be performed to rule out septic joint (see Chapter 100, Gout).
- Rheumatoid arthritis presents with pain, inflammation, and loss of range of motion and is often symmetrical. Radiographic evidence of other small pedal joint involvement is usually evident (see Chapter 97, Rheumatoid Arthritis).
- Septic joint presents with acute pain, loss of range of motion, and systemic signs and symptoms of infectious process.

FIGURE 208-3 Severe bilateral bunion deformities causing lateral deviations in the other digits. Note the onychomycosis and flaking skin from tinea pedis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 208-4 A unilateral bunion deformity is often a result of limb length discrepancy. Note the prominent erythema around the first metatarsophalangeal joint of the left foot only. (Courtesy of Naohiro Shibuya, DPM.)

MANAGEMENT

Conservative measures and surgical treatments are described below.

CONSERVATIVE MEASURES

- Change to shoes with a wider toe box.
- Place a toe spacer in the first interdigital space to straighten the hallux and decrease the irritation caused by rubbing of the first and second digits.
- Pad the shoe to limit shearing force (**Figure 208-5**).
- Custom-made orthoses help slow progression of the deformity caused by biomechanical factors.
- Rest, NSAIDs, and ice may help an inflamed joint and/or shoe irritation.
- Physical therapy may help improve joint range of motion, reduce edema, or decrease nerve pain.

SURGICAL TREATMENT

- Consider surgical referral to a foot specialist for correction of the deformity.
- The tendon and ligament balancing procedure is used for minor, flexible deformities.
- Exostectomy may help patients who have no joint pain, but complain about extraarticular “bump pain.”
- Osteotomy to realign the bony structure is indicated for moderate to severe deformities (**Figure 208-6**).
- Arthrodesis of the first MTP or metatarsocuneiform joint is indicated in a severe deformity.
- Adjunctive procedures (e.g., correction of hammer-toe deformities, flatfoot deformity, ankle equinus, and resection of the sesamoid bone) may be required for a positive long-term outcome.

PREVENTION

- Treatment of underlying etiology, such as flatfoot can prevent progression of bunion deformity.
- Avoid shoes that push the hallux over in patients who are starting to develop a bunion.

PROGNOSIS

- The prognosis worsens as the deformity progresses.
- Function and quality of life can be affected in severe debilitating deformity. Surgical correction provides good prognosis in such patients.

FOLLOW-UP

The patient may be seen on an as-needed basis. Serial plain radiographs can be obtained to follow the progression of the deformity and arthritic changes in the first MTP joint.

FIGURE 208-5 Simple padding can alleviate shoe irritation from the bunion deformity. (Courtesy of Naohiro Shibuya, DPM.)

FIGURE 208-6 Surgical correction is indicated if conservative measures fail. (Courtesy of Naohiro Shibuya, DPM.)

PATIENT EDUCATION

Conservative measures may or may not provide temporary relief and prevent progression of the deformity. Surgical management is necessary to correct the deformity. Surgical treatment will typically require 2 to 6 weeks of non-weight-bearing status postoperatively, depending on the procedure performed. More severe deformities will require a more extensive surgical approach and longer recovery period.

PATIENT RESOURCE

- PubMed Health. *Bunions*—<http://www.ncbi.nlm.nih.gov/pubmedhealth/PMH0002211/>.

PROVIDER RESOURCE

- Medscape. *Bunion*—<http://emedicine.medscape.com/article/1235796>.

209 HAMMER TOE

Naohiro Shibuya, DPM, MS
Javier La Fontaine, DPM, MS

PATIENT HISTORY

A 44-year-old woman presented with pain in the ball of her left foot on weight-bearing. She works as a nurse and walks most of her 12-hour shift. Two months ago she noticed a new deformity of the second digit of her left foot (**Figure 209-1**). Her second digit was contracted with a nonreducible proximal interphalangeal joint and reducible metatarsophalangeal (MTP) joint. Her x-ray is seen in **Figure 209-2**.

She was referred to a podiatrist who diagnosed an acute isolated hammer-toe deformity. At the time of surgery a plantar plate rupture at the MTP joint was found. The podiatrist fused her proximal interphalangeal (PIP) joint and released her extensor tendon and dorsal capsule at the MTP joint to reduce the deformity. She began protective ambulation in a surgical shoe on postoperative day 3. An internal fixation wire, which was used to fixate the fusion site, was removed in 4 weeks. She returned to work and her regular activities within 6 weeks of the operation.

INTRODUCTION

Hammer-toe deformity is a flexion contracture in the PIP joint of a pedal digit, resulting in plantar flexion of the middle phalanx at the PIP joint with dorsal angulation of the proximal phalanx at the MTP joint. Hammer toes are associated with imbalance of soft-tissue structures around the joints in the digits and are often progressive. Surgical correction is required when deformity interferes with function.

SYNONYMS

- Hammer toe, claw toe, and mallet toe describe similar digital contractures.
- Claw toe refers to progression of hammer toe to include extension of the MTP joint along with flexion in the PIP joint.
- Mallet toe has a digital contracture at the distal interphalangeal (DIP) joint.

EPIDEMIOLOGY

Hammer-toe deformity is the most common digital deformity, and it can affect up to 60% of adults. The second digit is most commonly affected.¹

ETIOLOGY AND PATHOPHYSIOLOGY

A hammer toe is caused by multiple factors:

- Genetic and hereditary factors.

FIGURE 209-1 A plantar plate rupture at the metatarsophalangeal joint from overuse often causes an acute isolated hammer-toe deformity. (Courtesy of Naohiro Shibuya, DPM.)

FIGURE 209-2 This lateral plain film shows dorsiflexion of the proximal phalanx at the metatarsophalangeal joint and plantarflexion of the middle phalanx at the proximal interphalangeal joint of the second digit. (Courtesy of Naohiro Shibuya, DPM.)

- Abnormal biomechanics (cavus or high-arch foot, flatfoot deformity, loss of intrinsic muscle function, and hypermobile first ray).
- Long metatarsal and/or digit.
- Systemic arthritidis.
- Neuromuscular diseases such as Charcot-Marie-Tooth disease (**Figure 209-3**).
- Ill-fitting shoes.
- Trauma.
- Iatrogenic causes.

RISK FACTORS

- High-arch foot type (cavus foot).
- Flatfeet.
- Bunion deformity (**Figure 209-4**).

DIAGNOSIS

The diagnosis of hammer-toe deformity is made clinically and radiographically.

CLINICAL FEATURES

- Pain and deformity in 1 or more of the lesser toes.
- Dorsiflexed proximal phalanx at the MTP joint and plantarflexed middle phalanx at the PIP joint of a lesser digit.
- Callus formation at the dorsal aspect of the PIP joint and/or distal aspect of the digit.
- Edema and tenderness on the plantar aspect of the lesser MTP joint(s).
- Associated signs—Cavus foot deformity, flatfoot deformity, bunion deformity, transverse deformity of the digits, decreased ankle dorsiflexion, and bowstringing of the extensor and/or flexor tendons.
- Evaluation of the digit in weight-bearing and non-weight-bearing conditions helps assess reducibility and rigidity of the deformity. In the case of predislocation syndrome (acute rupture or tear of the MTP joint capsule or plantar plate), the deformity may not be appreciated unless the foot is evaluated in the weight-bearing position.²

IMAGING

Obtain weight-bearing plain radiographs in dorsoplantar, lateral, and medial oblique views (**Figure 209-2**).

- Dorsal angulation and/or translation of the proximal phalanx on the metatarsal head with plantar angulation of the middle phalanx (lateral view).
- Degenerative changes in the digital joints and dislocation in the MTP joint.
- Transverse deformity and abnormal metatarsal length (dorsoplantar view).

FIGURE 209-3 Severe hammer-toe deformity caused by Charcot-Marie-Tooth disease, an autosomal dominant neuromuscular disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 209-4 Hammer-toe deformity caused by a bunion. (Courtesy of Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

Pain and swelling in the digit may be caused by the following:

- Gout or pseudogout presents with acute pain with signs of inflammation, and prior history of gout/pseudogout. Joint aspiration may be performed to rule out septic joint (see Chapter 100, Gout).
- Rheumatoid arthritis presents with pain, inflammation, and loss of range of motion and is often symmetrical. Radiographic evidence of other small foot joint involvement usually is evident (see Chapter 97, Rheumatoid Arthritis).
- Septic joint presents with acute pain, loss of range of motion, and systemic signs and symptoms of infectious process.
- Fractured toe caused by sudden trauma.
- Neuroma in the intermetatarsal space (Morton neuroma) with compression of the intermetatarsal nerves—Numbness and cramping of the innervated toes are the most common symptoms.

MANAGEMENT

Conservative measures and surgical treatment may be used to correct this condition. Note that a neglected hammer-toe deformity could result in ulceration in a patient with diabetes.

NONPHARMACOLOGIC

- Change shoes.
- Pad shoes to limit shearing force. A crest pad can be used to prevent painful callus formation at the distal tip of the digit (**Figure 209-5**).
- Splinting can be used in an early flexible hammer toe.
- Custom-made orthoses are helpful to slow down progression of the deformity if it is caused by biomechanical factors.
- Rest, NSAIDs, and ice help an inflamed joint and/or shoe irritation.

SURGICAL TREATMENT

- Consider surgical referral to a foot specialist to correct the deformity.
- Percutaneous tenotomy and/or capsulotomy are used for mild, flexible deformities.
- Resectional arthroplasty at the PIP joint may be beneficial for a more rigid deformity.
- Shortening osteotomy of the metatarsal is indicated in the deformities resulting from the long metatarsal.
- Arthrodesis (fusion) of the PIP joint and/or flexor tendon transfer is indicated for a severe deformity (**Figure 209-6**).
- Adjunctive procedures (e.g., correction of bunion, cavus foot, flatfoot deformities, and ankle equinus) may be necessary for a good long-term outcome.

PREVENTION

- Proper shoes with an adequate toe box and heel counter prevent excessive contracture of the digits.

FIGURE 209-5 A crest pad prevents painful callus formation at the distal tip of the digit. (Courtesy of Naohiro Shibuya, DPM.)

FIGURE 209-6 Proximal interphalangeal joint arthrodesis (fusion) is often used to correct hammer-toe deformity. (Courtesy of Naohiro Shibuya, DPM.)

- Controlling associated deformities, such as bunion and flatfoot deformities via orthotic management can prevent progression of hammer-toe deformity.

PROGNOSIS

- The prognosis worsens as the deformity progresses.
- Function and quality of life can be affected in severe debilitating deformity. Surgical correction provides good prognosis in such patients.

FOLLOW-UP

Periodic debridement of the calluses developed from the deformity may be sufficient in many of the patients if the deformity is not progressive. Serial plain radiographs can be obtained to follow the progression of the deformity and arthritic changes in the first MTP joint. In a high-risk, immunocompromised, neuropathic patient, prophylactic surgical correction of the deformity may be indicated.

PATIENT EDUCATION

Explain to patients that conservative measures may prevent progression of the deformity and provide temporary relief, but that surgical

management is necessary to correct the deformity. Surgical treatment can require up to 4 to 6 weeks of non-weight-bearing status postoperatively in severe deformities. A less-involved surgical approach to correct a mild deformity can allow a patient to walk on the same day as the surgery. In many cases, fixation with a pin, small screw, or implant is necessary to correct the deformity.

210 ISCHEMIC ULCER

Javier La Fontaine, DPM, MS
Naohiro Shibuya, DPM, MS

PATIENT STORY

A 58-year-old woman with uncontrolled type 2 diabetes, hypercholesterolemia, and tobacco use presented with a 2-month history of a nonhealing ulceration on her left foot (**Figure 210-1**). She believes this started after she stepped on a tack. She presented with the ulcer, loss of protective sensation, and a nonpalpable posterior tibial pulse. She began treatment in a wound care center. Arterial noninvasive studies showed severe vascular disease and she underwent revascularization. While in the hospital, she quit smoking and gained control of her diabetes. Her ulcer healed and she continues to take her diabetes medications and does not smoke.

INTRODUCTION

Ulcerations occur from ongoing biomechanical forces or trauma and require normal blood flow to heal. Nonhealing ulcers are commonly a result of peripheral ischemia seen in patients with diabetes and other vascular diseases. Treatment includes local wound care and improvement or correction of underlying factors causing ischemia. Untreated ischemic ulcers become infected and may require amputation of the affected area.

SYNONYMS

Arterial ulcer.

EPIDEMIOLOGY

Of patients with diabetes, 15% to 25% will develop an ulcer at an annual incidence of 1% to 4%.¹

ETIOLOGY AND PATHOPHYSIOLOGY

Microvascular dysfunction is an important component of the disease process that occurs in diabetic foot disease. The abnormalities observed in the endothelium in patients with diabetes are not well understood and evidence suggests that endothelial dysfunction could be involved in the pathogenesis of diabetic macroangiopathy and microangiopathy.² Microangiopathy is a functional disease where neuropathy and autoregulation of capillaries lead to poor perfusion of the tissues, especially at the wound base.

RISK FACTORS

- Diabetes for more than 10 years, especially with poor glycemic control and the presence of other macro- or microvascular complications.

FIGURE 210-1 A 38-year-old woman with type 2 diabetes and an ischemic ulcer on the first digit of the left foot. The base of the wound is gray in color with pink surrounding wound margins. (Courtesy of Javier La Fontaine, DPM.)

- Peripheral vascular disease from any cause or other vascular risk factors, including dyslipidemia and tobacco use.
- Neuropathy caused by loss of protective sensation and as a sign of microvascular disease.
- History of a previous ischemic ulcer.

DIAGNOSIS

CLINICAL FEATURES

- Pain.
- Gray/yellow fibrotic base (**Figures 210-1** and **210-2**).
- Undermined skin margins.
- Punched-out appearance.
- Nonpalpable pulses.
- Associated trophic skin changes (e.g., absent pedal hair and thin shiny skin).

TYPICAL DISTRIBUTION

- Distal aspect of the toes.

IMAGING

- Noninvasive studies (e.g., arterial Doppler and pulse volume recordings) are important for baseline assessment of the patient's blood flow.³
- Radiographs may be necessary to rule out osteomyelitis.

DIFFERENTIAL DIAGNOSIS

- Neuropathic ulcer usually presents with beefy red wound base and hyperkeratosis at the skin margins (see Chapter 211, Neuropathic Ulcer).
- Infected wounds present with localized redness, edema, drainage, and warmth in any of the diabetic-type wounds with lack of systemic symptoms of infection.
- Gangrene usually is well-demarcated with black eschar in foot with vascular disease (see Chapter 213, Dry Gangrene).

MANAGEMENT

- Consider vascular surgery consultation to evaluate for revascularization.
- Carefully evaluate for a concomitant infection. Antibiotics are not indicated unless infection is present.
- Avoid aggressive debridement until optimization of blood flow occurs.
- Change dressings twice daily to evaluate the wound and keep a low bacterial load. Many advanced therapies can be added to accomplish the same goals.
- If the wound is plantar, offloading is important to prevent the wound from increasing in size.

FIGURE 210-2 A 57-year-old man with diabetes for 25 years with an ischemic ulcer of the third toe. A grayish base is a common finding in this type of ulcer. (Courtesy of Javier La Fontaine, DPM.)

PREVENTION

- In patients with diabetes, adequate glycemic control is essential. A yearly comprehensive foot examination should be performed.
- Smoking cessation.

PROGNOSIS

Prognosis of an ischemic ulcer depends on the possibility of revascularization. Many ulcers treated early heal. Untreated or inadequately treated ulcers lead to infection and amputation. Early recognition of underlying vascular disease is imperative for a successful outcome.

FOLLOW-UP

- Schedule weekly to biweekly visits to monitor the ulcer.
- Obtain serial radiographs every 4 weeks to monitor for the development of osteomyelitis.
- Closely monitor the patient every 3 to 4 months once healing has occurred. Patients who have had history of ulcerations are 36 times more likely to develop another ulcer.⁵

PATIENT EDUCATION

- Prevention measures, such as smoking cessation, are important to aid wound healing.⁴
- Promote successful treatment by encouraging adherence with use of offloading devices.
- Strive for normal glycemic control to optimize outcome for healing and surgical intervention.

211 NEUROPATHIC ULCER

Javier La Fontaine, DPM, MS
Naohiro Shibuya, DPM, MS

PATIENT STORY

A 57-year-old man with type 2 diabetes presented with history of a neuropathic ulceration to the right foot for 2 weeks (**Figure 211-1**). The patient recalled having a callus for several months. He noticed blood on his sock 3 days ago. He denied fever or chills, but his glucose has been running higher than normal. The patient demonstrated loss of protective sensation, but vascular status was intact. He was referred to a podiatrist who immediately offloaded his foot with a total contact cast. His ulcer healed in 1 month, and he was subsequently fitted with orthopedic shoes.

INTRODUCTION

Foot complications in patients with diabetes mellitus are common, costly, and impact quality of life. Neuropathic ulcers can lead to the most devastating outcome, which is an amputation. Eighty-five percent of all amputations related to diabetes are preceded by an ulcer. Prevention, early recognition, and treatment of foot ulcers are critical in avoiding amputations.

EPIDEMIOLOGY

- Of people with diabetes, 15% will experience a foot ulcer during their lifetime, and 15% of these will have osteomyelitis.¹
- Neuropathy causes approximately 50% of diabetic foot ulcers.²
- The prevalence of neuropathic ulcer is 20% in patients with diabetic neuropathy.

ETIOLOGY AND PATHOPHYSIOLOGY

- Peripheral neuropathy is an important factor in the development of a diabetic foot ulcer.
- Neuropathy causes autonomic denervation of precapillary arterioles, leading to persistent vasodilation and chronic edema.
- Moderate pressure with repetitive trauma occurs in a particular site, often from poorly fitting footwear, which then leads to ulceration.

RISK FACTORS

- Diabetic neuropathy increases the risk of developing a foot ulcer by 70%.³
- Patients with pedal deformity combined with diabetic neuropathy are 12 times more likely to develop a foot ulcer.³
- Limited joint mobility, high level of activity, and poorly fitting footwear also increase the risk of the repetitive trauma that leads to ulceration.

FIGURE 211-1 Neuropathic ulcer under the third metatarsal head of the right foot in a patient with diabetes. Note the red base with a white rim of hyperkeratotic tissue, a classical finding of this type of ulcer. (Courtesy of Javier La Fontaine, DPM.)

DIAGNOSIS

The diagnosis of neuropathic ulceration is made clinically.

CLINICAL FEATURES

- A red, granular base (**Figures 211-1** and **211-2**).
- Surrounding hyperkeratosis with white, macerated margins (**Figures 211-1** and **211-2**).

TYPICAL DISTRIBUTION

- Foot ulcers are most common under the metatarsal heads, hallux, heel, or other weight-bearing areas.
- Foot ulcers can develop in any location of the foot such as the distal and plantar aspects of the toes (**Figures 211-1** and **211-2**).

LABORATORY STUDIES

- Cultures are only indicated if infection is suspected. Swab cultures are not reliable. Curettage of the base of the wound may be more reliable.

IMAGING

- Radiographs may identify a foreign body or underlying osteomyelitis.

BIOPSY

- A biopsy may be necessary to rule out a suspected malignancy.

DIFFERENTIAL DIAGNOSIS

- Ischemic ulcer presents in the dysvascular foot and may have black eschar at the wound base. Usually presents with pink to gray wound base (see Chapter 210, Ischemic Ulcer).
- Puncture wounds may become neuropathic ulcers in the presence of neuropathy.

MANAGEMENT

NONPHARMACOLOGIC

- Offloading pressure from the foot is the standard of care.
- Multiple devices (e.g., removable cast boot, surgical shoes, and wedge shoes) are used for offloading; however, a total contact cast is the gold standard.^{4,5}
- Diabetic shoes should not be used as offloading devices for ulcerations.
- Serial tissue debridement should be performed weekly to biweekly to maintain minimal bacterial load, low pressure surrounding the ulcer, and a metabolically active wound base.

MEDICATIONS

- Oral antibiotics are not indicated unless infection is suspected.
- If no improvement in 4 weeks, the ulcer should be considered a chronic wound and adjunctive therapy such as topical growth factors and bioengineered skin products (i.e., Apligraf, Dermagraft, or Regranex) must be considered.

FIGURE 211-2 Neuropathic ulcers in the plantar aspect of both feet. Multiple amputations in this patient caused increased pressure in different areas of the feet, which, in combination with neuropathy, led to new ulcerations. (Courtesy of Richard P. Usatine, MD.)

REFERRAL

- Consider early referral to a podiatrist, wound care center, or physician with experience treating neuropathic ulcers.

PREVENTION

Patients need to understand the importance of checking their feet daily.

PROGNOSIS

Prognosis is good for patients with neuropathic ulcers as long as they adhere to the treatment plan. A neuropathic ulcer should heal in approximately 4 to 6 weeks once aggressive offloading therapy has been implemented.

FOLLOW-UP

- Weekly to biweekly visits are needed to monitor and treat the ulcer.
- Serial radiographs every 4 weeks may be necessary to monitor for the development of osteomyelitis.
- Closely monitor the patient every 3 to 4 months once healing is accomplished. Patients who have had history of ulcerations are 36 times more likely to develop another ulcer.³

PATIENT EDUCATION

- Tell patients that adherence with offloading devices is essential.
- Inform patients that control of blood sugar and blood pressure promotes healing.

212 CHARCOT ARTHROPATHY

Javier La Fontaine, DPM, MS
Naohiro Shibuya, DPM, MS

PATIENT STORY

A 62-year-old man with type 2 diabetes for 15 years presents with history of erythematous, hot, swollen right foot for 2 weeks (**Figure 212-1**). He is on multiple medications for management of his diabetes, but it is not successfully controlled. The patient does not recall any trauma to the foot. Three days ago, he noticed pain in his foot. He denies fever or chills. The radiograph of his foot (**Figure 212-2**) shows midfoot osteopenia, an early sign of acute Charcot arthropathy.

INTRODUCTION

Charcot arthropathy is an uncommon foot complication in patients with neuropathy. Patients often present with pain, swelling, and erythema, similar to the presentation with a foot infection. Patients may have a rockerbottom foot deformity. Radiographs confirm the diagnosis.

SYNONYMS

Charcot foot, Charcot neuroarthropathy.

EPIDEMIOLOGY

The incidence of Charcot arthropathy in diabetes ranges from 0.1% to 5%.¹

ETIOLOGY AND PATHOPHYSIOLOGY

Charcot arthropathy is a gradual destruction of the joint in patients with neurosensory loss, most commonly seen in patients with diabetic neuropathy.² The pathogenesis is unknown. Proposed theories include:

- Neurotraumatic theory—Following sensory-motor neuropathy, the resulting sensory loss and muscle imbalance induces abnormal stress in the bones and joints of the affected limb, leading to bone destruction.
- Neurovascular theory—Following the development of autonomic neuropathy there is an increased blood flow to the extremity, resulting in osteopenia from a mismatch in bone reabsorption and synthesis.
- Stretching of the ligaments because of joint effusion may lead to joint subluxation.
- It is most likely that Charcot arthropathy involves all of the above mechanisms together.

FIGURE 212-1 Charcot arthropathy in the right foot. Notice the swelling and discoloration compared to the contralateral side. (Courtesy of Javier La Fontaine, DPM.)

FIGURE 212-2 Anterior–posterior view of same foot demonstrating midfoot osteopenia, an early sign of acute Charcot arthropathy. (Courtesy of Javier La Fontaine, DPM.)

RISK FACTORS

- Advanced peripheral neuropathy.
- Micro- or macrotrauma.
- Microangiopathy.
- Nephropathy.

DIAGNOSIS

The diagnosis of Charcot arthropathy is suspected based on the presentation and confirmed with imaging.

CLINICAL FEATURES

- Red, hot, swollen foot (**Figure 212-1**).
- Even with neurosensory loss, 71% of patients present with the chief complaint of pain.³
- Rockerbottom foot deformity is a classic finding of this entity (**Figure 212-3**).
- Patients may present with an open wound in the plantar aspect of the foot, which may complicate the diagnosis between Charcot arthropathy and infection.

IMAGING

Radiographs are imperative for diagnosis.

- Arch collapse within the joints of the midfoot (tarsometatarsal joints) (**Figure 212-4**).
- Erosions and cystic degeneration of the tarsometatarsal joints in Charcot arthropathy (**Figure 212-5**) may also be present.
- Bone scan and MRI may be ordered when infection is suspected, but are often inconclusive as cellulitis and osteomyelitis have similar findings.

CULTURE AND BIOPSY

- If osteomyelitis is suspected, bone cultures and bone biopsy are recommended. Cultures need to be taken during the bone biopsy so that the suspected infected bone can be visualized for accurate sampling. Send cultures for aerobic and anaerobic cultures as well as for acid-fast bacilli.

DIFFERENTIAL DIAGNOSIS

- Infections, including cellulitis and osteomyelitis, should be considered and treated if present (see Chapter 120, Cellulitis).
- Gouty arthropathy of the foot or ankle can resemble a Charcot foot (see Chapter 100, Gout).
- Acute trauma to the foot can cause swelling and erythema, but should be easy to distinguish by the history.
- Deep venous thrombosis in the leg will generally cause swelling that extends above the ankle.

FIGURE 212-3 Lateral view of the right foot demonstrating the classic rockerbottom deformity. (Courtesy of Javier La Fontaine, DPM.)

FIGURE 212-4 Lateral radiographic view of the left foot demonstrating the classic rockerbottom deformity in Charcot arthropathy with the arch collapsed at the tarsometatarsal joints. (Courtesy of Javier La Fontaine, DPM.)

MANAGEMENT

- Offloading of pressure from the foot is the standard of care. The total contact cast is most effective, and it covers the toes for protection. Other methods that are used include the removable cast boot, crutches, and the wheelchair.
- Diabetic shoes should not be used as offloading devices for Charcot arthropathy.
- Skin temperature assessment with infrared thermometry has been demonstrated to be successful in monitoring improvement.
- Prevention of rockerbottom deformities, plantar ulcers, and amputations is the major goal of the treatment. Untreated Charcot foot may lead to a rockerbottom foot, which in turn leads to increased plantar pressure in the neuropathic foot. This cascade will lead to an ulceration (**Figure 212-6**) and possible amputation.³
- The bones will take approximately 4 to 5 months to heal in presence of neuropathy.
- Oral antibiotics are not indicated unless infection is suspected.
- If deformity develops, custom-molded shoes and insoles must be ordered to prevent plantar ulcers that can lead to amputation.
- If the foot develops instability at the fracture sites, surgical reconstruction may be required.

PREVENTION

- Control of blood glucose helps to prevent diabetic complications, including Charcot arthropathy.
- Appropriate footwear and foot care is essential to preventing many types of diabetic foot problems.

PROGNOSIS

Patients with history of Charcot arthropathy are always at risk to develop foot complications. The combination of severe foot deformity in presence of neuropathy places them at risk for more ulceration, and further amputation. Almost 50% of these patients will require complex foot surgery to fix the deformity.

FOLLOW-UP

- Weekly to biweekly visits to the podiatrist is needed.
- Serial radiographs every 4 weeks are required to monitor bone healing and deformity.
- Once healing is accomplished, it is imperative to continue monitoring the patient every 3 to 4 months. Patients who have had history of Charcot arthropathy are 36 times more likely to develop another ulcer and are at risk of amputation.⁴

FIGURE 212-5 Anterior–posterior radiograph of the right foot demonstrating erosion and cystic degeneration at the tarsometatarsal joints in Charcot arthropathy. (Courtesy of Javier La Fontaine, DPM.)

FIGURE 212-6 Foot ulcer as a result of diabetic neuropathy and a Charcot foot. Note the collapse of the arch. (Courtesy of Richard P. Usatine, MD.)

PATIENT EDUCATION

- Tell the patient that all efforts should be made to control blood sugar and blood pressure to promote healing.
- Educate the patient to recognize the clinical signs of Charcot arthropathy.
- Educate patient to wear shoe gear prescribed by physician.
- Ensure that patients with Charcot arthropathy understand that adherence with offloading devices is essential.

213 DRY GANGRENE

Javier La Fontaine, DPM, MS
Naohiro Shibuya, DPM, MS

PATIENT STORY

A 36-year-old woman with type 1 diabetes presented with a 4-week history of a dry, black great toe and third toe on the right foot (**Figure 213-1**). She said that she noticed severe maceration between the first and second interspace approximately 6 weeks ago. Subsequently, the toes changed color and became very painful. Two days ago, she noticed a foul odor from both toes. The patient reported smoking since she was 13 years old. On physical examination, there were no palpable pulses in the right foot. The patient was admitted for IV antibiotics and revascularization was performed. Subsequently, the toes were partially amputated and the wounds healed without any complications. Her physicians attempted to help her to quit smoking without success.

INTRODUCTION

Dry gangrene develops following arterial obstruction and appears as dark brown/black dry tissue. Peripheral arterial disease is common in patients with diabetes and dry gangrene is most commonly seen on the toes. The nonviable tissue becomes black in color from the iron sulfide released by the hemoglobin in the lysed red blood cells.

SYNONYMS

Mummification necrosis.

EPIDEMIOLOGY

- Peripheral arterial disease (PAD) is a common finding in patients with diabetes. PAD is an important factor leading to lower-extremity amputation in patients with diabetes.¹
- Thirty percent of diabetic patients with an absent pedal pulse will have some degree of coronary artery disease.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- PAD manifests in the lower extremity in two ways: macro- and microvascular diseases.
- The pattern of occlusion in the macrovascular tree is distal and multisegmental.²
- Multiple occlusions occur below the trifurcation of the popliteal artery into the anterior tibial artery, posterior tibial artery, and peroneal artery.

FIGURE 213-1 Dry gangrene of the first and third toes in a 36-year-old woman with poorly controlled diabetes demonstrating the typical demarcation of the necrotic eschar from the normal tissue. (Courtesy of Richard P. Usatine, MD.)

- Risk factors, such as hypercholesteremia, hyperlipidemia, and hypertension, are often associated with patients with PAD and, therefore, poor wound healing.^{3,4}

RISK FACTORS

- Diabetes.
- Dyslipidemia.
- Smoking.
- Neuropathy.

DIAGNOSIS

CLINICAL FEATURES

- Dry, black eschar, which most commonly begins distally at the extremities (**Figures 213-1** and **213-2**).
- There is a clear demarcation between healthy tissue and necrotic tissue (**Figures 213-1** and **213-2**).
- Foul odor.
- Pain may be present.
- Trauma is the most common etiology.
- Nonpalpable pulses are common. Palpable pulses do not preclude the presence of limb-threatening ischemia. Also, the dorsalis pedis pulse is reported to be absent in 8% of healthy individuals, and the posterior tibial pulse is absent in 2% of the population.
- Smoking is commonly associated with this problem.
- Associated trophic skin changes (e.g., absent pedal hair and thin shiny skin).
- Indicators of vascular insufficiency include pallor upon elevation of the limb and rubor upon dependency, along with prolonged digital capillary filling time.

TYPICAL DISTRIBUTION

- Distal extremities, especially the toes.

IMAGING

- Even in the presence of a palpable pulse, noninvasive studies (e.g., arterial Doppler and pulse volume recordings) are important for baseline assessment of the patient's blood flow.
- Angiogram is required to evaluate the possibility of revascularization.
- Radiographs may be necessary to rule out osteomyelitis.

DIFFERENTIAL DIAGNOSIS

- Wet gangrene is an acute, urgent problem that is caused by a severe infection in the dysvascular foot (**Figure 213-3**). Wet gangrene usually presents with cyanosis, purulence, foul odor, and systemic signs and symptoms of infection.

FIGURE 213-2 A 55-year-old man with type 2 diabetes presenting with dry gangrene of the third toe. Note a visible line of demarcation between the gangrene and normal tissue. The dry, black eschar is more distal than proximal. (Courtesy of Javier La Fontaine, DPM.)

FIGURE 213-3 A 53-year-old diabetic man with wet gangrene of the second and third toes of the right foot. This diagnosis should always be considered when evaluating the ischemic limb. Wet gangrene is an emergency caused by an infectious process with severe ischemia. (Courtesy of Javier La Fontaine, DPM.)

- Ischemic ulcer is an actual foot ulcer that usually presents with a pink to gray wound base (see Chapter 210, Ischemic Ulcer).
- Although diabetes is the most common cause of dry gangrene of the toes, severe frostbite and Buerger disease can also lead to dry gangrene by damage to the microvasculature.

MANAGEMENT

- Consult vascular surgery.
- Rule out wet gangrene. Wet gangrene is an emergent infectious process in combination with severe ischemia. Consequently, immediate debridement of infected tissue is required with antibiotics.
- Avoid amputation or debridement until optimization of blood flow occurs. This may require a vascular bypass procedure and/or interventional radiology for percutaneous angioplasty and stent placement.
- Antibiotics are not indicated for dry gangrene unless infection is suspected.

PREVENTION

- Smoking cessation.
- Diet and exercise to control blood sugar and lipids.
- Vascular examination at least on a yearly basis.

PROGNOSIS

Once dry gangrene has been established, gangrenous tissue will need to be amputated. On occasion, the toes will autoamputate. Successful revascularization must occur for the patient to heal. If the problem is addressed early and aggressive wound care is provided, most of the amputations heal. Because delaying revascularization increases the risk of infection, early and aggressive management of vascular disease is imperative for a successful outcome.

FOLLOW-UP

Closely monitor the patient for new gangrene or ulcers every 3 to 4 months once healing has occurred.

PATIENT EDUCATION

- Avoid trauma to the amputated site.
- Advise and assist patients to stop smoking to help the wound heal and prolong the survival of the revascularization procedure.

214 INTESTINAL WORMS AND PARASITES

Heidi Chumley, MD

PATIENT STORY

A parent brings in a 4-year-old boy suffering with anal itching. On examination the physician finds several excoriations around the anus and suspects pinworms. The physician then applies scotch tape to the perianal area and places the tape on a glass slide. Review of the slide demonstrates adult worms and ova of *Enterobius vermicularis* (pinworms) (**Figure 214-1**). The boy is treated with a single dose of chewable mebendazole and his symptoms resolve. The parent is told to repeat the mebendazole dose in 2 weeks to increase the long-term cure rate. If the scotch tape test were negative, the physician could choose to treat empirically as mebendazole is a very safe medication. Another option is to test again having the parent apply the scotch tape to the boy's perianal area first thing in the morning and bring that back to the office (the yield is higher in the morning).

INTRODUCTION

Intestinal parasites are most common in places with warmer temperatures and high humidity, poor sanitation and unclean water, and a large number of individuals (especially children) living in close proximity. In general, the parasites are either asymptomatic or cause symptoms related to their presence in the GI tract. Several migrate through the lungs and can also cause pulmonary symptoms during the migration. Diagnoses are made by history of worms being seen by the patient or parents or by laboratory examination for ova and parasites in the stool.

EPIDEMIOLOGY

- Nematoda is the phylum that contains pinworms, hookworms, *Ascaris*, *Strongyloides*, and whipworms.
 - *E. vermicularis* (pinworm) is the most prevalent nematode in the United States. Populations at risk include preschool and school aged children, institutionalized persons, and household members of persons with pinworm infection¹ (**Figure 214-1**).
 - *Necator americanus* (hookworm) is found predominately in the Americas and Australia, and is the second most common nematode identified in stool studies in the United States¹ (**Figures 214-2 and 214-3**). *Ancylostoma duodenale* (hookworm) is found mostly in southern Europe, North Africa, the Middle East, and Asia.¹
 - *Ascaris lumbricoides* is the largest and most common roundworm found in humans in the world; although less common in the United States, it is seen mostly in the rural southeast. It is found in tropical and subtropical areas, including the southeastern rural United States (**Figures 214-4 and 214-5**).¹

FIGURE 214-1 *Enterobius vermicularis* (pinworms and ova) seen under the microscope from a scotch tape specimen taken of the perianal region of a 4-year-old boy with anal itching. (Courtesy of James L. Fishback, MD.)

FIGURE 214-2 *Necator americanus* (hookworm) larvae can penetrate the skin, travel through veins to the heart then lungs, climb the bronchial tree to the pharynx, are swallowed, and attach to intestine walls. (Courtesy of James L. Fishback, MD.)

- *Strongyloides stercoralis* is seen mostly in tropical and subtropical areas, but can be found in temperate areas, including the southern United States (Figure 214-6). It is more frequently found in rural areas, institutional settings, and lower socioeconomic groups.¹
- *Trichuris trichiura* (whipworm) is the third most common roundworm found in humans worldwide. Infections are more frequent in areas with tropical weather and poor sanitation practices, and among children (Figure 214-7). It is estimated that 800 million people are infected worldwide. Trichuriasis occurs in the southern United States.¹
- Cestodes (tapeworm) are a class in the phylum Platyhelminthes that contains *Taenia solium* (pork tapeworm).
 - *T. solium* is found worldwide where pigs and humans live in close proximity.
- Protozoa is the kingdom of one-celled organisms that includes *Giardia lamblia* and *Entamoeba histolytica*.
 - *G. lamblia* (*Giardia intestinalis*) is the most common parasite infection worldwide and the second most common in the United States (after pinworm), causing 2.5 million infections annually (Figure 214-8).¹
 - *E. histolytica* is seen worldwide, with higher incidence in developing countries. In the United States, risk groups include men who have sex with men, travelers and recent immigrants, and institutionalized populations.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- Nematodes (roundworms).
 - *E. vermicularis* (pinworm) (Figure 214-1) is acquired through an oral route when hands that have contacted contaminated objects are placed in the mouth. Larvae hatch in the small intestine. Adults live in the cecum. The pregnant female goes to the perianal region at night to lay eggs.
 - *N. americanus* (hookworm) (Figure 214-2) larvae penetrate the skin, travel through veins to the heart and then to the lungs, climb the bronchial tree to the pharynx, and then are swallowed and attach to intestine walls (Figure 214-3).
 - When fertilized eggs of *A. lumbricoides* (Figure 214-4) are ingested, they hatch and the larvae enter the circulation through intestinal mucosa, travel to the lungs, climb to the pharynx, then are swallowed, and finally the adult *Ascaris* worms live in the small intestine.
 - *S. stercoralis* have both a free-living and parasitic cycle. In the parasitic cycle, larvae penetrate the skin, travel through the circulation to the lungs and are swallowed, and travel to the small intestine (Figures 214-5 and 214-6) to become adults. Adult females lay eggs, which become rhabditiform larvae, which can either become free living or can cause autoinfection by reentering the parasitic cycle or disseminating widely in the body.
 - *T. trichiura* (whipworm) (Figure 214-7) eggs are ingested and hatch in the small intestine; worms live in the cecum or colon.
 - Cestodes (tapeworms)—*T. solium* is acquired by ingesting undercooked contaminated pork. *Diphyllobothrium latum* is the fish tapeworm that is acquired by ingesting uncooked contaminated fresh-water fish.

FIGURE 214-3 Adult hookworm attached to the intestinal wall. (Courtesy of Centers for Disease Control and Prevention.)

FIGURE 214-4 *Ascaris lumbricoides* in the resected bowel of a patient with bowel obstruction. (Courtesy of James L. Fishback, MD.)

FIGURE 214-5 *Ascaris lumbricoides* in the appendix after being removed from a young adult with acute appendicitis. (Courtesy of James L. Fishback, MD.)

- Protozoa.
 - *G. lamblia* cysts are ingested from contaminated water, food, or fomites and travel to the small intestine (**Figure 214-8**).
 - *E. histolytica* cysts or trophozoites are ingested from fecally contaminated food, water, or hands or from fecal contact during sexual practices; these then travel to the large intestine, where these either remain or travel through the bloodstream to the brain, liver, or lungs.

RISK FACTORS

- Endemic in developing countries with limited access to clean water.
- Living in an environment conducive to parasites (warm, humid climate) and parasitic transfer (crowded conditions, contaminated water supply, poor hygiene) dramatically raises the risk of parasitic infection.
- Household contacts or caretakers of persons with intestinal parasites are at risk for contracting the parasites.
- Children or others with poor hygiene are also at high risk.
- Immunocompromised patients, once infected, may have a more serious course.

DIAGNOSIS

CLINICAL FEATURES

- Nematodes.
 - *E. vermicularis* (pinworm)—Perianal pruritus is the most common; female genital tract irritation also reported; rarely abdominal pain or appendicitis; infants show irritability, but can be asymptomatic.¹
 - *N. americanus* (hookworm)—Most commonly presents with iron-deficiency anemia.¹
 - *A. lumbricoides*—Frequently asymptomatic; high numbers of worms can cause abdominal pain or intestinal obstruction. Cough, dyspnea, hemoptysis, or eosinophilic pneumonitis when in the lungs. Patients may cough up visible worms.
 - *S. stercoralis*—Frequently asymptomatic; eosinophilia; may cause abdominal pain or diarrhea, cough, shortness of breath, or hemoptysis when in the lungs; can disseminate in immunocompromised patients causing abdominal pain, distention, septicemia, shock, or death.
 - *T. trichiura* (whipworm)—Frequently asymptomatic; high number of worms can cause abdominal pain or intestinal obstruction, especially in children.
- Cestodes.
 - *T. solium*—Frequently asymptomatic; risk of developing cysticercosis with symptoms based on location of cysts in brain (e.g., seizures, focal neurologic signs, and death), eyes, heart, or spine.
- Protozoa.
 - *G. lamblia*—Diarrhea, nausea, emesis, abdominal bloating occurs 1 to 14 days after ingestion for up to 3 weeks, and can be asymptomatic.

FIGURE 214-6 *Strongyloides stercoralis* ova and parasite in stool. (Courtesy of James L. Fishback, MD.)

FIGURE 214-7 *Trichuris trichiura* (whipworm) egg in stool. (Courtesy of James L. Fishback, MD.)

- *E. histolytica*—Asymptomatic, intestinal symptoms (e.g., colitis and appendicitis), or extraintestinal (e.g., abscess in the liver or lungs, peritonitis, and skin or genital lesions).

LABORATORY TESTING

- Nematodes.
 - *E. vermicularis* (pinworm)—Microscopic identification of eggs (**Figure 214-1**) collected from perianal area; apply transparent adhesive tape to the unwashed perianal area at the time of presentation or in the morning and then place tape on slide.
 - *N. americanus* (hookworm)—Microscopic identification of eggs in the stool (**Figure 214-2**).
 - *A. lumbricoides*—Microscopic identification of eggs in the stool.
 - *S. stercoralis*—Microscopic identification of larvae in stool (**Figure 214-6**) or duodenal fluid; often requires several samples. Immunologic tests are useful when infection is suspected, but larvae are not seen in several samples. Immunologic tests do not differentiate from past or present infections.
 - *T. trichiura* (whipworm)—Microscopic identification of eggs in stool (**Figure 214-7**).
- Cestodes.
 - *T. solium*—Microscopic identification of eggs or proglottids in stool indicates taeniasis; presumed neurocysticercus diagnosed from Centers for Disease Control and Prevention (CDC)'s immunoblot assay.¹
- Protozoa.
 - *G. lamblia*—Microscopic identification of cysts or trophozoites in stool or trophozoites in duodenal fluid or biopsy (**Figure 214-8**). Antigen tests and immunofluorescence are available.
 - *E. histolytica*—Microscopic identification of cysts or trophozoites in stool (difficult to distinguish from nonpathogens); antibody detection for extraintestinal disease; antigen detection can distinguish pathogenic and nonpathogenic infections.¹

IMAGING

- Cestodes.
 - *T. solium*—MRI is typically used to identify brain cysts.

DIFFERENTIAL DIAGNOSIS

- Abdominal symptoms seen with several intestinal parasites can also be caused by the following:
 - Viral or bacterial infections—May present with acute onset of emesis and diarrhea often with fever.
 - Irritable bowel disease—Chronic symptoms of abdominal cramping with diarrhea or loose stools and/or constipation; usually no bloody stools, weight loss, or anemia.
 - Inflammatory bowel disease—Intermittent abdominal pain and bloody stools; diagnosis confirmed by colonoscopy with biopsy.
 - Iron-deficiency anemia seen with hookworms can be seen with blood loss from any site from one of many causes. Of course, iron deficiency can be seen with a diet deficient in iron without having hookworms.
 - GI blood loss can be seen with other infections or inflammation, polyps, or masses.

FIGURE 214-8 *Giardia lamblia* in a duodenal biopsy obtained by esophagogastroduodenoscopy in a patient with typical symptoms of chronic giardiasis (excessive flatulence and sulfurous belching) that failed to improve on metronidazole. (Courtesy of Tom Moore, MD.)

MANAGEMENT

MEDICATIONS

All medication doses are from *The Medical Letter*² and apply to adults and children unless specified.

- Nematodes
 - *E. vermicularis* (pinworm)—Pyrantel pamoate 11 mg/kg once (maximum 1 g), repeat in 2 weeks; or mebendazole 100 mg once, repeat in 2 weeks.
 - *N. americanus* (hookworm)—Albendazole 400 mg once; or mebendazole 100 mg twice a day for 3 days 500 mg once or pyrantel pamoate 11 mg/kg (maximum 1 g) for 3 days.
 - *A. lumbricoides*—Albendazole 400 mg once; alternate therapy mebendazole 500 mg once or ivermectin 150 to 200 mcg/kg po once.
 - *S. stercoralis*—Ivermectin 200 mcg/kg per day for 2 days; alternate therapy albendazole 400 mg bid for 7 days.
 - *T. trichiura* (whipworm)—Mebendazole 100 mg twice a day for 3 days or 500 mg once; alternate therapy albendazole 400 mg once a day for 3 days or ivermectin 0.2 mg/kg daily for 3 days.
- Cestodes
 - *T. solium*—Praziquantel 5 to 10 mg/kg once for intestinal stage; cysticercosis require seizure prophylaxis and steroids in conjunction with albendazole 400 mg bid (adults) or 15 mg/kg per day up to 400 mg bid (children) for 8 to 30 days; ophthalmologic examination for eye cysts is recommended.
- Protozoa
 - *G. lamblia*—Metronidazole 250 mg tid for 5 to 7 days (adults), 15 mg/kg per day divided tid for 5 to 7 days (children); or tinidazole 2 g once (adults), 50 mg/kg (maximum 2 g) once (children); or nitazoxanide 500 mg bid for 3 days (age >12 years), 100 mg bid for 3 days (age 1 to 3 years), 200 mg po bid for 3 days (age 4 to 11 years).
 - *E. histolytica*—Metronidazole 500 to 750 mg tid for 7 to 10 days (adults), 35 to 50 mg/kg per day divided in 3 doses for 7 to 10 days (children) or tinidazole 2 g once daily for 3 days (adults), 50 mg/kg per day in 3 doses up to 2 g for 3 days. Then iodoquinol 650 mg tid for 20 days (adults), 30 to 40 mg/kg per day up to 2 g in 3 doses for 20 days (children); or paromomycin 25 to 35 mg/kg per day in 3 doses for 7 days.

REFERRAL OR HOSPITALIZATION

Refer or hospitalize patients

- Who do not respond to initial therapy or have recurrent infections.
- Suspected of having cysticercosis.
- Experiencing severe abdominal symptoms suggesting obstruction or an acute abdomen.

PREVENTION

- Clean uncontaminated water for drinking and cooking—Use bottled water, chemically treated water, or boiled water in endemic areas.

- Good hygiene, especially hand washing.
- When travelling to endemic areas, drink bottled water when possible. Water can also be treated with chlorine, iodine, or boiled if bottled water is not available. Clean water should be used for brushing teeth. Avoid eating fresh salads washed in local water.
- Children in developing countries who are drinking contaminated water (and lack access to clean water) should be considered for deworming with albendazole every 3 to 6 months (see Chapter 7, Global Health Issues).

PROGNOSIS

Prognosis is excellent for most infections if adequate therapy and clean water is available.

FOLLOW-UP

Follow-up at completion of therapy.

PATIENT EDUCATION

Most intestinal parasites are asymptomatic and easily treatable. Avoid infecting others by practicing good hygiene, including hand washing.

PATIENT RESOURCE

215 URETHRITIS IN MEN

Heidi Chumley, MD
Richard P. Usatine, MD

PATIENT STORY

A 24-year-old man presents to a skid row shelter clinic with 3 days of dysuria and penile discharge. A heavy purulent urethral discharge is seen (**Figure 215-1**). He admits to using crack cocaine and having multiple female sexual partners. He was diagnosed with gonococcal urethritis by clinical appearance and a urine specimen was sent for testing to confirm the gonorrhea and test for *Chlamydia*. He was treated with Ceftriaxone 250 mg IM for gonorrhea and 1 g of oral azithromycin for possible coexisting *Chlamydia*. He was offered and agreed to testing for other sexually transmitted diseases. He was told to inform his partners of the diagnosis. He was counseled about safe sex, and drug rehabilitation was recommended. On his 1-week follow-up visit, his symptoms were gone and he had no further discharge. His gonorrhea nucleic acid amplification test was positive and his *Chlamydia*, rapid plasma reagin (RPR), and HIV tests were negative. His case was reported to the Health Department for contact tracing.

INTRODUCTION

Urethritis is urethral inflammation caused by infectious (gonococcal or chlamydial) or noninfectious causes (trauma or foreign bodies). Gonococcal and chlamydial infections in men occur most commonly between the ages of 20 and 24 years, and the prevalence is highest in black men. Diagnosis is suspected clinically, reinforced by an office urine test positive for leukocyte esterase, and confirmed by a urine nucleic acid amplification test. Treat for both gonorrhea and *Chlamydia* until one or both are ruled out by laboratory testing.

EPIDEMIOLOGY

- Worldwide, 151 million cases of gonococcal and nongonococcal urethritis are reported annually (**Figures 215-1** and **215-2**).¹
- Urethritis of all types occurs in 4 million Americans each year.¹
- The prevalence of gonorrhea in men was 94.1 per 100,000 population among men in the US in 2010. The rate was highest among those men aged 20–24 years (421.0 per 100,000 population). In 2010, gonorrhea rates remained highest among black men and women (432.5), which was 18.7 times the rate among whites (23.1 per 100,000 population). The rates among Hispanics (49.9) was 2.2 times those of whites.²
- The prevalence of *Chlamydia* in men in the US in 2010 was 233.7 cases per 100,000 males. Age-specific rates among men were highest in those aged 20–24 years (1,187.0 cases per 100,000 males).

FIGURE 215-1 A 24-year-old man with gonococcal urethritis and a heavy purulent urethral discharge. (Courtesy of Richard P. Usatine, MD.)

FIGURE 215-2 Nongonococcal urethritis caused by *Chlamydia*. Note the discharge is more clear and less purulent than seen with gonorrhea. (Courtesy of Seattle STD/HIV Prevention Training Center, University of Washington.)

The rate of chlamydia among black men and women was more than eight times the rate among whites (1,167.5 and 138.7 cases per 100,000 population, respectively). The rate among Hispanics was 2.7 times the rate among whites.²

ETIOLOGY AND PATHOPHYSIOLOGY

- Urethritis is urethral inflammation caused by infectious or noninfectious causes.
- *Neisseria gonorrhoeae* and *Chlamydia trachomatis* are the most important infectious causes. When transmitted, they can cause other illnesses and complications in men (epididymitis, prostatitis, and reactive arthritis) and women (pelvic inflammatory disease and infertility).
- Other infectious agents include *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Trichomonas vaginalis*, herpes simplex viruses 1 and 2, adenovirus, and enteric bacteria.
- Noninfectious causes include trauma, foreign bodies, granulomas or unusual tumors, allergic reactions, or voiding dysfunction (any abnormal holding or voiding pattern not caused by an anatomical or a neurologic process).

DIAGNOSIS

CLINICAL FEATURES

Male patients with urethritis can be asymptomatic or present with urethral discharge, dysuria, or urethral pruritus.

Urethritis is diagnosed when one of the following is present:³

- Mucopurulent or purulent urethral discharge (**Figures 215-1** and **215-2**).
- First-void urine positive leukocyte esterase test ≥ 10 white blood cells (WBCs) per high-power field. (This can also be seen with a urinary tract infection [UTI]; however, the incidence of UTI in men younger than 50 years of age is approximately 50 per 100,000 per year, much lower than the incidence of gonococcal or chlamydial urethritis in this age group.)

LABORATORY TESTING

- Nucleic acid amplification test (NAAT) is the recommended test for screening asymptomatic at-risk men and testing symptomatic men.³ Urine is a better specimen than urethral swab and does not hurt.^{3,4}
- Gram stain of urethral secretions with ≥ 5 WBC per oil immersion field. (If Gram-negative intracellular diplococci are seen, gonococcal urethritis is present.) Gram stain will identify most cases; ≥ 5 WBCs are seen in 82% of *Chlamydia* and 94% of gonococcal infections.⁵ Government regulations concerning in-office laboratory testing have severely curtailed the use of Gram stains in the office.
- Leukocyte esterase test on urine has a good negative predictive value (NPV) but poor positive predictive value (PPV) in a low-prevalence population (NPV 96.4% and PPV 35.4%).⁶ Urethral culture is less commonly necessary when NAAT is available.

- Consider culture when tests for gonorrhea and *Chlamydia* are negative, or symptoms persist despite adequate treatment in a patient who is unlikely to have been reinfected by an untreated partner.

DIFFERENTIAL DIAGNOSIS

Dysuria in men can be caused by the following:⁷

- Infections in other sites or the urogenital tract—Cystitis, prostatitis with perineal pain or prostate tenderness, or epididymitis with scrotal pain.
- Penile lesions—Vesicles of herpes simplex, ulcers of syphilis, chancre, or lymphogranuloma venereum, and glans irritation from balanitis.
- Mechanical causes—Obstruction from benign prostatic hyperplasia (BPH) causing inflammation without infection, trauma including catheterization, urethral strictures, or genitourinary cancers.
- Inflammatory conditions—Spondyloarthropathies, drug reactions, or autoimmune diseases.

MANAGEMENT

Treat patients who meet criteria for urethritis. Test patients with dysuria who do not meet criteria for urethritis, for *N. gonorrhoeae* and *C. trachomatis*, and treat if positive. Advise sex partners to be evaluated and treated.²

NONPHARMACOLOGIC

- Encourage safe-sex practices.

MEDICATIONS

- The 2010 CDC STD treatment guidelines recommend treating uncomplicated gonococcal urethritis with ceftriaxone 250 mg IM in a single dose plus treatment for *Chlamydia* with azithromycin or doxycycline. Most gonococci in the United States are susceptible to doxycycline and azithromycin, so that routine cotreatment might also hinder the development of antimicrobial-resistant *N. gonorrhoeae*.⁸ Avoid fluoroquinolones and oral cefixime as drug resistance is too high.^{8,9} **SOR A**
- The 2010 CDC STD treatment guidelines recommend treating *Chlamydia* urethritis with azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice a day for 7 days.¹⁰ **SOR A** Acceptable alternate regimens include:
 - Erythromycin base 500 mg 4 times a day for 7 days or erythromycin ethylsuccinate 800 mg 4 times a day for 7 days or ofloxacin 300 mg orally twice a day for 7 days or levofloxacin 500 mg orally once daily for 7 days.¹⁰
- For persistent urethritis, consider *Trichomonas vaginalis* as a possible cause—Culture and treat with a single dose of metronidazole 2 g.
- Consider expedited partner therapy (EPT). EPT is the delivery of medications or prescriptions by persons infected with a sexually transmitted disease (STD) to their sex partners without

clinical assessment of the partners. Legal status by state is available at <http://www.cdc.gov/std/ept/legal/default.htm>.

PREVENTION

Consider screening the following groups of men for *Chlamydia*, using urine NAAT for testing and screening.² Twelve percent of male patients with chlamydial and 5% with gonococcal infections had no Gram stain evidence of urethral inflammation.⁵

- Men attending an STD clinic.
- Men attending a national job training program.
- Men younger than 30 years of age who are military recruits.
- Men younger than 30 years of age entering jail.

PROGNOSIS

Gonococcal and chlamydial urethritis respond well to appropriate antibiotic therapy. Partners must be treated to avoid reinfection.

FOLLOW-UP

- Reevaluate patients with persistent or recurrent symptoms after treatment. Reexamine for evidence of urethral inflammation and retest for gonorrhea and *Chlamydia*.
- Routine test-of-cure laboratory examination is not recommended by the CDC for gonorrhea or chlamydia infections unless therapeutic compliance is in question, symptoms persist, or reinfection is suspected.^{8,10}
- However, patients who have symptoms that persist after treatment of gonorrhea should be evaluated by culture for *N. gonorrhoeae*, and any gonococci isolated should be tested for antimicrobial susceptibility.⁸
- Consider chronic prostatitis if symptoms persist for more than 3 months.

PATIENT EDUCATION

The Centers for Disease Control and Prevention (CDC) recommends the following for patients diagnosed with gonorrhea or *Chlamydia*:²

- Return for evaluation if the symptoms persist or return after therapy is completed.
- Abstain from sexual intercourse until 7 days after starting therapy, symptoms have resolved, and sexual partners have been adequately treated.
- Undergo testing for other STDs, including HIV and syphilis.
- Advise sexual partners of the need for treatment and/or take medications directly to them using EPT.

216 SYPHILIS

Richard P. Usatine, MD
Heidi Chumley, MD

PATIENT STORY

A 39-year-old woman presents with a nonhealing ulcer over her upper lip for 1 week and a new-onset rash on her trunk (**Figures 216-1** and **216-2**). The ulcer on her upper lip was misdiagnosed as herpes simplex by the previous physician. Sexual history revealed that the patient had oral sex with a boyfriend who had a lesion on his penis and she suspected that he had been having sex with other women. The examining physician recognized the nonpainful ulcer and rash as a combination of primary and secondary (P&S) syphilis. An RPR (rapid plasma reagin) was drawn and the patient was treated immediately with IM benzathine penicillin. The RPR came back as 1:128 and the ulcer was healed within 1 week.

INTRODUCTION

Syphilis, caused by *Treponema pallidum*, is a systemic disease characterized by multiple overlapping stages: primary syphilis (ulcer), secondary syphilis (skin rash, mucocutaneous lesions or lymphadenopathy), tertiary syphilis (cardiac or gummatous lesions), and early or late latent syphilis (positive serology without clinical manifestations). Neurosyphilis can occur at any stage. Diagnosis is made using treponemal and nontreponemal tests. Treatment is penicillin; the dose and duration depend on the stage.

SYNONYMS AND ACRONYMS

Lues is another word for syphilis.

Nontreponemal tests:

- VDRL—Venereal Disease Research Laboratory.
- RPR.

Treponemal tests:

- EIA—Enzyme immunoassay.
- TPPA—*T. pallidum* particle agglutination.
- FTA-ABS—Fluorescent treponemal antibody absorption.
- MHA-TP—Microhemagglutination assay for *T. pallidum*.

EPIDEMIOLOGY

- Primary and secondary (P&S) syphilis cases reported to CDC decreased from 13,997 in 2009 to 13,774 in 2010, a decrease of 1.6%. The rate of P&S syphilis in the US in 2010 (4.5 cases per 100,000 population) was 2.2% lower than the rate in 2009 (4.6 cases). This is the first overall decrease in P&S syphilis in 10 years.¹

FIGURE 216-1 Primary syphilis with a chancre over the lip of a woman. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-2 A nonpruritic rash of secondary syphilis on the abdomen of the patient shown in **Figure 216-1**. (Courtesy of Richard P. Usatine, MD.)

- The rate of P&S syphilis increased 1.3% among men (from 7.8 to 7.9 cases per 100,000 men) during 2009–2010. During this same period, the rate decreased 21.4% among women (from 1.4 to 1.1 cases per 100,000 women).¹
- In 2010, the rate of P&S syphilis was highest among persons aged 20–24 years and 25–29 years (13.5 and 11.3 cases per 100,000 population, respectively).¹
- The distribution of primary and secondary syphilis reported in 2010 differed by gender and sexual preferences: among men who have sex with women only (MSW), 35.8% had primary syphilis, and 64.2% had secondary syphilis. Among women, 16.0% had primary syphilis, and 84.0% had secondary syphilis. Among men who have sex with men (MSM), 25.0% had primary syphilis, and 75.0% had secondary syphilis.¹
- Syphilis by races/ethnicities varied in 2010: Among women with P&S syphilis, 16.8% were white, 72.8% were black, 6.6% were Hispanic. Among MSW, 14.8% were white, 67.0% were black, 13.8% were Hispanic. Among MSM, 38.1% were white, 37.0% were black, 19.8% were Hispanic.¹
- In 2008, 63% of the reported cases of P&S were in men who have sex with men (MSM).²
- HIV-infected patients were found to have syphilis rates of 62.3 per 1000 compared to 0.8 per 1000 in HIV-uninfected patients in a population study in California.³

ETIOLOGY AND PATHOPHYSIOLOGY

- Syphilis is caused by the spirochete *T. pallidum* and contracted through direct sexual contact with primary or secondary lesions. Congenital syphilis can be contracted across the placenta.

RISK FACTORS

- Sexual contact with a person with primary or secondary syphilis.
- MSM.
- Prostitution.
- Sex for drugs.
- HIV/AIDS.

DIAGNOSIS

CLINICAL FEATURES

- Primary syphilis is associated with a chancre—Usually a non-painful ulcer (**Figures 216-1, 216-3, and 216-4**). The presence of pain does not rule out syphilis, and the patient with a painful genital ulcer should be tested for both syphilis and herpes.
- Secondary syphilis occurs when the spirochetes become systemic and may present as a rash with protean morphologies, condyloma lata, and/or mucous patches (**Figures 216-2 and 216-5 to 216-11**).
- Tertiary syphilis may be visualized with gummas on the skin, but many of the manifestations are internal such as the cardiac and

FIGURE 216-3 A painless chancre at the location of treponemal entry. (Courtesy of the Public Health Image Library, Centers for Disease Control and Prevention.)

FIGURE 216-4 Primary syphilis with a large chancre on the glands of the penis. The multiple small surrounding ulcers are part of the syphilis and not a second disease. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-5 Papular squamous eruption on the hands of a woman with secondary syphilis. (Courtesy of Richard P. Usatine, MD.)

neurologic diseases that occur (e.g., aortitis, tabes dorsalis, and iritis). **Figure 216-12** shows a gumma of the scrotum.

- Neurosyphilis can occur at any stage. Clinical symptoms include cognitive dysfunction, vision or hearing loss, uveitis or iritis, motor or sensory abnormalities, cranial nerve palsies, or symptoms of meningitis.

TYPICAL DISTRIBUTION

- Primary syphilis is usually a single ulcer (chancre) that is not painful in the genital region (**Figures 216-3** and **216-4**). A chancre can be seen on the lip (**Figure 216-1**).
- Secondary syphilis may present with various eruptions on the trunk, palms, and soles (**Figures 216-2**, **216-5**, **216-6**, **216-8**, and **216-13**).
- Mucous patches are on the genitals or in the mouth (**Figures 216-7**, **216-9**, and **216-10**).

LABORATORY TESTING

- Serologic tests are either nontreponemal (RPR or VDRL), which measure anticardiolipin antibodies, or treponemal (EIA, TPPA, FTA-ABS, or MHA-TP), which measure antibodies to *T. pallidum*.
- There are two algorithms for laboratory testing currently in use around the world:
 1. Start with a low-cost nontreponemal test and confirm a positive result with a treponemal test.
 2. Start with the EIA treponemal test, followed by a nontreponemal test for confirmation.
- In 2008, the Centers for Disease Control and Prevention (CDC) recommended a treponemal EIA initially, with positive results followed by a nontreponemal test for confirmation, a strategy that detected an additional 3% of positive samples not identified in the nontreponemal–treponemal sequence.⁴
- A nontreponemal test is required for confirmation, as a treponemal EIA indicates exposure but not active infection.
- A positive EIA with a negative RPR can be a previous treated or untreated infection, a false positive, or early primary syphilis. In this case, retest with a second treponemal test.
- Dark-field microscopy is useful in evaluating moist cutaneous lesions, such as chancre, mucous patches, and condyloma lata (**Figure 216-14**).
- Test all patients with syphilis for HIV (**Figure 216-15**).
- Patients with syphilis who have any signs or symptoms suggesting neurologic disease including vision or hearing need a cerebrospinal fluid (CSF) exam, a slit-lamp ophthalmologic examination, and an otologic examination to determine if neurosyphilis is present.

DIFFERENTIAL DIAGNOSIS

- Herpes simplex—Most common cause of genital ulcers in the United States. These ulcers are painful and often start as vesicles (see Chapter 129, Herpes Simplex).

FIGURE 216-6 Papular squamous eruption on the foot of the woman in **Figure 216-5**, with secondary syphilis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-7 Mucous patches on the labia of the woman in **Figure 216-5**, with secondary syphilis teeming with spirochetes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-9 Mucous patches on the penis and scrotum of the same man with secondary syphilis in Figure 216-8. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-12 Tertiary syphilis presenting as a swollen scrotum, which was diagnosed as a syphilitic gumma of the testicle. (Courtesy of the Public Health Image Library, Centers for Disease Control and Prevention.)

FIGURE 216-10 Oral lesion on the palate of the same man with secondary syphilis in Figure 216-9. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-13 Middle-age married man with diffuse eruption of secondary syphilis from neck to feet. The eruption remained undiagnosed for months as the patient denied any risk factors. His RPR was 1:256. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-11 Condylomata lata (arrows) on the vulva of a woman with secondary syphilis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-14 Live spirochetes of *T. pallidum* seen in a darkfield preparation. (Courtesy of the Public Health Image Library, Centers for Disease Control and Prevention.)

- Chancroid—Painful beefy red ulcers on the penis or vulva, less common than syphilis. Chancroid is also known to cause large painful inguinal adenopathy (bubo) (**Figures 216-16 and 216-17**).
- Drug eruptions—Can be on the genital area such as seen in a fixed drug eruption. Also whole-body drug eruptions can appear similar to secondary syphilis (see Chapter 203, Cutaneous Drug Reactions).
- Erythema multiforme—Can look like the rash of secondary syphilis but may have target lesions (see Chapter 177, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Pityriasis rosea—A self-limited cutaneous eruption that often begins with a herald patch and may have a Christmas tree distribution on the back (see Chapter 153, Pityriasis Rosea).

MANAGEMENT

MEDICATIONS

Benzathine penicillin is the treatment of choice for all stages of syphilis. Dose and duration depend on stage. Treatment information below is from the CDC.⁵

- Primary, secondary, and early latent (immunocompetent and nonpregnant):
 - Adults: Benzathine penicillin G 2.4 million U IM one time.
 - Children older than 1 month with acquired primary or secondary: 50,000 U/kg IM up to 2.4 million U one time.
- Penicillin allergy:
 - Doxycycline 100 mg twice daily × 14 days or
 - Ceftriaxone 1 g IM/IV daily × 10 to 14 days (limited studies) or
 - Azithromycin 2 g single oral dose; however, azithromycin resistance has been documented in several areas of the United States. Use only when penicillin or doxycycline cannot be used. Do not use in MSM.
- Late latent syphilis or syphilis of unknown duration
 - Adults: Benzathine penicillin G 2.4 million U IM every week for 3 weeks.
 - Children: 50,000 U/kg IM (up to 2.4 million U) every week for 3 weeks.
- Penicillin allergy: Doxycycline 100 mg twice a day for 28 days (or tetracycline 500 mg 4 times a day for 28 days) are the only acceptable alternatives.
- For the management of congenital, tertiary, and neurosyphilis, see the *Sexually Transmitted Diseases Treatment Guidelines* published by the CDC in 2010: <http://www.cdc.gov/std/treatment/2010/genital-ulcers.htm#syphilis>.

REFERRAL OR HOSPITALIZATION

- Refer patients when the stage of syphilis is unclear. Consider referral to an infectious disease specialist in children younger than 1 month of age, pregnant women with a penicillin allergy, patients with tertiary or neurosyphilis, or patients who have failed treatment.

FIGURE 216-15 Secondary syphilis in a 20-year-old woman with a history of injection drug use and multiple sexual partners. Her HIV test was also positive. (Courtesy of Richard P. Usatine, MD.)

FIGURE 216-16 Culture-proven indurated beefy chancroidal ulcers in an HIV positive man. (Courtesy of Professor David Lewis.)

FIGURE 216-17 Left-side inguinal bubo in a patient with a culture-proven chancroidal ulcer. (Courtesy of Professor David Lewis.)

PREVENTION

Primary prevention: Safe sex practices—sexual transmission occurs when mucocutaneous syphilitic lesions are present.

Secondary prevention:

- Treat presumptively (regardless of serology) sexual partners who were exposed within 90 days of the partner's diagnosis of primary, secondary, or early latent syphilis.
- Consider presumptive treatment when exposure was greater than 90 days before partner's diagnosis if serology is unavailable or follow-up is uncertain.⁵

PROGNOSIS

When syphilis is recognized and appropriately treated, the prognosis is excellent.

FOLLOW-UP

Reexamine clinically and serologically at 6 and 12 months. Consider treatment failure if signs and/or symptoms persist or the nontreponemal test titer does not decline by 2 dilutions after 6 to 12 months of therapy. Fifteen percent will not achieve this decline in titer after 1 year.⁵

For treatment failures: Retest for HIV and perform a lumbar puncture for CSF analysis and treat for neurosyphilis if positive.

PATIENT EDUCATION

Condoms can prevent the spread of syphilis. Patients should be advised to get HIV testing and need to know that syphilis is a risk factor for the spread of HIV. HIV/AIDS is also a risk factor for acquiring syphilis (**Figure 216-18**). Patients should be advised of the importance of completing treatment and follow-up to prevent complications.

217 AIDS AND KAPOSI'S SARCOMA

Heidi Chumley, MD

PATIENT STORY

A 35-year-old gay man presented with papular lesions on his elbow (**Figure 217-1**). Shave biopsy demonstrated Kaposi's sarcoma (KS). He subsequently tested positive for HIV and began treatment with antiretroviral combination therapy. The KS resolved with topical alitretinoin gel treatment.

INTRODUCTION

In the United States, KS is most often seen in patients with AIDS and patients on immunosuppressants after organ transplantation. KS can also be classic (older Mediterranean men) or endemic (young men in sub-Saharan Africa). KS is caused by Kaposi's sarcoma-associated herpesvirus (KSHV), which promotes oncogenesis. KS cannot be cured, but treatment can result in improvement or disease stabilization. Current therapies improve the immune system or target KSHV. Therapies that modulate KSHV-mediated signaling are being studied.

EPIDEMIOLOGY

- KS can be classic (older Mediterranean men), endemic (young men in sub-Saharan Africa), epidemic (AIDS patients), or posttransplantation (organ recipients).¹
- In the United States, 81.6% of KS is seen in patients with AIDS² (**Figure 217-1**).
- In HIV-positive patients, the prevalence is 7.2/1000 person years; 451 times higher than general population.³
- In transplant patients, the prevalence is 1.4/1000 person years; 128 times higher than general population.³
- The prevalence of classic KS in the general population of southern Italy is 2.5/100,000⁴ (**Figure 217-2**).
- The male-to-female ratio for epidemic KS in the United States is approximately 50:1 but is falling as the prevalence of AIDS increases among women.⁵ The male-to-female ratio has been approximately 10:1 for classic and endemic KS.
- KS is the most common malignancy seen in AIDS patients.

ETIOLOGY AND PATHOPHYSIOLOGY

- KS is caused by KSHV, also known as human herpes virus 8 (HHV-8). KSHV acts through host cell signal transduction to activate multiple oncogenic pathways.⁶
- KS is an angioproliferative neoplasm, with abnormal proliferation of endothelial cells, myfibroblasts, and monocyte cells.

FIGURE 217-1 Several reddish-purple papular lesions of Kaposi's sarcoma on the elbow of a man with human immunodeficiency virus/acquired immunodeficiency syndrome. (Courtesy of Heather Wickless, MD.)

FIGURE 217-2 Classic Kaposi's sarcoma on the foot of an 88-year-old Italian man who does not have HIV/AIDS. These painful purple-red "growths" were present on his left foot for several years before diagnosis. (Courtesy of John P. Welsh, MD, and Herbert B. Allen, MD.)

- Lesions often begin as papules or patches and progress to plaques as proliferation continues.
- Some lesions ulcerate (nodular stage), and lymphedema can occur.

RISK FACTORS

- Immunodeficiency as a consequence of AIDS.
- Immunosuppressants for solid-organ transplantation.

DIAGNOSIS

The diagnosis is often made clinically in a patient who has AIDS and a typical presentation of KS. In atypical presentations, diagnosis is made by biopsy.

CLINICAL FEATURES

- Cutaneous lesions are usually multifocal, papular, and reddish-purple in color (**Figures 217-1** and **217-2**).
- Plaques or fungating lesions can be seen on the lower extremities, including the soles of the feet (**Figure 217-3**).
 - Vascular-appearing papules on the feet and lower legs are typical of classic KS without AIDS (**Figure 217-4**).
- Oral cavity lesions can be flat or nodular and are red to purple in color (**Figure 217-5**).
- GI lesions can be asymptomatic or can cause abdominal pain, nausea, vomiting, bleeding, or weight loss.
- Pulmonary lesions can cause shortness of breath or may appear as infiltrates, nodules, or pleural effusions on chest radiographs.

TYPICAL DISTRIBUTION

AIDS-related KS⁷:

- Skin lesions are seen mainly on the lower extremities (**Figure 217-6**), face, and genitalia. Presence of skin lesions should prompt an oral examination as oral involvement may change prognosis and management.
- Lesions in the oral cavity are common (33%), typically seen on the palate or gingiva (**Figure 217-4**).
- GI involvement is noted in 40% of newly diagnosed KS in HIV patients at diagnosis and up to 80% in autopsy studies. GI lesions can occur without skin lesions.
- Pulmonary involvement is also common, and up to 15% may occur without skin lesions in patients with KS and HIV. A chest radiograph often demonstrates pulmonary involvement.
- Any organ can be involved.

LABORATORY TESTING

- Check an HIV test in any person with KS who is not known to be HIV-positive.
- CD4+ T lymphocyte count is an important prognostic indicator.

FIGURE 217-3 Kaposi's sarcoma on the foot in a man with AIDS in the 1990s. Note the purple color. (From Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 217-4 Classic Kaposi's sarcoma on the foot of an 85-year-old Hispanic man from Mexico who is HIV-negative. He initially declined radiation and his lesions grew and multiplied over 3 years. Now he is receiving palliative radiation to improve his ability to walk. (Courtesy of Richard P. Usatine, MD.)

FIGURE 217-5 Early Kaposi's sarcoma on the palate. The color is abnormal but the lesion is still flat. (Courtesy of Ellen Eisenberg, DMD.)

IMAGING

Chest radiograph if there is pulmonary involvement. GI endoscopy if GI involvement is suspected.

BIOPSY

Often required for definitive diagnosis. If the lesions are nodular a simple shave biopsy should be sufficient. If the lesions are flat, a 4-mm punch biopsy should provide adequate tissue for diagnosis.

DIFFERENTIAL DIAGNOSIS

The diagnosis of KS requires a biopsy as several other lesions can mimic early KS.⁷

- Purpura—Bleeding under the skin caused by a variety of platelet, vascular, or coagulation disorders; usually not palpable and more widespread.
- Hematomas—Localized swelling usually from a break in a blood vessel; history of trauma and usually not palpable.
- Hemangiomas or angiomas—Benign growths of small blood vessels that blanch with pressure (Chapter 201, Acquired Vascular Skin Lesions).
- Dermatofibromas—Small, firm, red-to-brown nodules made up of histiocytes and collagen deposits in the mid dermis, often seen on the legs; lesions are usually small (<6 mm) and dimple downward when compressed laterally (Chapter 160, Dermatofibroma).
- Bacillary angiomatosis—A systemic infectious disease caused by *Bartonella* species. Cutaneous lesions appear as scattered papules and nodules or an abscess. Bacillary angiomatosis may occur when the CD4 count is below 200 and is treated with antibiotics (Figure 217-7).

MANAGEMENT

KS is not curable, but treatments can reduce disease burden and slow progression (Figure 217-8).

MEDICATIONS

- In patients with HIV/AIDS, HAART (highly active antiretroviral therapy) improves KS. Treat with antiretroviral drugs or refer to a physician with experience initiating and following antiretroviral therapy. Antiretroviral therapy inhibits HIV replication, decreases the response to KSHV, and has antiangiogenic activity. **SOR A**
- Avoid high-dose steroids, as they can severely aggravate KS, especially pulmonary KS.
- Consider KS-specific therapies:
 - Alitretinoin gel 0.1%—Patient applies gel to lesions 2 times a day, increasing to 3 to 4 times a day if tolerated, for 4 to 8 weeks (66% response rate).⁸ **SOR A**
 - Liposomal doxorubicin 20 mg/m² every 3 weeks or liposomal daunorubicin 40 mg/m² every 2 weeks (50% response rate).⁹ **SOR A**
 - Paclitaxel 100 mg/m² every 2 weeks or 135 mg/m² every 3 weeks; response rates 60% to 70% in patients who had failed a prior chemotherapy regimen.¹⁰ **SOR A** Premedication with dexamethasone is recommended.¹⁰

FIGURE 217-6 Kaposi's sarcoma in a 43-year-old man with HIV/AIDS already on antiretroviral therapy. He presented with a diffuse rash and lymphedema in the right leg. The initial biopsy was negative but a second biopsy demonstrated Kaposi's sarcoma. The right leg is significantly larger than the left leg due to the lymphedema. (Courtesy of Richard P. Usatine, MD.)

FIGURE 217-7 Cutaneous bacillary angiomatosis in a man with HIV/AIDS. (From Usatine RP, Moy RL, Tobinick EL, Siegel DM. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 217-8 Kaposi's sarcoma on the arm of a 43-year-old man with HIV/AIDS. The patient is on antiretroviral therapy and has received radiation treatment for the Kaposi's sarcoma. The Kaposi's sarcoma is in remission but the discoloration has remained. Prior to treatment all of the patches on his arms were dark purple like the 1 remaining dark patch. (Courtesy of Richard P. Usatine, MD.)

- Interferon- α at 1 million U/day demonstrated the most benefit to patients with KS limited to the skin and CD4+ T-lymphocyte counts more than 200.¹¹
- Intralesional vinblastine (70% response rate)¹² or radiation therapy (80% response rate) are also effective for skin lesions.¹³ **SOR A**
- Classic and endemic KS are rare in the United States and are often treated with radiation or surgical excision.
- Removing immunosuppressants or radiation can treat transplant-related KS.

In addition to the medications that target KSHV, new therapies are undergoing study that target KSHV-mediating signaling.⁶

PROGNOSIS

- In severe disease requiring systemic therapy, 50% to 85% of patients will respond with either improvement or disease stability; however, the response lasts only 6 to 7 months before therapy has to be repeated. When therapy is repeated, the response times generally decrease.⁶
- Patients with AIDS-related KS have 5-year survival rates of greater than 80% when KS is the AIDS-defining illness and the CD4+ T-lymphocyte count is greater than 200. Survival rates fall to less than 10% when the patient is older than age 50 years and there is another AIDS-defining illness at the time of presentation.¹⁴

FOLLOW-UP

KS, particularly AIDS-related KS, is generally treated by physicians with advanced training in HIV/AIDS management and oncology. Follow-up is determined by disease progression and response to therapy.

PATIENT EDUCATION

- KS is not curable, but several treatments can result in regression of the lesions for a better cosmetic result.
- KS can affect most parts of the body, commonly the skin, oral cavity, GI tract, and lungs.
- During treatment, lesions typically flatten, shrink, and fade (**Figure 217-8**).
- Rarely, starting antiretroviral therapy may cause lesions to flare because of an inflammatory reaction as the immune system begins to recover (immune reconstitution).

218 LYME DISEASE

Thomas J. Corson, DO
Richard P. Usatine, MD
Heidi Chumley, MD

PATIENT STORY

On a warm, summer afternoon a 32-year-old woman presents having had low-grade fevers for 5 days and a rash. On physical examination, the physician notes a large, erythematous, annular patch with central clearing on her back (**Figure 218-1**). The patient states that the rash has gotten progressively larger during the last 3 days and she has had a recent onset of intermittent joint pain. She does not recall being bitten by an insect. She denies taking medications within the last month and has no known allergies. When asked about recent travel, she admits to a camping trip in eastern Massachusetts, which she returned from 4 days ago. The patient was diagnosed with Lyme borreliosis and started on doxycycline 100 mg twice daily for 14 days. She responded quickly to the antibiotics and never developed the persistent stage of Lyme disease.

INTRODUCTION

Lyme disease is an infection caused by the spirochete *Borrelia burgdorferi*, transmitted via tick bite. Most cases of Lyme disease occur in the northeast United States between April and November. Patients experience flu-like symptoms and may develop the pathognomonic rash, erythema migrans. Lyme disease is prevented by avoiding exposure to the tick vector using insect repellent and protective clothing.

EPIDEMIOLOGY

- In 1977, clusters of patients in Old Lyme, Connecticut, began reporting symptoms originally thought to be juvenile rheumatoid arthritis.¹
- In 1981, American entomologist, Dr. Willy Burgdorfer, isolated the infectious pathogen responsible for Lyme disease from the midgut of *Ixodes scapularis* (a.k.a., black-legged deer ticks) (**Figure 218-2**), which serve as the primary transmission vector in the United States.¹
- It was identified as a bacterial spirochete and named *B. burgdorferi* in honor of its founder.
- Based on Centers for Disease Control and Prevention (CDC) data reported in 2007, Lyme disease (or Lyme borreliosis) is the most common tickborne illness in the United States, with an overall incidence of 7.9 per 100,000 persons.²
- In 2010, 94% of Lyme disease cases were reported from 12 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota,

FIGURE 218-1 A 32-year-old woman presents having had 5 days of low-grade fevers and the typical eruption of erythema migrans on her upper back. Note the expanding annular lesion with a target-like morphology. (Courtesy of Thomas Corson, MD.)

FIGURE 218-2 The deer tick transmits the *Borrelia* spirochete. This is an unengorged female black-legged deer tick. The tick is tiny and can be undetected in its unengorged state. (Courtesy of Thomas Corson, MD.)

New Jersey, New Hampshire, New York, Pennsylvania, Virginia, and Wisconsin.³

- Patients living between Maryland and Maine accounted for 93% of all reported cases in the United States in 2005, with an overall incidence of 31.6 cases for every 100,000 persons.²
- More than 90% of cases report onset between April and November.²

ETIOLOGY AND PATHOPHYSIOLOGY

- *B. burgdorferi* begins to multiply in the midgut of *I. scapularis* ticks upon attaching to humans.
- Migration from midgut to salivary glands of ticks requires 24 to 48 hours.
- Prior to this migration, host infection rarely occurs.
- Common hosts include field mice, white-tailed deer, and household pets.
- Ticks must feed on infested hosts in order to infect humans.
- Thirty percent of infected patients do not recall being bitten.⁴
- Once a human is infected, disease progression is categorized into three stages: localized, disseminated, and persistent.

DIAGNOSIS

CLINICAL FEATURES

Localized (days to weeks)

Erythema migrans (formerly known as *erythema chronicum migrans*)

This pathognomonic finding occurs in roughly 68% of Lyme disease cases.⁴ Described as a “bull’s-eye” eruption (**Figures 218-1 and 218-3 to 218-6**), this nonpruritic, maculopapular lesion typically occurs near the site of infection. The erythematous perimeter migrates outward over several days while the central area clears. Multiple lesions in different sites can develop in some individuals (**Figures 218-3 and 218-4**). Erythema migrans can persist for 2 to 3 weeks if left untreated.

Flu-like symptoms

Roughly 67% of patients will develop flu-like symptoms that can include fever, myalgias, and lymphadenopathy. Symptoms usually subside within 7 to 10 days.

Disseminated (days to months)

Inflammatory arthritis

Typical onset occurs around 3 to 6 months after localized infection. Patients will often present with polyarticular, migratory joint pain with or without erythema, and swelling, which is exacerbated with

FIGURE 218-3 An 11-year-old girl with erythema migrans eruption on her shoulder. She is febrile and systemically ill. (Courtesy of Jeremy Golding, MD.)

FIGURE 218-4 Same 11-year-old girl in **Figure 218-3** with multiple erythema migrans eruptions on her legs. (Courtesy of Jeremy Golding, MD.)

motion. After more than 24 to 48 hours, these symptoms localize to one joint (especially knee, ankle, or wrist) and last approximately 1 week. Recurrence is common and usually happens every few months, but typically resolves within 10 years even without treatment.

Cranial nerve palsy

Bell palsy (seventh cranial nerve) is the most common neurologic manifestation of Lyme disease. However, nearly every cranial nerve has been reported to be involved. Facial nerve palsy is a lower motor neuron lesion that results in weakness of both the lower face and the forehead. Lasting up to 8 weeks, the resolution of symptoms is gradual and begins shortly after initial onset (see Chapter 233, Bell Palsy).

Atrioventricular blockade

Present in only 1% of patients with Lyme disease, syncope, lightheadedness, and dyspnea are classic symptoms consistent with atrioventricular (AV) dysfunction.³ However, patients can be completely asymptomatic. The degree of Lyme-associated blockade varies so that symptoms are generally episodic. Most cases resolve spontaneously within 1 week.⁴ Any patient with history and/or examination findings suspicious of Lyme disease should undergo ECG testing. Hospitalization and continuous monitoring are advisable for symptomatic patients, for patients with second- or third-degree AV block, as well as for those with first-degree heart block when the PR interval is prolonged to 30 or more milliseconds, because the degree of block may fluctuate and worsen very rapidly in such patients.⁵

Aseptic meningitis

Patients may present with complaints similar to bacterial meningitis (photophobia, nuchal rigidity, and headache), but symptoms are generally less severe in nature. This can also occur with or without concomitant cranial nerve palsy.⁴

Fatigue

A depressed level of activity as a result of fatigue is one of the most common complaints, affecting up to 80% of infected patients. Even after adequate treatment, symptoms consistent with chronic fatigue syndrome have developed in patients with known Lyme disease.

Persistent (longer than 1 year)

Chronic arthritis

Generally occurs in the knee, although other sites such as the shoulder, ankle, elbow, or wrist are not uncommon. Approximately 10% of patients with intermittent arthritis will progress to this stage.⁴

Chronic fatigue

Commonly misdiagnosed as fibromyalgia or chronic fatigue syndrome, patients develop debilitating malaise and myalgias that can persist for months or years after infection.

Meningoencephalitis

Symptoms vary from mild (memory loss, mood lability, irritability, or panic attacks) to severe (manic or psychotic episodes, paranoia, and obsessive/compulsive symptoms).⁵

FIGURE 218-5 A 12-year-old girl with erythema migrans eruption on her right arm. The annular border is somewhat raised and there is central clearing. (Courtesy of Jeremy Golding, MD.)

FIGURE 218-6 A 26-year-old man with erythema migrans eruption on right medial thigh. The central papule is the site of the bite, and there has not been much central clearing yet. (Courtesy of Gil Shlamovitz, MD.)

LABORATORY TESTING

Diagnosing Lyme disease is generally based on pertinent history findings and/or the presence of an erythema migrans lesion, especially in endemic areas. In cases where an erythema migrans lesion is absent, serologic testing may be warranted utilizing the following tests:

- Enzyme-linked immunosorbent assay (ELISA) (sensitivity: 94%, specificity: 97%)⁶—Used as a *screening* test in patients lacking physical signs of erythema migrans. Up to 50% of patients with early infection can have a false-negative result. If strong suspicion remains, convalescent titers should be obtained in 6 weeks.⁶ Prior infection does not indicate immunity. Lyme titers may be falsely positive in patients with mononucleosis, periodontal disease, connective tissue disease, and other less common conditions.⁷
- Western blot (immunoglobulin [Ig] M and IgG for *B. burgdorferi*)—If ELISA test yields a positive result, Western blot test is used as a *confirmatory* test. IgM antibodies are detectable between 2 weeks and 6 months after inoculation. IgG may be present indefinitely after 6 weeks, despite appropriate antibiotic therapy. Once it is determined that a person is seropositive for Lyme disease, antibiotic therapy should be initiated promptly.

Empiric antibiotic therapy (no test necessary) should be considered in any of the following clinical presentations: presence of EM rash, flu-like symptoms (in absence of upper respiratory infection [URI] or GI symptoms) after known tick bite, Bell palsy in endemic areas, especially between June and September, and tick bites occurring during pregnancy.

Characteristic laboratory findings

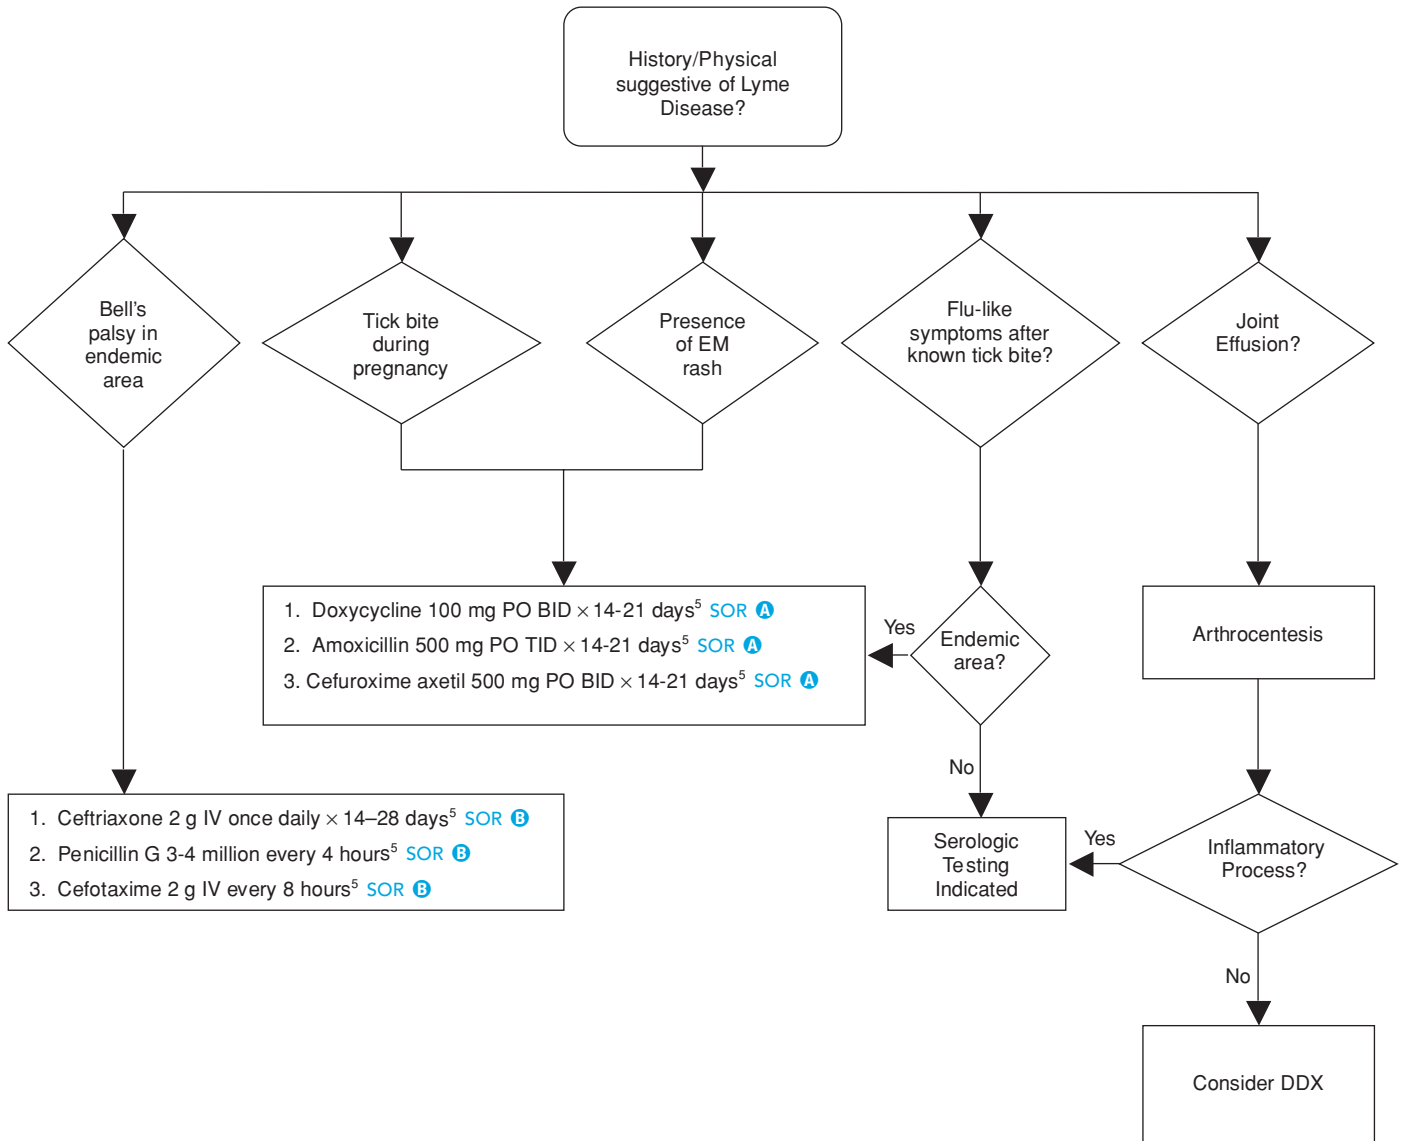

- Complete blood count (CBC)—Leukocytosis (11,000 to 18,000/ μ L). Anemia and thrombocytopenia are rare.
- Elevated erythrocyte sedimentation rate (ESR) (>20 mm/h).
- Elevated γ -glutamyltransferase (GGT) and aspartate aminotransferase (AST).
- Cerebrospinal fluid—Pleocytosis and elevated protein levels if central nervous system (CNS) is involved. Spirochete antibodies may be detectable.
- Blood culture—Low yield; not recommended.
- Nerve conduction studies and EM—Useful in patients with paresthesias or radicular pain.
- ECG should be performed in all patients with history and physical examination suspicious for Lyme disease to detect AV block and arrhythmias.

DIFFERENTIAL DIAGNOSIS⁸

- Cellulitis—Spreads more rapidly than Lyme disease. Induration and tenderness are more common. Negative Lyme serologies (see Chapter 120, Cellulitis).

- Urticaria—Can resemble erythema migrans when the urticarial lesions are annular. Urticaria is generally more widespread and the wheals come and go over time whereas the lesion of EM is more fixed (see Chapter 150, Urticaria and Angioedema).
- Rocky Mountain spotted fever—Associated with *Dermacentor variabilis* (American dog) tick; rash is petechial and the spots are widely distributed over the body (see Chapter 179, Vasculitis, Figure 179-17). Patients often appear toxic.
- Cutaneous fungal infections—Usually pruritic and may be annular; associated with scaling, which is not characteristic of erythema migrans; and spreads slowly if at all. The similarity is that the annular appearance of tinea corporis can mimic EM (see Chapter 138, Tinea Corporis).
- Local reaction to tick bites—Tick bites may cause a local reaction in skin and do not expand with time; generally less than 2 cm in diameter, and are usually papular.
- Febrile viral illnesses (particularly enteroviruses during summer)—Rash, myalgias, arthralgias, and headache; GI symptoms; sore throat and/or cough. Perform Lyme serologic test in the absence of erythema migrans.
- Facial nerve palsy—May be bilateral in Lyme disease. This is uncommon in facial nerve palsy not associated with Lyme disease (see Chapter 233, Bell Palsy).
- Viral meningitis—Lymphocytic (aseptic) meningitis caused by viral infection generally results in transient illness that resolves within several days, usually after a monophasic course.
- Heart block—Idiopathic conduction system disease (sick sinus syndrome) can present with the same symptoms and signs as Lyme carditis. Use serologic testing and epidemiologic history to discriminate.
- Inflammatory arthritis (reactive arthritis, gout, pseudogout, and rheumatoid arthritis)—acute, large joint monoarticular or oligoarticular arthritis from multiple causes; may be indistinguishable from acute arthritis associated with Lyme disease at the time of presentation; joint fluid examination, and culture and x-ray may help distinguish from Lyme arthritis (see Chapter 95, Arthritis Overview).
- Peripheral neuropathy is more often associated with diabetes mellitus, peripheral vascular disease, endocrinopathies, and nerve root impingement syndromes. If Lyme disease is the cause, the serologies should be positive.
- Radiculoneuropathy—Dermatomal pain, sensory loss, and/or weakness in a limb or the trunk. Check serologies if Lyme disease is suspected.
- Encephalomyelitis—Focal inflammation of the brain or spinal cord. Check serologies if Lyme disease is suspected.

MANAGEMENT

MEDICATIONS

Localized:

- Adults—Doxycycline 100 mg twice a day (nonpregnant patients only) or amoxicillin 500 mg 3 times a day or cefuroxime 500 mg twice a day for 14 days.⁵ **SOR A**
- Children—Amoxicillin 50 mg/kg divided 3 times a day up to 500 mg per dose or cefuroxime 30 mg/kg divided twice a day up to 500 mg per dose; older than 8 years of age—doxycycline 4 mg/kg divided twice a day up to 100 mg/dose.⁵ **SOR A**

Meningitis or other neurologic manifestations:

- Adults—Ceftriaxone 2 g IV every day for 14 days; alternative therapy cefotaxime 2 g IV every 8 hours or penicillin G 18 to 24 million U every day divided into 6 daily doses for 14 days.⁵ **SOR B**
- Children—Ceftriaxone 50 to 75 mg/kg IV up to a maximum of 2 g/day for 14 days; alternative therapy cefotaxime 150 to 200 mg/kg per day up to a maximum of 6 g/day, divided into 3 to 4 doses per day.⁵ **SOR B**
- Doxycycline (oral) 100 to 200 mg twice a day for 10 to 28 days may be effective; consider for nonpregnant adults or children older than 8 years of age who are intolerant to β -lactam antibiotics.⁵ **SOR B**
- Lyme carditis—Oral or IV antibiotics as above with hospitalization and continuous cardiac monitoring in patients with symptoms including syncope, shortness of breath, or chest pain, or in patients with AV block.⁵ **SOR B**

Persistent Lyme disease

- Arthritis without neurologic disease—Doxycycline, amoxicillin, or cefuroxime; amoxicillin, cefuroxime in children younger than 8 years of age; medications at doses shown under early disease with therapy extended to 28 days.⁵ **SOR B** If arthritis persists, treat for another 28 days with oral antibiotics or a 28-day regimen of IV antibiotics.
- Neurologic disease—IV therapy with ceftriaxone for 14 to 28 days.⁵ **SOR B**

REFERRAL OR HOSPITALIZATION

- Symptomatic patients with Lyme carditis should be hospitalized with continuous cardiac monitoring.
- Consider referring patients in whom the diagnosis is unclear or who do not respond to initial therapy.

PREVENTION

- Avoid exposure to ticks by using protective clothing and tick repellent. If hiking in tick-infested areas check body daily for ticks and promptly remove any attached ticks.
- Prophylactic doxycycline (1 dose of 200 mg) is recommended only if the tick is identified as an adult or nymphal *I. scapularis* tick that has been attached for at least 36 hours; medication can be started within 72 hours of tick removal; local rate of infection of ticks with *B. burgdorferi* is at least 20%; and doxycycline is not contraindicated.⁵

PROGNOSIS

- Most patients respond to appropriate therapy with prompt resolution of symptoms within 4 weeks.
- Posttreatment Lyme disease syndrome (persistent or recurrent symptoms) occurs in 10% to 20% of patients despite appropriate treatment. Prolonged antibiotic treatment is not effective.³ Most patients eventually feel completely well, but this can take months or years.
- True treatment failures are uncommon and prolonged oral or parenteral antibiotic courses are emphatically discouraged. In patients who continue to present with residual subjective symptoms, providers should seek alternate diagnoses and/or referral to an appropriate specialist.

FOLLOW-UP

Follow patients during antibiotic therapy through recovery.

PATIENT EDUCATION

Prevention is accomplished by reducing exposure to ticks. If you live in an area that has Lyme disease then use tick repellent, tick checks, and other simple measures to prevent tick bites. This is especially important during the high-risk months of April through November. Patients should know the early signs of Lyme disease so that they can get care early when it is most curable.

If a tick is found on the skin, remove it early using fine-tipped tweezers. See patient resources below.

Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1447–1450 for further information.

219 DIABETES OVERVIEW

Mindy A. Smith, MD, MS

PATIENT STORY

A 66-year-old man with obesity and mild hypertension controlled with a diuretic presents with increasing nocturia and excessive thirst. He has no other urinary symptoms and denies any visual problems. His mother had diabetes and died at age 85 years from a heart attack. His only other concern is a recurrent fungal infection on his feet. His blood pressure in the office today is 135/85 mm Hg and his finger stick blood sugar is 220 mg/dL. You explain that based on his elevated blood sugar, he has diabetes mellitus. Physical exam findings confirm the diagnosis of tinea pedis (**Figure 219-1**). A monofilament test demonstrates normal sensation in his feet. You order a fasting blood sugar, lipid profile, serum electrolytes, creatinine, and hemoglobin A_{1c}. You ask him to return next week for a more complete examination, review of his test results, and diabetes education. You ask him and his wife to consider meeting with a nutritionist, and briefly review treatment options, including diet, exercise, and metformin, as well as a possible need to improve his blood pressure control or switch to another agent. You suggest a nonprescription antifungal cream and will see if he needs additional treatment for his feet at follow-up. The patient is referred to an ophthalmologist who finds diabetic nonproliferative retinopathy (**Figure 219-2**).

INTRODUCTION

Diabetes is a group of disorders caused by a complex interaction between genetic susceptibility, environmental factors, and personal lifestyle choices that share the phenotype of hyperglycemia. Type 2 diabetes mellitus (DM) is a heterogeneous group of chronic disorders caused by a progressive insulin secretory defect and increased glucose production in the setting of insulin resistance.

EPIDEMIOLOGY¹

- Prevalence—In the United States, 25.8 million adults and children (8.3% of the population), including 18.8 million who have been diagnosed, have diabetes. This includes about 1 in 400 children and adolescents and 26.9% of people age 65 years and older. Type 2 DM is the most common form, accounting for more than 90% of cases.
- Incidence—In the United States in 2010, there were 1.9 million new cases among individuals 19 years of age and older.
- Highest rates of diabetes are in non-Hispanic blacks (12.6%), followed by Hispanics (11.8%), Asian Americans (8.4%), and non-Hispanic whites (7.1%).

FIGURE 219-2 Nonproliferative diabetic retinopathy, with scattered intraretinal dot-blot and flame hemorrhages, along with macular exudates. Macular exudates can be related to diabetic macular edema, which accounts for a large portion of poor vision and disability secondary to diabetic retinopathy. (Courtesy of Andrew Sanchez, COA.)

- In 2007, total costs of diagnosed DM in the United States were \$174 billion (\$116 billion in direct medical costs).

ETIOLOGY AND PATHOPHYSIOLOGY

- Insulin resistance is attributed to obesity, inactivity, and genetic factors (including defects in β -cell function and insulin action).
- Initially, the pancreatic β cells increase insulin production to overcome insulin resistance and maintain euglycemia. Eventually, β cells fail, resulting in hyperglycemia.
- Other contributing factors include diseases of the pancreas (e.g., pancreatitis, hemochromatosis), infection (e.g., cytomegalovirus), and other endocrinopathies (e.g., hyperthyroidism [see Chapter 227, Graves Disease and Goiter] and acromegaly [see Chapter 228, Acromegaly]).
- Microvascular and macrovascular diseases may result from hyperglycemia or other metabolic changes.

RISK FACTORS¹⁻⁴

- Obesity.*
- Red meat consumption (relative risk [RR] 1.51; 95% confidence interval [CI], 1.25, 1.83 for 50 g processed red meat/day).⁵
- Physical inactivity (also television viewing 2 h/day; odds ratio [OR] 1.20; 95% CI, 1.14 to 1.27).^{6*}
- Nonwhite race.*
- First-degree relative with diabetes, hypertension, or myocardial infarction.*
- Prior gestational diabetes.*
- Impaired glucose tolerance (hazard ratio [HR] 13.2, 95% CI, 10.8 to 16.2).⁷
- Polycystic ovarian syndrome.
- Coronary heart disease, hypertension.*
- Smoking (OR [current smoker] 1.44; 95% CI, 1.31 to 1.58).
- Antipsychotic therapy for patients with schizophrenia or severe bipolar disease.*
- Previously identified glucose intolerance.*
- Prolonged use of oral corticosteroids.

*Risk factors used by the American Association of Clinical Endocrinologists (AACE) in making decisions for screening patients for DM (see below).⁴

Many risk models and scores have been developed to predict the development of DM.⁸ Authors of a systematic review identified seven risk scores that had high potential for use in practice based on similar components and discriminatory properties.⁴ One of these, the Framingham Offspring Study,⁹ uses fasting plasma glucose levels, body mass index, high density lipoprotein cholesterol and triglyceride levels, parental history of diabetes and blood pressure to determine risk. Unfortunately, none of the models were developed on a cohort recruited prospectively, and no studies have demonstrated a reduction in incident DM using risk scoring and intervention.

DIAGNOSIS

The AACE guideline defines the diagnosis of diabetes as a fasting (8 or more hours of no caloric intake) glucose level 126 mg/dL or greater (≥ 7.0 mmol/L), or a 2-hour plasma glucose 200 mg/dL or greater (≥ 11.1 mmol/L) on a 75-g oral glucose tolerance test, or a random plasma glucose level of greater than 200 mg/dL with symptoms of diabetes, or a hemoglobin A_{1c} level of 6.5% or higher.⁴ **SOR A** The same test should be repeated on a different day to confirm the diagnosis unless the patient has unequivocal hyperglycemia or severe metabolic stress. **SOR C**

CLINICAL FEATURES

- Many patients with type 2 DM are asymptomatic.
- Patients may report polydipsia, polyuria, and blurred vision.
- Fundoscopic examination may reveal signs of retinopathy (hard exudates, hemorrhages) (**Figure 219-2**; see Chapter 20, Diabetic Retinopathy).
- Patients with diabetic neuropathy may have abnormalities on monofilament, vibration, and superficial pain testing.
- Skin changes in patients with DM include diabetic dermopathy in 15% to 40% of patients (**Figure 219-3**; see Chapter 221, Diabetic Dermopathy),¹⁰ acanthosis nigricans in approximately one-third of patients (**Figure 219-4**; see Chapter 220, Acanthosis Nigricans),¹¹ diabetic foot ulcers (**Figure 219-5**; see Chapter 210, Ischemic Ulcer), and, uncommonly, necrobiosis lipoidica (**Figure 219-6**; see Chapter 222, Necrobiosis Lipoidica).
- Hyperlipidemia may result in eruptive xanthomas (**Figure 219-7**) or xanthelasma.
- Patients with DM of prolonged duration may also have Charcot joints (**Figure 219-8**; see Chapter 212, Charcot Joints).¹²

LABORATORY TESTS

- The American Diabetes Association (ADA) recommends fasting plasma glucose as the preferred diagnostic test because of poor patient acceptance of the glucose tolerance test.¹³ A value of 126 mg/dL or greater is diagnostic, although a second confirming test is recommended. Other tests that can be used for diagnosis are listed above.
- Hemoglobin A_{1c} is less sensitive to low levels of hyperglycemia than either the fasting plasma glucose or glucose tolerance tests and is not currently recommended by the ADA as a diagnostic test.
- A random capillary blood glucose may be a reasonable alternative. Compared with traditional criteria, a capillary blood glucose level of greater than 120 mg/dL has a sensitivity of 75% and specificity of 88% for the diagnosis of type 2 DM.¹⁴
- In cases where there is uncertainty regarding the diagnosis of type 1 or type 2 DM, glucagon-stimulated C-peptide, 2-hour postprandial urinary C-peptide-to-creatinine ratio, and 4-hour postprandial urinary C-peptide concentration can be used help distinguish between the types.

FIGURE 219-4 Acanthosis nigricans in a woman with type 2 diabetes and obesity. She is requesting that her skin tags be removed. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT

The primary treatment goals for the patient with DM are to aggressively control blood pressure (<130/80 mm Hg) and lower lipids (low-density lipoprotein [LDL] goal is <100 mg/dL) to improve cardiovascular and all-cause mortality. Reasonable blood glucose control (hemoglobin A_{1C} near 7%) is usually undertaken with metformin; this author believes that tight/strict control should no longer be stressed as it does not improve most outcomes and increases episodes of hypoglycemia. In the ADVANCE (Action in Diabetes and Vascular Disease: Preterax and Diamicon Modified-Release Controlled Evaluation) trial (N = 11,140), there were no differences seen in the rates of major macrovascular events or overall mortality between patients randomized to intense control (hemoglobin A_{1C} ≤6.5%) or standard control.¹⁵ Furthermore, in the ACCORD (Action to Control Cardiovascular Risk in Diabetes) trial, intensive insulin therapy in patients with type 2 DM was associated with increased mortality in participants randomized to the very intensive glycemic control arm (hemoglobin A_{1C} <6%).¹⁶ A recent metaanalysis of 14 trials also concluded that intensive control did not reduce all-cause mortality; data were insufficient to confirm a relative risk reduction for cardiovascular morbidity or mortality, composite microvascular complications, or retinopathy at a magnitude of 10%.¹⁷ Intensive glycemic control increased the relative risk of severe hypoglycemia by 30%.¹⁷

In epidemiologic research, a hemoglobin A_{1C} level less than 7% is associated with the best outcomes and the ADA uses a hemoglobin A_{1C} of less than 7% as the benchmark for adequate control. The AACE recommends a glucose target of 6.5% or less in most nonpregnant adults if it can be achieved safely, as near-normal levels may prevent microvascular (e.g., retinopathy) complications.⁴ **SOR C**

NONPHARMACOLOGIC

Diet and exercise interventions:

- Diet—Nutrition advice may be best delivered by a registered dietician familiar with DM. Guidelines from the ADA and AACE agree that the diet should contain carbohydrate from fruits, vegetables, whole grains, legumes, and low-fat milk, and be kept consistent on a day-to-day basis with respect to time and amount.¹⁸ In otherwise healthy patients with DM, optimal diets include protein (15% to 20% of daily energy intake), fiber (25 to 50 g/day, with special emphasis on soluble fiber sources [7 to 13 g], to help to lower cholesterol), and dietary fat of less than 30% of daily energy intake.
- A Cochrane review of 11 randomized controlled trials (RCTs) concluded that a low-glycemic index diet improved glycemic control over a higher-glycemic index diet with fewer hypoglycemic episodes in one trial and fewer hyperglycemic episodes in another trial.¹⁹
- Daily consumption of vitamin D (500 IU as a fortified yogurt drink or supplement vs. placebo) improved glycemic control in one trial of patients with type 2 DM,²⁰ but not in another trial with patients with type 2 DM and normal vitamin D levels.²¹ Vitamin D appears to have a positive effect on insulin resistance.²²
- Weight-loss strategies for those who are overweight include diet, physical activity, and behavioral interventions. This combination can result in slight sustained weight loss (1.7 kg or 3.1% of baseline body weight) in comparison with usual care and lowers hemoglobin

FIGURE 219-5 Diabetic foot ulcer that has occurred at the amputation site. (Courtesy of Richard P. Usatine, MD.)

FIGURE 219-6 Necrobiosis lipoidica diabetorum on the lower leg with typical findings of skin atrophy, yellow coloration, and prominent blood vessels. (Courtesy of Richard P. Usatine, MD.)

A_{1C}.²³ **SOR A** A more recent RCT (N = 593) found an intensive dietary intervention (dietary consultation every 3 months with monthly nurse support) reduced hemoglobin A_{1C} over the control group (actually had increased hemoglobin A_{1C}); the activity intervention did not confer additional benefit.²⁴

- Even without weight loss, structured exercise (>150 min/wk) significantly improves glycemic control in patients with type 2 DM.²⁵ **SOR A** In this metaanalysis, a combination of dietary and exercise advice also lowered hemoglobin A_{1C}.²⁵ Individuals with type 2 DM are advised to get 30 to 90 min/day (AAACE) or 90 to 150 min/wk (ADA) of exercise to improve glycemic control.^{7,13}

Education, self-management, and self-monitoring interventions:

- Group-based diabetes education is associated with reductions in hemoglobin A_{1C}, systolic blood pressure, body weight, and the need for diabetic medications.²⁶ **SOR A** In another Cochrane review, use of a specialized diabetes nurse or case manager improved short-term glycemic control but not improve longer-term outcomes, such as hospital admission rates and quality of life.²⁷ Although one recent trial (N = 201) of behavioral support (video and five telephone sessions) for patients with poorly controlled DM did not show benefit on outcomes,²⁸ another trial (N = 222) using five educator-led group sessions for patients with poorly controlled DM did find improved glycemic control over the control group, although there were no differences in quality of life or frequency of diabetes self-care.²⁹
- Authors of a Cochrane review of 12 trials on blood glucose self-monitoring in patients with type 2 DM not using insulin found a small effect of self-monitoring on glycemic control (reduced hemoglobin A_{1C}) that lasted up to 6 months after initiation but not at or beyond 12 months.³⁰ There was no evidence that self-monitoring affected patient satisfaction, general well-being, or general health-related quality of life. However, self-monitoring of glucose may be useful for assessing and preventing hypoglycemia and adjusting medications, medical nutrition therapy, and physical activity.⁴
- Structured goal setting was shown in a RCT (N = 87) to improve glycemic control up to 1-year postintervention.³¹

MEDICATIONS

Agents that can be used for initial blood pressure control include diuretics, angiotensin-converting enzyme (ACE) inhibitors, and β blockers. The AAACE considers ACE inhibitors or angiotensin II receptor blockers (ARBs) the preferred choice in patients with DM.⁷ Combinations of medications may be needed. The blood pressure target is less than 130/80 mm Hg.^{4,13} **SOR C**

- In one trial, an ACE inhibitor plus an ARB increased the risk of advancement to renal dialysis.³²
- In the ACCORD trial of intensive blood pressure control in patients with type 2 DM (N = 4733), there were no additional cardiovascular benefits to targeting a systolic blood pressure of 120 mm Hg versus 140 mm Hg. Patients treated with intensive blood pressure lowering were more likely to experience serious adverse effects (3.3% vs. 1.3%).³³
- In a subgroup analysis from another large blood pressure (BP) trial, progressively greater systolic BP reductions were associated with reduced risk for the primary outcome (pooled cardiovascular [CV]

FIGURE 219-7 Eruptive xanthomas on the extremities and trunk of a young man with untreated type 2 diabetes and hyperlipidemia. (Courtesy of Richard P. Usatine, MD.)

FIGURE 219-8 Charcot feet bilaterally in a person with poorly controlled diabetes. Note the pronation of the feet with the abnormal bulging of the medial foot. X-rays showed abnormal tarsal bones secondary to diabetic neuropathy. (Courtesy of Richard P. Usatine, MD.)

death, nonfatal myocardial infarction or stroke, or hospitalized heart failure) only if the baseline systolic BP levels ranged from 143 to 155 mm Hg; there was no benefit in fatal or nonfatal CV outcomes by reducing systolic BP below 130 mm Hg.³⁴

Agents used for glycemic control include metformin (biguanide that suppresses hepatic glucose production), sulfonylureas (e.g., glyburide that potentiates insulin secretion), glinides (e.g., nateglinide that potentiates insulin secretion), α -glucosidase inhibitors (e.g., acarbose that decreases intestinal carbohydrate absorption), thiazolidinediones (e.g., rosiglitazone that improves insulin sensitivity), incretin mimetic agent (Bydureon enhances insulin secretion and slows gastric emptying), and a dipeptidyl peptidase inhibitor (sitagliptin that improves glucagon-like peptide levels). Details on efficacy, dosing, and safety can be found elsewhere.⁴

- Of the oral hypoglycemic agents, only metformin and the sulfonylureas have been shown to decrease long-term vascular complications and only metformin decreases all-cause mortality (independently of its effect on glycemic control).^{35,36} **SOR A** Monotherapy, although initially effective for many patients, fails to sustain control in approximately half of patients at 3 years.³⁷
- Addition of a second oral agent should be considered when monotherapy does not provide adequate control, usually a sulfonylurea is added and is likely most cost-effective.³⁸ **SOR C** Sulfonylureas, glinides, and α -glucosidase inhibitors appear equal in effectiveness when added to metformin.³⁹ A thiazolidinedione also can be used, but there is concern about increased risk of myocardial infarction; data are conflicting.
- If dual therapy does not provide adequate control, options include adding a basal insulin (e.g., glargine or detemir), a thiazolidinedione, or dipeptidyl peptidase inhibitor. A metaanalysis of 18 trials did not find a clear difference in benefit between drug classes when adding a third agent for patients who were already on metformin and a sulfonylurea.⁴⁰ Bydureon, a once-weekly injection, although recently FDA approved, is costly and data are limited as this is so new. In the United Kingdom Prospective Diabetes Study (UKPDS) trial, the use of insulin therapy for patients with type 2 DM was not associated with decreased CV or all-cause mortality despite reductions in blood sugar.⁴¹ A Cochrane review of six trials also did not find evidence of major clinical benefit for use of long-acting insulin analogues for patients with type 2 DM.⁴² Finally, if insulin is added, continuing metformin if possible is advised as there is less weight gain associated with this combination.⁴³
- Consultation with an endocrinologist is suggested if a third agent is needed and choice of agent should be made with consideration of the patient's age (decline in renal and cardiac function may preclude use of metformin, a thiazolidinedione, or long-acting sulfonylurea), weight (metformin, acarbose, exenatide, sitagliptin, and human amylin are more often associated with weight loss or maintenance), and comorbidities.⁴ **SOR C**
- If further control is needed, options include discontinuing oral therapy and using combination insulin therapy.

Agents used for lipid control in patients whose lipids are not controlled by diet and exercise is usually achieved with statin therapy.⁴ If the initial statin does not result in adequate control, the AACE recommend intensifying that statin to meet the LDL cholesterol goals.⁴

SOR A If the LDL goal cannot be met with high-dose statin therapy, there is no evidence to prove that adding other LDL-lowering drug classes will improve outcomes for people with DM.

Treatment of complications of DM is described in detail elsewhere.⁴

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Several Chinese herbal medicines (e.g., Xianzhen Pian, Qidan Tongmai) show hypoglycemic effects in patients with type 2 DM but current evidence does not support widespread use.⁴⁴
- In another Cochrane review of herbal mixtures, significant reductions in hemoglobin A_{1c}, fasting blood sugar or both were observed with Diabecan, Inolter, and Cogent db compared to placebo; however, small sample sizes precluded definite conclusions regarding efficacy.⁴⁵

REFERRAL OR HOSPITALIZATION

- Consider referral for bariatric surgery for patients with DM who have a body mass index (BMI) of 35 kg/m² or more as this facilitates weight loss and improvement or reversal of hyperglycemia⁴; surgery has not yet been shown to decrease all-cause mortality or provide long-term benefit, and long-term risk is unknown. **SOR A**
- Consultation with a foot specialist is recommended for patients with DM and foot deformity, infected lesions, foot ulcers, or deformed nails or thick calluses.⁴ **SOR C**
- Refer patients with diabetic retinopathy to an ophthalmologist for evaluation and treatment. **SOR B**
- Consider consultation with a vascular surgeon for patients with peripheral vascular disease. **SOR C**
- Patients with type 2 DM may require hospitalization for hyperglycemic crises (e.g., hyperosmolar hyperglycemic state, ketoacidosis).

PREVENTION AND SCREENING

Primary prevention is considered for patients who have prediabetes, defined by the AACE as the presence of impaired glucose tolerance (i.e., an oral glucose tolerance test glucose value of 140 to 199 mg/dL, 2 hours after ingesting 75 g of glucose and/or a fasting glucose value of 100 to 125 mg/dL).⁴ Each year 3% to 10% of individuals with prediabetes will progress to type 2 DM.⁴⁶

- Lifestyle changes that can prevent or at least delay type 2 DM in persons who have prediabetes include weight loss of 5% to 10% of body weight in overweight individuals and participation in moderate physical activity.^{4,47,48} **SOR A**
- Smoking cessation should be encouraged; tobacco smoking increases the risk of macrovascular complications approximately 4% to 400% in adults with type 2 DM (see Chapter 236, Tobacco Addiction).
- Provide annual influenza immunization and pneumococcal vaccine as needed; repeat the pneumococcal vaccine at 5 years for patients with nephrotic syndrome, or chronic renal disease, or who are immunocompromised, or who are receiving the vaccine before age 65 years if 5 years has passed since the primary vaccine was given.⁴

- The AACE also recommends that metformin be considered for those with prediabetes who are younger patients at moderate to high risk for developing DM; for patients with additional cardiovascular disease risk factors including hypertension, dyslipidemia, or polycystic ovarian syndrome; for patients with a family history of DM in a first-degree relative; and/or for patients who are obese.⁴ A recent RCT found pioglitazone effective in reducing the risk of conversion of impaired glucose tolerance to type 2 DM (annual incidence rate 2.1% vs. 7.6% with placebo), but was associated with significant weight gain and edema.⁴⁹
- In a metaanalysis of lifestyle and pharmacologic interventions for the prevention or delay of DM in patients with impaired glucose tolerance, the number needed to treat to benefit was 6.4 for lifestyle (95% CI, 5.0 to 8.4), 10.8 for oral diabetes drugs (95% CI, 8.1 to 15.0), and 5.4 for orlistat (95% CI, 4.1 to 7.6).⁵⁰ **SOR A**
- Low-dose aspirin is recommended for patients with DM who have risk factors for CV disease and are older than age 40 years.¹³

Secondary prevention for micro- and macrovascular disease:

- Use of an ACE inhibitor or ARB can prevent progression of diabetic nephropathy.⁵¹ **SOR A**
- Patients with DM should undergo a dilated comprehensive eye examination at diagnosis and annually.¹³ **SOR C** Panretinal scatter photocoagulation reduces the risk of severe visual loss by more than 50% in eyes with high-risk characteristics, and immediate focal laser photocoagulation reduces the risk of moderate visual loss by at least 50% in patients with clinically significant macular edema.⁵²
- Patients with DM should also undergo screening for peripheral neuropathy at diagnosis and annually, with inspection and assessment of pulses and sensation, using a monofilament and one additional sensory test (e.g., pinprick, vibration perception).¹³ Patients with peripheral vascular disease, foot ulcers, or diabetic foot deformity should be considered for referral (as above) to prevent limb loss.
- As discussed above, patients with well-controlled BP, lipids, and good glycemic control have a lower risk of macrovascular and microvascular disease, and diabetic dermopathy.^{4,10} For example, estimates for years of life saved with lipid lowering in patients with diabetes are 3 years to 3.4 years for men and 1.6 years to 2.4 years for women; greater increases than for patients without diabetes.⁵³

The United States Preventive Services Task Force (USPSTF) recommends screening for type 2 DM in asymptomatic adults with sustained BP (either treated or untreated) greater than 135/80 mm Hg, **SOR B** but finds insufficient evidence to promote screening for asymptomatic adults with lower BP.⁵⁴

- Screening for type 2 DM should be considered in the presence of risk factors for DM (see “Risk Factors” above) and for patients who have increased levels of triglycerides or low concentrations of high-density lipoprotein cholesterol.⁴ **SOR C**
- All pregnant women should be screened for gestational DM at 24 to 28 weeks’ gestation, using a 75-g (glucose), 2-hour oral glucose tolerance test.⁴ **SOR B** There is currently a lack of consensus, however, on optimal screening; the American College of Obstetricians and Gynecologists recommends selective (risk-based) screening, the ADA recommends universal screening, and the USPSTF found insufficient evidence for or against screening.

PROGNOSIS

- Sustained elevation in fasting blood glucose levels and 2-hour post-load glucose testing, even when below the threshold for a diabetes diagnosis, is significantly associated with future CV events and mortality. Approximately 75% of patients with type 2 DM die of macrovascular complications, particularly CV disease.⁴
- Poorly controlled diabetes before conception and during the first trimester of pregnancy among women with type 1 DM can cause major birth defects in 5% to 10% of pregnancies and spontaneous abortions in 15% to 20% of pregnancies.¹
- In 2007, diabetes was listed as the underlying cause on 71,382 death certificates and was listed as a contributing factor on an additional 160,022 death certificates.¹ Complications of diabetes contributing to death included heart disease (noted on 68% of death certificates among those age 65 years or older) and stroke (16%).
- Diabetes is the leading cause of new cases of blindness (4.4% have advanced diabetic retinopathy), kidney failure (48,374 people began treatment for end-stage renal disease in 2008), and nontraumatic lower-limb amputation (65,700 amputations in 2006).¹

FOLLOW-UP

- Routine follow-up is recommended to continue to assist patients with risk factor reduction, adherence to treatment, screening for diabetes complications (including depression) and to provide ongoing support and guidance. Visit frequency depends on the patient's needs, recent changes in management, and severity of complications. The AACE recommends regular visits at least every 3 to 6 months to review and reinforce BP and blood glucose targets and management of ongoing risk factors (including alcohol and tobacco use).⁴
- The AACE also recommends contact within 1 week after a major modification of the treatment plan.⁴ At each encounter, ask if the patient has experienced symptoms of hypoglycemia and educate the patient on appropriate recognition, prevention, and management. They also recommend the following:⁴
 - Goal setting for nutrition and physical activity regularly.
 - Monitor hemoglobin A_{1c} every 3 to 6 months, LDL or fasting lipid profile yearly (unless stable and with no change in medication), and microalbuminuria annually with serum creatinine if albuminuria is abnormal. If microalbuminuria testing is positive (>30 mg/g), repeat twice in the next 3 months. If two of three of these screening microalbuminuria tests are positive, the individual has microalbuminuria and interventions should be considered.⁴ A negative finding should be followed yearly; a positive finding should be followed periodically to see if the interventions are effective in diminishing the albuminuria.
 - Remind the patient to schedule dilated ophthalmic exams with an optometrist or ophthalmologist.
 - Monitor foot exams annually or more frequently and educate the patient on appropriate recognition, prevention, and management of infections.

PATIENT EDUCATION

- Patient education includes information about DM (e.g., treatment options), primary and secondary prevention recommendations, and self-management.
- Recommended self-management activities include goal setting, incorporating nutrition management and physical activity into lifestyle, and prevention and early detection of complications (e.g., medication adherence, foot care).⁴

220 ACANTHOSIS NIGRICANS

Mindy A. Smith, MD, MS

PATIENT STORY

An adolescent girl with obesity and recently diagnosed type II diabetes mellitus (DM) presents to her family physician with concerns about a “dirty area” under her arms and on her neck that “couldn’t be cleaned” (**Figure 220-1**). She has irregular periods that often skip several months at a time. The physician makes the diagnosis of acanthosis nigricans.

INTRODUCTION

- Acanthosis nigricans (AN) is a localized form of hyperpigmentation that involves epidermal alteration. AN is usually associated with insulin resistance and is seen in patients with endocrine disorders (e.g., type II DM, Cushing syndrome, acromegaly), obesity, and polycystic ovary syndrome.

EPIDEMIOLOGY

- In a cross-sectional study conducted in a southwestern practice-based research network (N = 1133), AN was found in 17% of children and 21% of adults.¹
- In 2 studies, AN was present in 36% of patients with newly diagnosed DM and 39% of children with obesity.^{2,3}
- AN is sometimes associated with malignancy, primarily adenocarcinoma (60%) of the stomach, gallbladder, colon, ovary, pancreas, rectum, and uterus.^{4,5}
- Although most cases are idiopathic, there are also genetic causes of AN.⁵
- A condition of hyperandrogenism (HA), insulin resistance (IR), and AN called HAIR-AN syndrome occurs in approximately 1% to 3% of women with HA.⁶ This syndrome may also be seen in patients with autoimmune disorders like Hashimoto thyroiditis.
- AN can be an adverse effect from hormonal therapies.⁷

ETIOLOGY AND PATHOPHYSIOLOGY

- AN results from long-term exposure of keratinocytes to insulin.
- Keratinocytes have insulin and insulin-like growth receptors on their surface and the pathogenesis of this condition may be linked to insulin binding to insulin-like growth receptors in the epidermis.
- Fibroblast growth factor receptor 3 (FGFR3) gene mutations should be considered in patients with coexistent AN and skeletal dysplasia.⁸

FIGURE 220-1 Acanthosis nigricans in the left axilla of an overweight Hispanic 10-year-old girl. Note areas of dark velvety discoloration and pink filiform hypertrophy. (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

The diagnosis of AN is made clinically in a patient with or at risk for IR who has the characteristic lesions.

CLINICAL FEATURES

- AN ranges in appearance from diffuse streaky thickened brown velvety lesions to leathery verrucous papillomatous lesions (**Figures 220-1 to 220-9**).
- Women with HAIR-AN syndrome have evidence of virilization (e.g., increased body hair in male distribution, enlarged clitoris) in addition to AN.⁶

TYPICAL DISTRIBUTION

- Commonly located on the neck (**Figures 220-3 to 220-5**) or skin folds (i.e., axillae [**Figures 220-1, 220-2, and 220-9**], inframammary folds, groin, and perineum).
- Less often AN can be seen on the nipples or areolae, perineum, groin, and extensor surfaces of the legs.⁵
- Verrucous AN may affect the eyelids, lips, and buccal mucosa.⁵
- In patients with malignancy, the onset of AN can be abrupt and the distribution of lesions is more widespread and may include the palms and soles.⁹

BIOPSY

- May be needed in unusual cases.
- Histologic examination reveals hyperkeratosis and papillary hypertrophy, although the epidermis is only mildly thickened.¹⁰

DIFFERENTIAL DIAGNOSIS

Other hyperpigmented lesions that may be confused with AN include:

- Seborrheic keratosis (see Chapter 158, Seborrheic Keratosis)—Most commonly found on the trunk or the face; these lesions are more plaque-like with adherent, greasy scale and have a “stuck on” appearance.
- Pigmented actinic keratosis (see Chapter 166, Actinic Keratosis and Bowen Disease)—Usually in sun-exposed areas; the lesions can be macular or papular with dry, rough adherent scale.

MANAGEMENT

NONPHARMACOLOGIC

- Patients with AN are at higher risk of metabolic syndrome, and lipid screening should be considered along with consideration of testing for DM.
- Weight loss through diet and exercise helps reverse the process, probably by reducing both IR and compensatory hyperinsulinemia.

FIGURE 220-2 Acanthosis nigricans in the right axilla of a 25-year-old woman with type 2 diabetes. The skin appears velvety. (Courtesy of Richard P. Usatine, MD.)

FIGURE 220-3 Acanthosis nigricans on the neck of an obese Hispanic woman with type 2 diabetes. Note that multiple skin tags are also present. (Courtesy of Richard P. Usatine, MD.)

FIGURE 220-4 Acanthosis nigricans on the neck of an obese woman with type II diabetes. Note the hypertrophic thickening of the darker skin. (Courtesy of Richard P. Usatine, MD.)

MEDICATIONS

- Keratolytic agents (e.g., salicylic acid) can improve the cosmetic appearance. Other topical therapies, including 0.1% tretinoin cream (to lighten the lesion), combination tretinoin cream with 12% ammonium lactate cream, or topical vitamin D ointments,¹¹ may be useful.⁵ **SOR C**
- Metformin¹² and octreotide have also been used to manage AN. **SOR C**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- The use of omega-3-fatty acid and dietary fish oil supplementation has also been reported to improve AN.¹³ **SOR C**

PROCEDURES

- Long-pulsed alexandrite laser therapy¹⁴ and dermabrasion are alternative treatments.⁵
- Some patients have many skin tags within the area of acanthosis and request them to be removed (**Figure 220-9**). (See Chapter 157, Skin Tag for details on treatment.)

PROGNOSIS

- AN usually regresses when the underlying condition (e.g., diabetes, malignancy) is treated.⁵

PATIENT EDUCATION

- Patients who are overweight should be encouraged to lose weight through diet and exercise because weight loss often resolves this condition.

221 DIABETIC DERMOPATHY

Mindy A. Smith, MD, MS

PATIENT STORY

A 60-year-old woman with diabetes mellitus (DM) for the past 10 years began to notice reddish-colored lesions on both anterior shins that turned brown over the past year (**Figure 221-1**). She reported no pain with the hyperpigmented areas but does have foot pain secondary to neuropathy. The patient is diagnosed with diabetic dermopathy, and she begins working with her physician on achieving better control of her diabetes.

INTRODUCTION

Diabetic dermopathy is a constellation of well-demarcated, hyperpigmented, atrophic depressions, macules, or papules located on the anterior surface of the lower legs that is usually found in patients with DM. It is the most common cutaneous marker of DM.

EPIDEMIOLOGY

- Diabetic dermopathy is found in 12.5% to 40% of patients and most often in the elderly. It is less common in women.¹
- In a case series of 100 consecutive inpatients or outpatients in India with DM and skin lesions, diabetic dermopathy was found in 36%.² The incidence was much lower in a second case series of 500 patients attending a diabetes clinic in India, with only 0.2% diagnosed with diabetic dermopathy; the authors concluded that because the majority of patients were well controlled (fasting blood sugar <130 mg/mL in 60%), cutaneous signs of chronic hyperglycemia were decreased.³
- Sometimes seen in persons without DM, especially patients with circulatory compromise.

ETIOLOGY AND PATHOPHYSIOLOGY

The cause of diabetic dermopathy is unknown.

- Diabetic dermopathy may be related to mechanical or thermal trauma, especially in patients with neuropathy.
- Lesions have been classified as vascular because histology sections demonstrate red blood cell extravasation and capillary basement membrane thickening. In one study, patients with type 1 DM and diabetic dermopathy had marked reduction in skin blood flow at normal-appearing skin areas on the pretibial surface of the legs compared with type 1 control and nondiabetic control patients.⁴
- There is an association between diabetic dermopathy and the presence of retinopathy, nephropathy, and neuropathy.^{5,6} In a Turkish study, women with diabetic dermopathy appeared to have a more severe sensorial neuropathy (e.g., loss of deep tendon reflexes,

FIGURE 221-1 Lesions of diabetic dermopathy (also called pigmented pretibial papules) on both lower extremities of a 60-year-old woman with diabetes. The skin appears atrophic and the lesions are flat and hyperpigmented. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

superficial sensory loss, and the loss of vibration sense) than did patients without these skin lesions; a high prevalence of carpal tunnel syndrome (63.8%) was also found in these patients.⁷

DIAGNOSIS

CLINICAL FEATURES

The diagnosis is usually clinical. Lesions often begin as pink patches (0.5 to 1 cm), which become hyperpigmented with surface atrophy and fine scale (Figures 221-1 to 221-4).

TYPICAL DISTRIBUTION

Pretibial and lateral areas of the calf (Figures 221-1 to 221-4).

BIOPSY

Histology shows epidermal atrophy, thickened small superficial dermal blood vessels, increased epidermal melanin and hemorrhage with hemosiderin deposits. These findings are not all present in biopsy specimens; in an autopsy series, only 4 of 14 skin biopsies of diabetic dermopathy lesions showed moderate to severe wall thickening of arterioles or medium-sized arteries, 11 of 14 showed mild basement membrane thickening, and 9 of 14 had markedly increased epidermal melanin.⁸

DIFFERENTIAL DIAGNOSIS

Consider the following when evaluating patients with similar skin conditions:

- Early lesions of necrobiosis lipoidica diabetorum—Erythematous papules or plaques beginning in the pretibial area, but become larger and darker with irregular margins and raised erythematous borders. Telangiectasias, atrophy, and yellow discoloration may be seen. The lesion may be painful (see Chapter 222, Necrobiosis Lipoidica).
- Schamberg disease (pigmented purpuric dermatosis) is a capillaritis that produces brown hemosiderin deposits along with visible pink-to-red spots like cayenne pepper on the lower extremities. It is not more common in diabetes but may resemble diabetic dermopathy. A biopsy could be used to distinguish between them (see Chapter 179, Vasculitis).
- Stasis dermatitis—The typical site is the medial aspect of the ankle. Early lesions are erythematous, scaly, and sometimes pruritic, becoming progressively hyperpigmented (see Chapter 52, Venous Stasis).
- Traumatic scars—There is no scale, lesions are permanent, and edema is not usually present.

MANAGEMENT

- There is no effective treatment.
- It is not known whether the lesions improve with better control of diabetes.
- One informal case report stated that patients may benefit from 15 to 25 mg chelated zinc daily for several weeks.⁹ [SOR](#) 

FIGURE 221-2 Diabetic dermopathy on the leg showing pretibial hyperpigmentation and healed ulcers with hypopigmentation. There are also signs of erythema and fine scale. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

FIGURE 221-3 Diabetic dermopathy on both lower extremities of a middle-age man with diabetes. The sparse hair is secondary to his vasculopathy. (Courtesy of Dan Stulberg, MD.)

PREVENTION

- It is possible that patients with well-controlled DM have a lower risk of diabetic dermopathy.

PROGNOSIS

- Lesions may resolve spontaneously.

PATIENT EDUCATION

- Reassure patients that the lesions are asymptomatic and may resolve spontaneously within 1 to 2 years, although new lesions may form.

PATIENT RESOURCE

- American Diabetes Association. *Skin Complications*—

222 NECROBIOSIS LIPOIDICA

Mindy A. Smith, MD, MS

PATIENT STORY

A 30-year-old woman presents with discoloration on both lower legs. She has no personal history of diabetes; however, type 2 diabetes does run in her family. Visible inspection of the lesions is highly suggestive of necrobiosis lipoidica (NL) (**Figure 222-1**). There is hyperpigmentation, yellow discoloration, atrophy, and telangiectasias. The patient is not overweight and had no symptoms of diabetes. Her blood sugar at this visit is 142 after eating lunch 1 hour prior to testing. The following day, the patient's fasting blood sugar is 121, with a glycosylated hemoglobin of 6.1. The patient is informed of her borderline diabetes, and diet and exercise are prescribed. She is disturbed by her skin appearance and chooses to try a moderate-strength topical corticosteroid for treatment.

INTRODUCTION

- NL is a chronic granulomatous skin condition with degenerative connective-tissue changes most often seen in patients with diabetes mellitus (DM). It was previously called *necrobiosis lipoidica diabetorum* before the recognition of a significant minority of patients with NL who do not have DM.

EPIDEMIOLOGY

- NL is a rare condition that occurs in approximately 1% (0.3% to 2.3%) of patients with DM.¹⁻⁴
- NL primarily affects women (80%), particularly those with type 1 DM, but it can occur with type 2 DM.^{1,2} Approximately 75% of patients with NL have or will develop DM.⁵
- Average age of onset is 34 years.^{1,2}
- In a study comparing young patients with type 1 DM (N = 212, ages 2 to 22 years) with sex- and age-matched control patients, most (68% vs. 26.5% of controls) had at least 1 cutaneous disorder, with 2.3% versus 0% of control patients having NL.⁴
- NL has also been reported in patients with Hashimoto thyroiditis.³
- Cases of familial NL not associated with DM have also been reported.⁶

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of NL remains unknown.
- Angiopathy leading to thrombosis and occlusion of the cutaneous vessels has been implicated in its etiology. However, microangiopathic changes are less common in lesions on areas other than the shins and, therefore, are not necessary for developing the lesions.² In addition, one study found that NL lesions exhibited significantly

FIGURE 222-1 Necrobiosis lipoidica in a 30-year-old woman with impaired glucose tolerance (borderline diabetes). Note the brown pigmentation and prominent blood vessels. (Courtesy of Suraj Reddy, MD.)

higher blood flow rates than areas of unaffected skin close to the lesions.⁷

- Antibodies and C3 have been found at the dermal-epidermal junction, suggesting vasculitis.
- The presence of fibrin in these lesions associated with palisading histiocytes may indicate a delayed hypersensitivity reaction.
- In a study using focus-floating microscopy, a modified immunohistochemical technique was developed to detect *Borrelia* spirochetes. *Borrelia* was detected in 75% of NL lesions overall and 92.7% of inflammatory-rich (38 of 41) versus inflammatory-poor (4 of 15, 26.7%) cases.⁸ The authors posit that these findings indicate a potential role for *Borrelia burgdorferi* or other similar strains in the development of or trigger for NL.

DIAGNOSIS

CLINICAL FEATURES

- The lesions begin as erythematous papules or plaques in the pretibial area and become larger and darker with irregular margins and raised erythematous borders (**Figures 222-1 to 222-4**). The lesion's center atrophies and turns yellow in color, appearing waxy (**Figures 222-3, 222-4, and 222-5A**).
- There is often a prominent brown color or hyperpigmentation visible (**Figures 222-1 to 222-4**).
- The lesions may ulcerate (occurs in approximately one-third) and become painful (**Figure 222-5B**).
- Telangiectasias and prominent blood vessels may be seen within the lesions (**Figures 222-1 to 222-4**).
- The yellow color may be because of lipid deposits or beta-carotene.

TYPICAL DISTRIBUTION

- The lesions are usually located on the shins (90%) (**Figures 222-1 to 222-4**).
- NL lesions have been reported on many skin areas, including the face, scalp, and penis.^{9,10}

BIOPSY

- Biopsy is usually not needed as the clinical picture is usually clear. The dangers of a biopsy include delayed healing and infection in a patient who often has diabetes. The shin region of the leg is notorious for delayed healing even in healthy persons and so biopsy should be avoided in most cases.
- If the diagnosis is uncertain, a punch biopsy will show a thin atrophic epidermis with dermal granulomatous inflammation and obliterative endarteritis. The dermal change shows increased necrobiosis or degeneration of collagen with absence of elastic tissue.

DIFFERENTIAL DIAGNOSIS

NL may be confused with the following conditions:

- Erythema nodosum (EN) is an inflammatory panniculitis that occurs in the same areas (especially shins) as NL. These nodules are pink in color and the skin is smooth above them. The color and lack

FIGURE 222-2 Necrobiosis lipoidica in a patient with type 1 diabetes. Note the pink area at the site of a healed superficial ulcer. (Courtesy of Amber Tully, MD.)

FIGURE 222-3 Necrobiosis lipoidica on the leg of a man with type 2 diabetes. Note the central atrophy and yellow discoloration with a well-demarcated brown border. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

of epidermal changes should differentiate EN from NL (see Chapter 178, Erythema Nodosum).

- Granuloma annulare—Appears as asymmetric annular red plaques on the dorsum of the hands, extensor surface of the extremities, or posterior neck. They lack the yellow discoloration of NL. These lesions are so visibly like red raised rings that they should appear different from NL. If biopsy is needed, the presence of abundant mucin deposits helps to distinguish these lesions from NL (see Chapter 173, Granuloma Annulare).²
- Lichen simplex chronicus—A chronic pruritic eczematous lesion. The lesions are well-circumscribed plaques or papules with lichenified or thickened skin caused by chronic scratching or rubbing. Lesions are commonly located on the ankles, wrists, or posterior nuchal region. The prominent scale and lichenification should help differentiate these lesions from NL (see Chapter 145, Atopic Dermatitis).
- Sarcoidosis skin lesions—Including EN, maculopapular eruptions on the face, nose, back, and extremities; skin plaques that are often purple and raised; and broad macules with telangiectasias that are most commonly seen on the face or hands. Punch biopsy will distinguish between sarcoidosis and NL (see Chapter 175, Sarcoidosis).
- Stasis dermatitis—Occurs on the lower extremities secondary to venous incompetence and edema.¹¹ Affected patients are usually older, and the typical site is the medial aspect of the ankle. Early lesions are erythematous, scaly, and sometimes pruritic that progressively become hyperpigmented. These lesions are rarely well circumscribed, as seen in NL (see Chapter 52, Venous Stasis).

FIGURE 222-4 Multiple lesions of necrobiosis lipoidica in a young adult with type 1 diabetes. Note the central yellow discoloration and well-circumscribed brown borders. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

MANAGEMENT

Evaluate patients not previously diagnosed with DM for diabetes. Even though glycemic control does not correlate with progression of these lesions, DM should be treated to decrease the risk of macro- and microvascular complications.

MEDICATIONS

Data on successful treatment is largely based on case reports. Necrobiosis lesions may respond to the following treatments:

- Local application of potent steroids or intralesional injections of 2.5 mg/mL of triamcinolone.² **SOR C** The major risk of these treatments includes increasing the existing atrophy, so patients should be informed of risks and benefits before initiating steroid treatments.
- Topical tacrolimus (0.1% ointment twice daily for 8 weeks followed by once daily for 8 weeks) was successful in a single case report.¹² **SOR C**
- Pentoxifylline (400 mg 2 to 3 times daily), an agent that improves blood flow and decreases red cell and platelet aggregation, was shown in 2 case reports to completely resolve the lesions at 8 weeks in one³ and at 6-month follow-up in the other.⁴ The latter patient continued therapy and remained in remission at a 2-year follow-up. **SOR C**
- Ulcerative NL has been reported to respond to tetracycline,¹³ antimalarial agents (e.g., hydroxychloroquine),¹⁴ clofazimine,¹⁵ systemic steroids,¹⁶ antiplatelet therapy,¹⁷ and biologic agents (e.g., infliximab infusion, subcutaneous etanercept).^{18,19} **SOR C**

REFERRAL

- Refer patients with intractable skin ulcers. In one study that included patients with NL, application of allogeneic cultured dermal substitute was successful in improving healing.²⁰
- Topical photodynamic therapy may also be successful in treating refractory NL lesions; in 1 case series (N = 18), overall response rate was 39% with complete resolution in 1 patient and partial resolution in 6.²¹ **SOR** 

PROGNOSIS

- Spontaneous resolution occurs in 10% to 20% of cases.
- In a study of patients with DM undergoing pancreatic transplantation (N = 11), all 5 patients with NL achieved resolution of NL following transplantation; 1 patient had recurrent NL associated with transplant rejection.²² The single patient with NL who underwent kidney transplantation had persistent NL.

PATIENT EDUCATION

- Patients with NL without DM should be advised about the increased risk of developing the disease and counseled about symptoms and periodic surveillance.
- NL may resolve spontaneously and does respond to several treatments.

223 HYPERLIPIDEMIA AND XANTHOMAS

Mindy A. Smith, MD, MS

PATIENT STORY

A 27-year-old Hispanic man reported new painful nonpruritic bumps, which started 6 months ago, over his entire body. The patient had not seen a physician for 10 months and had run out of his oral medicines for type 2 diabetes mellitus. His grandmother had a milder version of bumps like this years ago. The firm yellowish papules were present all over his body from the neck down (**Figures 223-1 to 223-3**). Laboratory evaluation revealed a random blood sugar of 203, a fasting triglyceride level greater than 7000 mg/dL, and total cholesterol greater than 700 mg/dL. High-density lipoproteins were 32 mg/dL, and there were no chylomicrons present. The patient was diagnosed with xanthomas, poorly controlled diabetes mellitus, and hyperlipidemia, and was started on metformin, gemfibrozil, and a β -hydroxy- β -methylglutaryl-coenzyme A (HMG-CoA)-reductase inhibitor.

INTRODUCTION

Hyperlipidemia refers to an elevated concentration of one or more of the measured serum lipid components (total cholesterol [TC], low-density lipoprotein [LDL], high-density lipoprotein [HDL], and triglycerides [TGs]). Xanthomas are a skin manifestation of familial or severe secondary hyperlipidemia, although they can occur in patients with normal lipid levels. Hyperlipidemia is a major modifiable risk factor for cardiovascular disease.

EPIDEMIOLOGY

- During 2005 to 2006, 15.7% of adults in the United States had a high serum TC level.¹ The average cholesterol level of adults ages 20 to 74 years decreased from 222 mg/dL in 1959 to 1962 to 197 mg/dL in 2007 to 2008, reaching the *Healthy People 2010* goal.²
- An estimated 34% of the adult population had high LDL-C during 2005 to 2008 (LDL-C levels above the recommended goal levels or reported current use of cholesterol-lowering medication).³
- Among young adults (ages 12 to 19 years), 20.3% had abnormal lipids; boys are more likely than girls to have at least 1 lipid abnormality (24.3% vs. 15.9%, respectively).⁴
- Patients with homozygous familial hypercholesterolemia (FH) (1 in 1 million persons worldwide) present in childhood with cutaneous xanthomas on the hands, wrists, elbows, knees, heels, or buttocks.⁵

FIGURE 223-1 Close-up of eruptive xanthomas on the arm of a 27-year-old man with untreated hyperlipidemia and diabetes.¹ (Courtesy of Richard P. Usatine, MD.)

FIGURE 223-2 Eruptive xanthomas on the arm and trunk of the man in Figure 223-1. (Courtesy of Richard P. Usatine, MD.)

- Patients with heterozygous FH (1 in 500 persons worldwide) can present as adults with tendon xanthomas.

ETIOLOGY AND PATHOPHYSIOLOGY

- Lipoproteins are complexes of lipids and proteins essential for transporting cholesterol, TGs, and fat-soluble vitamins.
- Elevated levels can result from genetically based derangement of lipid metabolism and/or transport or from secondary causes such as diet, medical disorders (e.g., type 2 diabetes mellitus [DM], hypothyroidism, chronic kidney disease, cholestatic liver disease), cigarette smoking, obesity, or drugs (e.g., corticosteroids, estrogens, retinoids, high-dose β -blockers).
- Increased circulating LDL becomes incorporation into atherosclerotic plaques. These plaques can grow to block blood supply and oxygen delivery resulting in ischemia to vital organs. In addition, if the plaque ruptures, it can precipitate a clot, causing for example myocardial infarction.
- Elevated TG is an independent risk factor for coronary heart disease (CHD) and increases the risk of hepatomegaly, splenomegaly, hepatic steatosis, and pancreatitis. Contributing factors include obesity, physical inactivity, cigarette smoking, excess alcohol intake, medical diseases (e.g., type 2 DM, chronic renal failure, nephrotic syndrome), drugs (as above), and genetic disorders (e.g., familial combined hyperlipidemia).⁶
- Xanthomas are deposits of lipid in the skin or subcutaneous tissue, usually occurring as a consequence of primary or secondary hyperlipidemia. Xanthomas can also be seen in association with monoclonal gammopathy.⁷ There are five basic types of xanthomas:
 - Eruptive xanthomas (also called tuberoeruptive) are the most common form. These appear as crops of yellow or hyperpigmented papules with erythematous halos in white persons (Figures 223-1 to 223-3), appearing hyperpigmented in black persons (Figures 223-4 and 223-5).
 - Tendon xanthomas are frequently seen on the Achilles and extensor finger tendons.
 - Plane xanthomas are flat and commonly seen on the palmar creases, face, upper trunk, and on scars.
 - Tuberos xanthomas are found most frequently on the hand or over large joints.
 - Xanthelasma are yellow papules found on the eyelids (Figure 223-6). Fifty percent of individuals with xanthelasmas have normal lipid profiles.

RISK FACTORS

Risk factors to consider for treatment decisions for patients with hyperlipidemia include:

- Type 2 DM.
- Family history of early CHD or familial hyperlipidemia.
- Cardiac risk factors (cigarette smoking, obesity, hypertension, or sedentary lifestyle).

FIGURE 223-3 Eruptive xanthomas covering most of the body of the man in Figure 223-1. (Courtesy of Richard P. Usatine, MD.)

FIGURE 223-4 Eruptive xanthomas on the elbows of a hyperlipidemic black man with type 2 diabetes. His triglycerides and total cholesterol levels were high.¹ (Courtesy of Richard P. Usatine, MD. Previously published in the *Western Journal of Medicine*.)

DIAGNOSIS

CLINICAL FEATURES

- Most patients with hyperlipidemia are asymptomatic.
- A very high TC level (>2000 mg/dL) may result in eruptive xanthomas or lipemia retinalis (white appearance of the retina; also seen with isolated high TG). Very high LDL may lead to the formation of tendinous xanthomas.
- Xanthomas manifest clinically as yellowish papules, nodules, or tumors (**Figure 223-1**).
- Eruptive xanthomas (**Figures 223-2 to 223-5**) begin as clusters of small papules on the elbows, knees, and buttocks that can grow to the size of grapes.
- There is a case report of a patient with normolipidemic xanthomatosis with lesions involving the bones and mucous membranes in addition to skin.⁸

TYPICAL DISTRIBUTION

Xanthomas are most commonly found in superficial soft tissues, such as skin and subcutis, or on tendon sheaths.

LABORATORY TESTING

- The National Cholesterol Education Program (NCEP) III recommends a fasting lipid profile (FLP) as the initial test⁶; alternatively patients may be tested initially with a random TC and HDL.
- If the TC is greater than 200 mg/dL or the HDL less than 40 mg/dL for men or less than 50 mg/dL for women, an FLP is obtained for LDL determination.⁶ LDL cannot be determined if TG are greater than 400 mg/dL.
- If thyroid dysfunction is suspected, obtain a thyroid-stimulating hormone level to determine whether thyroid dysfunction is contributing to the lipid abnormalities.
- Other secondary causes to consider include anorexia nervosa, Cushing syndrome, hepatitis, nephrotic syndrome, renal failure, and systemic lupus erythematosus.
- If a statin is under consideration, a baseline creatine phosphokinase (CPK) is recommended before starting statin therapy.

BIOPSY

Biopsy is rarely needed and shows collections of lipid-filled macrophages.

DIFFERENTIAL DIAGNOSIS

Other skin papules that can be mistaken for xanthomas include the following:

- Gouty tophi—Deposits of monosodium urate that are usually firm and occasionally discharge a chalky material (**Figure 223-7**, see Chapter 100, Gout).
- Pseudoxanthoma elasticum—A disorder caused by abnormal deposits of calcium on the elastic fibers of the skin and eye.

FIGURE 223-5 Eruptive xanthomas on the knees in the patient in **Figure 223-4**. (Courtesy of Richard P. Usatine, MD. Previously published in the *Western Journal of Medicine*.)

FIGURE 223-6 Xanthelasma around the eyes (xanthoma palpebrarum); most often seen on the medial aspect of the eyelids, with upper lids being more commonly involved than lower lids. (Courtesy of Richard P. Usatine, MD.)

FIGURE 223-7 Ear gouty tophus in a young man with gout. (Courtesy of Richard P. Usatine, MD.)

- Molluscum contagiosum—Caused by a virus; lesions can be papular and widespread but generally have a central depression (see Chapter 130, Molluscum Contagiosum). The patient in **Figures 223-1** to **223-3** was originally misdiagnosed with molluscum.

MANAGEMENT

Management of patients with hyperlipidemia emphasizes reduction of cardiovascular risk factors (as noted above) and targets elevated LDL cholesterol for the goal of cholesterol-lowering therapy.⁶ Optimal LDL is considered to be less than 100 mg/dL, near optimal LDL is 100 to 129 mg/dL, and high LDL is equal to or greater than 160 mg/dL. The Institute for Clinical Systems Improvement (ICSI) suggests consideration of a goal of less than 70 mg/dL for patients with established CHD, noncardiac atherosclerosis, or CHD equivalent.⁹

- The intensity of therapy should be based on the patient's risk status.⁶ The recommended LDL goal is less than 160 for individuals with zero to 1 risk factor (or 10-year CHD risk of <10%), less than 130 mg/dL for 2 or more risk factors, and less than 100 mg/dL for those with CHD or CHD equivalents (e.g., DM or 10-year CHD risk of >20%).
- For those with 2 or more risk factors, a 10-year risk assessment is conducted using the Framingham scoring system (<http://hp2010.nhlbihin.net/atpiii/calculator.asp>) to help identify which individuals would benefit most from intensive treatment.
- For children with elevated lipids, diet is recommended as first-line treatment to achieve a TC of less than 215 mg/dL or an LDL of less than 155 mg/dL.¹⁰ Referral to a pediatric endocrinologist or dietician may be beneficial.

NONPHARMACOLOGIC

- Smoking cessation should be encouraged and attempts actively supported; cessation lowers both cardiovascular risk and lipid levels. **SOR A**
- Patients should be encouraged to modify their risk factors through exercise and dietary changes. High cholesterol can be lowered through dietary changes. **SOR A**
- Patients who are overweight should be encouraged to reduce calories to achieve weight loss. **SOR C**
- Features of a lipid-lowering diet include reducing intake of total fats to 25% to 35% of total calories (provided trans fatty acids and saturated fats are kept low [$<7\%$ of total calories for saturated fats]), reducing cholesterol intake to less than 200 mg/day, and increasing fiber intake to 20 to 30 g/day (5 to 10 g/day of soluble fiber).⁶ **SOR C** Authors of a Cochrane review, however, found no trials on long-term (>6 months) effects of a low-fat diet in patients with hyperlipidemia.¹¹
- Similarly, of 11 small trials of dietary intervention identified by authors of a Cochrane review, only short-term outcomes were reported.¹² There were no differences between low-cholesterol diets and other dietary interventions (e.g., omega-3 fatty acids, soya proteins, plant sterols or plant stanols), with the exception of plant sterols lowering TC significantly more than a cholesterol-lowering diet.¹²

- Reducing saturated fat through fat modification diets reduces the risk of cardiovascular events by 14% (relative risk [RR] 0.86, 95% confidence interval [CI] 0.77 to 0.96).¹³ **SOR A** This reduction in cardiovascular events was directly related to the degree of effect on serum total and LDL cholesterol and TGs. The strongest evidence was for trials of at least 2 years, duration and in studies of men (not of women). However, there were no clear effects of dietary fat changes on total mortality (RR 0.98, 95% CI 0.93 to 1.04) or cardiovascular mortality (RR 0.94, 95% CI 0.85 to 1.04).
- NCEP recommends beginning with lifestyle therapies and reassessing LDL after 6 weeks. If the LDL goal is not met, reinforce lifestyle change along with adding plant sterols and fiber; also consider dietician referral. If the LDL goal is not met at the next 6-week visit, consider medications.⁶ Patients hospitalized for a coronary event or procedure should be discharged on drug therapy if their LDL is equal to or greater than 130 mg/dL.⁶
- Addition of plant sterols/stanols up to 2 g/day should be considered, particularly if the initial LDL goal is not met with diet modification and exercise. **SOR B**
- Treatment should also be initiated for patients with high TG (>200 to 499 mg/dL) or very high TG (≥500 mg/dL) beginning with weight reduction and exercise; for those with very high TGs, a very-low-fat diet is used (≤15% of calorie intake).
- Initial treatment of xanthomas should target the underlying hyperlipidemia (when present).

MEDICATIONS

In addition to primary interventions noted above, secondary therapy includes statins, niacin, fibric acids, ezetimibe, and a bile acid sequestrant.^{6,9} The use of combination therapy has not been supported by outcome-based studies.

- Statins (HMG-CoA reductase inhibitors; lovastatin [20 to 80 mg], pravastatin [20 to 40 mg], simvastatin [20 to 80 mg], fluvastatin [20 to 80 mg], atorvastatin [10 to 80 mg], cerivastatin [0.4 to 0.8 mg]) are considered first-line for most patients. Evidence supports use of statins in patients with risk factors for CHD (lowers all-cause mortality [odds ratio (OR) 0.88, 95% CI 0.81 to 0.96], major coronary events [OR 0.70, 95% CI 0.61 to 0.81], and major cerebrovascular events [OR 0.81, 95% CI 0.71 to 0.93])¹⁴ and in patients with CHD or CHD equivalent (reduces mortality risk from CHD and possibly overall mortality).¹⁵ **SOR A** Number needed to treat (NNT) to prevent one additional death in patients with CHD is approximately 30 to 50. There do not appear to be important differences by type of statin.¹⁶
- Statin side effects include myopathy and increased liver enzymes; statins are associated with a small increase in the risk of developing DM (number needed to harm = 255).¹⁷ The major contraindication is liver disease.
- Niacin (immediate release [crystalline] nicotinic acid [1.5 to 3 g], extended-release nicotinic acid [Niaspan] [1-2 g], sustained release) is considered a second-line agent to be used in combination with a statin if the LDL goal is not achieved with intensifying monotherapy or as first-line agent for patients with very high TG. Evidence supports reduction in major CHD events with niacin. **SOR A** Niacin is nonprescription.

- Niacin side effects include GI distress, flushing, hyperuricemia, hyperglycemia in patients with DM, and hepatotoxicity. Contraindications are chronic liver disease and severe gout; use with caution in patients with DM, hyperuricemia, peptic ulcer disease.
- Fibrates (gemfibrozil [600 mg bid], fenofibrate [200 mg], clofibrate [1000 mg bid]) is a second-line agent shown to reduce major CHD events but not overall mortality.¹⁸ **SOR A** Fibrates can be used as primary therapy for very high TG. Side effects include dyspepsia, gallstones, myopathy, and unexplained non-CHD deaths. Contraindications are severe renal or hepatic disease.
- Bile acid sequestrants (cholestyramine [4 to 16 g], colestipol [5 to 20 g], colesevelam [2.6 to 3.8 g]) are second-line agents shown to reduce CHD mortality.¹³ **SOR A** These drugs are considered first-line agents for children.¹⁰ Side effects include GI distress, constipation, and decreased absorption of other drugs. Contraindications are dysbetalipoproteinemia or TG greater than 400 mg/dL.

Hypolipidemic drug treatment often results in regression of xanthomas. **SOR C** In patients with xanthomas associated with monoclonal gammopathy, hematologic remission following chemotherapy was associated with improvement in the xanthomas in several patients.⁷

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Artichoke leaf extract, red yeast rice, and several Chinese herbal medicines (in particular Xuezhikang) lower cholesterol compared with placebo; data on patient-oriented outcomes are lacking.¹⁹⁻²¹
- It is not clear whether supplementing with omega-3 fatty acids reduces mortality when combined primary and secondary prevention data are analyzed. A 2006 metaanalysis failed to find a reduction in overall mortality or cardiovascular events.²²
- Benefit is suggested for whole flaxseed and lignan, especially for women, but not for flaxseed oil.²³
- In a randomized crossover trial, consuming walnuts (42.5 g walnuts/10.1 mJ) and fatty fish (113 g salmon, twice a week) in a healthy diet significantly lowered serum cholesterol and triglyceride concentrations, respectively.²⁴ In a metaanalysis, nut consumption (67 g) reduced lipid levels.²⁵

SURGICAL PROCEDURES

- Between 1975 and 1983, a randomized controlled trial was conducted of primarily male patients following a first myocardial infarction (MI) (N = 838) of partial ileal bypass surgery or no surgery. The initial report found improved lipid patterns in patients in the intervention arm,²⁶ and a 25-year follow-up study found improved survival and cardiovascular disease-free survival in the surgery arm.²⁷
- Xanthelasma lesions may be treated for cosmetic purposes. Methods of treatment include surgery, electrosurgery, cryotherapy, and laser therapy. In a case report of 24 patients, argon laser coagulation was well-tolerated and the cosmetic outcome was considered to be good in 85% of patients.²⁸ **SOR C**

When standard therapy fails, LDL apheresis has lowered lipid levels with subsequent regression of tendon xanthomas.²⁹ **SOR C**

REFERRAL

- Referral for nutritional counseling should be considered, especially if initial attempts at dietary control fail. Dietary advice has been shown to result in modest improvements in cardiovascular risk factors, such as blood pressure and total and LDL-cholesterol levels.³⁰ **SOR A**

PREVENTION AND SCREENING

- The United States Preventive Services Task Force (USPSTF) strongly recommends screening men age 35 years and older for lipid disorders.³¹ **SOR A** There is strong evidence that drug therapy reduces CHD events and mortality in middle-aged men (ages 35 to 70 years) with abnormal lipids and a potential risk of CHD events greater than 1% per year. A Cochrane review confirmed reductions in all-cause mortality, major vascular events, and revascularizations with no cancer excess in 14 trials, 11 recruiting patients with risk factors.³² In one metaanalysis, NNT for primary prevention in patients (primarily men) with risk factors was 173 to prevent 1 premature death, 81 to prevent 1 CHD event, and 245 to prevent 1 stroke.¹⁴
- The USPSTF strongly recommends screening women age 45 years and older if they are at increased risk for CHD.³¹ **SOR A** The USPSTF also recommends screening men ages 20 to 35 years and women ages 20 to 45 years if they are at increased risk for CHD.³¹ **SOR B** There is less direct evidence suggesting effectiveness of drug therapy in other adults, including men older than age 70 years and middle-aged and older women (age 45 years and older) with similar levels of risk.³³ In fact, in a metaanalysis of primary prevention trials including women, there was insufficient evidence of reduced risk of any clinical outcome in women.³⁴
- Secondary prevention trials do show reductions in CHD mortality, CHD events, nonfatal MI, and revascularization for women that is similar to reductions seen for men and demonstrate decreased mortality for older men.³⁵
- Retesting every 1 to 5 years is recommended by the USPSTF based on CHD risk.³¹
- Studies are not available to assess the efficacy of screening children and adolescents for dyslipidemia for delaying the onset and reducing the incidence of CHD-related events.

PROGNOSIS

- Based on observational data, each 30-mg/dL increase in LDL increases the relative risk of CHD by 30%.
- Use of strategies to lower elevated lipid levels will likely reduce CHD events and possibly overall mortality.
- With medical (diet or drugs) treatment of hyperlipidemia, many xanthomas and about half of xanthelasma resolve or improve. with surgical treatment, recurrence is uncommon.³⁶

FOLLOW-UP

- NCEP recommends reassessing LDL approximately every 6 weeks until the LDL goal is met, then every 6 to 12 months.⁶

- It is not clear if monitoring liver enzymes in patients on statins is necessary.³⁷ Repeat a CPK if a patient experiences symptoms of myopathy. Statin therapy should be discontinued if the CPK is more than 10 times normal. For patients with myopathy and moderate or no CPK elevation, conduct weekly monitoring until symptoms improve or discontinue statins if there is worsening or failure to resolve.³⁸

PATIENT EDUCATION

- Patients should be counseled about benefits and risks of screening.
- Lifestyle changes should be stressed as primary prevention for patients with hyperlipidemia.
- If persistent elevations in lipids continue despite lifestyle change, those with high risk or CHD should consider medications.
- Patients with hyperlipidemia and/or DM should be encouraged to establish and maintain good control of these diseases, as this often results in regression of xanthomas.

224 OBESITY

Mindy A. Smith, MD, MS

PATIENT STORY

Diane is a 35-year-old woman who has struggled with obesity for most of her life. Her current body mass index (BMI) is 36. She has tried “every kind of diet you can imagine” but has always gotten stuck after losing the first 10 pounds and gets discouraged. She is not currently exercising regularly. She is concerned about all the skin tags on her neck and wants them removed if possible. She and her husband are talking about having another baby and she would like to be in better shape before she attempts pregnancy. She wants to discuss risks of pregnancy considering her weight and asks for any advice that you can give her on how to successfully lose weight. You obtain a random blood sugar because of the acanthosis nigricans and obesity (**Figure 224-1**). The result is 150 mg/dL and you order a fasting blood sugar (FBS) before her next visit, at which time you will remove her skin tags. After discussing diet and exercise, you encourage her to pursue Weight Watchers or a similar program.

INTRODUCTION

Obesity is defined as a BMI greater than or equal to 30. BMI is calculated as weight in kilograms divided by height in meters squared, rounded to 1 decimal place.¹ Obesity in children is defined as a BMI greater than or equal to the age- and sex-specific 95th percentiles of the 2000 Centers for Disease Control and Prevention (CDC) growth charts. Adults with a BMI greater than 40 have substantially more serious health consequences, including heart disease and diabetes, and a reduced life expectancy.

EPIDEMIOLOGY

- Based on the National Health and Nutrition Examination Surveys, more than one-third of U.S. adults (35.7%) and 16.9% of children and adolescents are obese (2010).¹ Slightly more women than men are obese (35.8% vs. 35.5%), although obesity is more prevalent in boys than girls at ages 2 to 19 years (18.6% vs. 15%). The prevalence of obesity has dramatically increased over the past 20 years.
- At the 6-year follow-up of the Nurses' Health Study (NHS; a prospective cohort study of 50,277 women), 3757 (7.5%) women who had a BMI of less than 30 in 1992 became obese (BMI \geq 30).²
- The medical care costs of obesity in the United States (2008 dollars) are approximately \$147 billion.³

ETIOLOGY AND PATHOPHYSIOLOGY

Obesity is a complex problem involving genetics, health behaviors, environment, and sometimes medical diseases (see “Differential Diagnosis” below) or drugs (e.g., steroids, antidepressants). The

FIGURE 224-1 Neck circumference enlargement with acanthosis nigricans and many skin tags in a woman with obesity and impaired glucose tolerance. (Courtesy of Richard P. Usatine, MD.)

simplest explanation of obesity is an imbalance between intake (calories eaten) and output (physical activity).

GENETICS

The genetic contribution to interindividual variation in common obesity has been estimated at 40% to 70%.⁴ Despite this relatively high heritability, the search for obesity susceptibility genes has been difficult. At least five variants in four candidate genes are associated with obesity-related traits. Although genome-wide linkage studies have been unable to pinpoint genetic loci for common obesity, high-density genome-wide association studies have discovered at least 15 previously unanticipated genetic loci associated with BMI and extreme obesity risk.⁴ Genetic influences, however, cannot explain the recent increased prevalence in the rate of weight gain by age; rather significant changes in lifestyle factors are likely responsible.⁵

- Two GI “hormones” that appear to integrate into the brain may regulate appetite; these hormones—ghrelin (increases appetite) and obestatin (slows gastric emptying, blocking ghrelin action)—may also play a role in obesity. A metaanalysis concluded that obestatin and total and active ghrelin were significantly higher in normal weight subjects than those of obese groups.⁶ It is not clear why this occurs but lower levels of ghrelin in obese subjects may be a response to hyperinsulinemia.

HEALTH BEHAVIORS

Lifestyle factors associated with obesity include physical activity level (low levels and associated behaviors such as television viewing), diet, and sleep.

- In the NHS, each 2-hour per day increment in TV watching was associated with a 23% (95% confidence interval [CI], 17% to 30%) and each 2-hour per day increment in sitting at work was associated with a 5% (95% CI, 0% to 10%) increase in obesity.²
- Based on second-wave interview data from the National Longitudinal Study of Adolescent Health (N = more than 14,000 adolescents), increasing levels of vigorous physical activities lowered the risk for obesity among all adolescents, while eating sufficient fruits and vegetables was inversely associated with adolescents' obesity.⁵ As in the above study, sedentary lifestyle was associated with adolescents' obesity. However, in models based on race, low family socioeconomic status, and being sedentary were associated with overweight and obesity among whites and increased nighttime sleep hours was associated with obesity among African Americans.
- In one study, belief that obesity was inherited was associated with lower reported levels of physical activity and fruit and vegetable consumption while the belief that obesity was caused by lifestyle behaviors was associated with greater reported physical activity but not diet.⁷
- In a study of Latino men and women, men who did not exercise, rarely trimmed fat from meat, and ate fried foods the previous day were 16 pounds heavier than men with healthier habits.⁸ Women who had limited exercise (<2.5 hours per week), watched television regularly, ate chips and snacks, and ate no fruit the previous day were 45 pounds heavier than women with healthier habits.

ENVIRONMENT

Factors that have been discussed include location of grocery stores versus fast-food restaurants and safe places to exercise in relation to home proximity. Research studies suggest that neighborhood residents who have better access to supermarkets and limited access to convenience stores tend to have healthier diets and lower levels of obesity.⁹ Poor neighborhoods are often characterized by just the opposite. In fact, in one study, having the opportunity to move from a poor neighborhood to one with a lower level of poverty through housing vouchers was associated with modest reductions (4.6%) in the prevalence of extreme obesity and diabetes.¹⁰

RISK FACTORS

- Family history of obesity.
- Diet—High calorie, low fruits and vegetables,¹¹ snack foods, and fast-food consumption (obesity prevalence 24% of those going to fast-food restaurants less than once a week to 33% of those going 3 or more times per week).¹²
- Low levels of physical activity.

DIAGNOSIS

The diagnosis of obesity is based on a BMI greater than 30.

CLINICAL FEATURES

- Although elevated weight alone is a risk factor for the development of hypertension, diabetes mellitus (DM), and heart disease, increased waist circumference confers additional morbidity risk (**Figure 224-2**).¹³
- Neck circumference enlargement (**Figure 224-1**) along with increased BMI and waist circumference are significant risk factors for obstructive sleep apnea and metabolic syndrome.^{14,15}
- There is a strong direct correlation between epicardial fat and abdominal visceral adiposity with evidence supporting a role for epicardial fat in the pathogenesis of coronary artery disease.¹⁶
- Nonalcoholic fatty liver disease (NAFLD) is present in 57% of overweight individuals attending outpatient clinics compared to 98% of nondiabetic obese patients and in contrast to 10% to 30% of adults in the general population (see Chapter 61, Liver Disorders).¹⁷
- Obesity is also associated with an increased risk of varicose veins (odds ratio [OR] 3.28; 95% CI 1.25 to 8.63) (see Chapter 52, Venous Stasis) (**Figure 224-3**).
- Skin conditions associated with obesity include acanthosis nigricans (**Figures 224-1** and **224-4**), eruptive xanthomas (**Figure 224-5**), hidradenitis suppurativa (**Figure 224-6**), and psoriasis (**Figure 224-2**). (see Chapters 115, Hidradenitis Suppurativa, 152, Psoriasis, 220, Acanthosis Nigricans, and 223, Hyperlipidemia).

LABORATORY TESTING

Although no specific tests are suggested for patients with obesity, assessing a patient's cardiovascular risk status in addition to BMI, waist circumference, and a patient's motivation to lose weight may

FIGURE 224-2 Central obesity in a man with extensive plaque psoriasis. (Courtesy of Richard P. Usatine, MD.)

FIGURE 224-3 Serpiginous varicose veins in a woman with obesity. (Courtesy of Richard P. Usatine, MD.)

be helpful in planning treatment.¹³ Consider screening for DM and NAFLD.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with obesity includes the following medical conditions:

- Cushing syndrome—Caused by prolonged exposure to endogenous or exogenous glucocorticoids; in addition to truncal obesity, clinical features include moon facies, supraclavicular fat pads, buffalo hump, purple striae, proximal muscle weakness, and hirsutism. Diagnosis is confirmed with inappropriately high serum or urine cortisol levels.
- Polycystic ovary syndrome—Criteria include two of three of oligo-ovulation or anovulation, hyperandrogenism, and polycystic ovaries.
- Obesity is also a finding in many single-gene disorders such as Prader-Willi syndrome (abnormality of proximal arm of chromosome 15 with associated characteristics of obesity, hypotonia, mental retardation, short stature, hypogonadotropic hypogonadism, strabismus, and small hands and feet) and Bardet-Biedl syndrome (associated with truncal obesity, childhood-onset visual loss preceded by night blindness, and polydactyly).

MANAGEMENT

The initial weight loss goal is to reduce body weight by approximately 10% from baseline over approximately 6 months.¹³ Additional weight loss can be attempted if this goal is achieved.

NONPHARMACOLOGIC

- Dietary changes may be useful. In a metaanalysis of long-term weight loss strategies in adults, however, dietary/lifestyle therapy provides less than 5 kg weight loss after 2 to 4 years.¹⁸ **SOR A** Commercial weight management services appear to be more effective and cheaper than primary care-based services led by specially trained staff (range: 4.4 kg [Weight Watchers] to 1.4 kg [general practice]).¹⁹ **SOR A**
- Exercise should be encouraged and can result in small weight losses and improvement in cardiovascular risk factors; greater intensity exercise results in additional small weight loss (weighted mean difference [WMD] approximately -1.5 kg).^{20,21} **SOR A** The addition of diet to exercise also increases weight loss (WMD -1 kg).
- Although data are limited, lifestyle interventions appear to reduce overweight in children.²² **SOR B**
- Behavioral and cognitive-behavioral strategies are also effective (WMD -2.5 kg and -2.3 kg, respectively), but are most effective when used in combination with diet and exercise (WMD [added cognitive-behavioral strategies] -4.9 kg).²³ **SOR A**
- Behavioral strategies found to be effective include various forms of support, motivational interviewing, and reducing TV screen time.
- Both remote weight-loss support (study-specific website and e-mail) and in-person support during group and individual sessions

FIGURE 224-4 Acanthosis nigricans in a 14-year-old Hispanic girl with obesity, insulin resistance, and a strong family history of type 2 diabetes. (Courtesy of Richard P. Usatine, MD.)

FIGURE 224-5 Eruptive xanthomas in a young man with untreated type 2 diabetes, hyperlipidemia and obesity. (Courtesy of Richard P. Usatine, MD.)

along with remote support resulted in greater sustained weight loss at 24 months than the control group (−4.6 kg, −5.1 kg, and −0.8 kg, respectively).²⁴

- A program entitled “High Five for Kids,” using motivational interviewing targeting television viewing, fast food, and sugar-sweetened beverage intake, was not effective in one randomized clinical trial (RCT) in reducing BMI at 1 year.²⁵
- With respect to psychological interventions, of three interventions (usual care with quarterly primary care physician educational visits, brief lifestyle counseling, or enhanced brief lifestyle counseling including meal replacements) examined in adult patients with obesity, enhanced care was more effective than usual care for initial weight loss and sustained weight loss at 2 years (1.7 ± 0.7 and 4.6 ± 0.7 kg, respectively).²⁶ **SOR B**

MEDICATIONS

- In the 2005 systematic review by Douketis et al., pharmacologic therapy for obesity resulted in to 10-kg average weight loss after 1 to 2 years.¹⁸ **SOR A** An older Cochrane review of orlistat, sibutramine, and rimonabant found more modest but significant weight reduction (2.9 to 4.7 kg); conclusions were limited by high attrition rates.²⁷
- The National Heart, Lung, and Blood Institute (NHLBI) *Clinical Guideline* recommends consideration of drug therapy approved by the FDA for long-term use as an adjunct to diet and physical activity for patients with a BMI of 30 with no concomitant obesity-related risk factors or diseases, and for patients with a BMI of 27 with concomitant obesity-related risk factors or diseases. **SOR B** The American College of Physicians (ACP) guideline also recommends that pharmacologic therapy may be offered to patients with obesity who fail to achieve their weight loss goals through diet and exercise alone. However, they recommend a discussion of the drugs’ side effects, the lack of long-term safety data, and the temporary nature of the weight loss achieved with medications before initiating therapy.²⁸
- Medication options include sibutramine, orlistat, phentermine, diethylpropion, rimonabant, fluoxetine, bupropion, and phentermine/topiramate. Most weight loss occurs in the first 6 months of treatment.²⁹ Investigators conducting a phase III trial of phentermine/topiramate reported greater weight loss for two different strengths of the drug over placebo at 1 year (−8.1 kg [lower dose] and −10.2 kg [higher dose] and −1.4 kg [placebo]).³⁰

COMPLEMENTARY AND ALTERNATIVE THERAPY

- A number of therapies have been proposed to assist in weight loss, including herbal and nonherbal food supplements, homeopathy, hypnotherapy, acupuncture, and acupressure.³¹ Of these, only ephedra sinica and other ephedrine-containing dietary supplements had convincing evidence of small reductions in body weight over placebo.
- A systematic review of food supplements (e.g., guar gum, chromium, chitosan) for weight reduction by some of the same authors also failed to find evidence of a clinically relevant weight loss (WMDs in the range of no benefit to −1.7 kg) using these preparations.³²

FIGURE 224-6 Hidradenitis suppurativa with significant scarring and sinus tract formation in an obese woman with a body mass index greater than 30. (Courtesy of Richard P. Usatine, MD.)

SURGERY

Surgical therapy provides approximately 25 to 75 kg of weight loss after 2 to 4 years.¹⁸ According to the NHLBI guideline, weight loss surgery is an option for well-informed, carefully selected patients with clinically severe obesity (BMI 40 or 35 with comorbid conditions) when less-invasive methods of weight loss have failed and the patient is at high risk for obesity-associated morbidity or mortality.¹³ **SOR B** The 2005 ACP guideline concurred and again added that a doctor–patient discussion of surgical options should include the long-term side effects (e.g., vitamin B₁₂ deficiency, incisional hernia, possible need for reoperation, gastritis, gallbladder disease, and malabsorption).²⁸ In addition, they recommend that patients should be referred to high-volume centers with surgeons experienced in bariatric surgery.

Two types of surgical procedures (gastric banding and gastric bypass) are in current use; all induce substantial weight loss and serve to reduce weight-associated risk factors and comorbidities.

- In a Cochrane review, authors found that weight loss was greater from gastric bypass than vertical banded gastroplasty or adjustable gastric banding, but similar to isolated sleeve gastrectomy and banded gastric bypass.³³ Compared to other interventions available, surgery has produced the longest period of sustained weight loss.
- In a metaanalysis of 8 trials with more than 44,000 patients, the authors concluded that bariatric surgery (both gastric banding and gastric bypass) reduced long-term all-cause mortality (OR = 0.70; CI, 0.59 to 0.84), although the risk reduction was smaller in the larger studies; gastric bypass had a greater effect than banding on cardiovascular mortality.³⁴
- In addition to reduced weight, a retrospective study of severely overweight patients with noninsulin-dependent diabetes who were referred for consideration of a gastric bypass procedure showed that patients undergoing the surgical procedure had a decrease in mortality rate for each year of follow-up compared to those who did not undergo the procedure because of personal preference or refusal of insurance payment.³⁵
- Bariatric surgery was also found to be cost-effective compared to other treatments for obesity.³⁶ Authors identified several remaining questions to be answered, including the influence of surgery on quality of life, late complications leading to reoperation, duration of comorbidity remission, and resource use.
- Laparoscopic bariatric surgery may be safer than open surgery with respect to wound infection (relative risk [RR] 0.21; 95% CI, 0.07 to 0.65) and incisional hernia (RR 0.11; 95% CI, 0.03 to 0.35). Risks appear similar for reoperation, anastomotic leak, and all-cause mortality.³⁷
- In one study, the rate of hospitalization in the year following gastric bypass surgery was more than double the rate in the preceding year (19.3% vs 7.9%). The most common reasons for admission prior to surgery were obesity-related problems (e.g., osteoarthritis, lower extremity cellulitis) and elective operation (e.g., hysterectomy). The most common reasons for admission after gastric bypass surgery were complications thought to be procedure related, such as ventral hernia repair and gastric revision.³⁸
- In a study of 16,155 Medicare beneficiaries who underwent bariatric procedures (mean age: 47.7 years [standard deviation (SD):

11.3 years]; 75.8% women), the rates of 30-day, 90-day, and 1-year mortality were 2.0%, 2.8%, and 4.6%, respectively. After adjustment for sex and comorbidity index, the odds of death within 90 days were 5-fold greater for older Medicare beneficiaries (age 75 years or older; n = 136) than for those age 65 to 74 years (n = 1381; OR 5.0; 95% CI, 3.1 to 8.0). The odds of death at 90 days were 1.6 times higher (95% CI, 1.3 to 2.0) for patients of surgeons with less than the median surgical volume of bariatric procedures.³⁹

REFERRAL

The Endocrine Society recommends that patients following bariatric surgery should receive care from a multidisciplinary team, including an experienced primary care physician, endocrinologist, or gastroenterologist. Primary providers should also consider enrolling patients postoperatively in a comprehensive program for nutrition and lifestyle management to prevent and detect nutritional deficiencies.⁴⁰

PREVENTION AND SCREENING

- In one recent study, although a behavioral intervention (face-to-face visit; weekly mailed materials promoting appropriate weight gain, healthy eating, and exercise; individual weight gain graphs; and telephone-based feedback) was able to reduce the number of women with excessive weight gain in pregnancy by approximately 10%,⁴¹ authors of a systematic review found insufficient quality data from four earlier trials to provide evidence-based recommendations.⁴²
- A behavioral approach of lifestyle counseling from nurse practitioners was not effective compared with usual care in preventing weight gain in overweight or obese adults, although approximately 60% of patients in both groups achieved weight maintenance after 3 years.⁴³
- Authors of a Cochrane review of 37 studies found strong evidence to support beneficial effects of child obesity prevention programs on BMI, particularly for programs targeting children age 6 to 12 years.⁴⁴ However, the overall effect was small (−0.15 kg/m² [95% CI, −0.21 to −0.09]).
- The United States Preventive Services Task Force (USPSTF) recommends that clinicians screen children age 6 years and older for obesity and offer them or refer them to comprehensive, intensive behavioral interventions to promote improvement in weight status.⁴⁵ **SOR B** This recommendation is based in part on data showing that moderate- to high-intensity programs (>25 hours of contact with the child and/or the family over a 6-month period) improve weight status primarily in children with obesity.
- For adults, the USPSTF recommends that clinicians screen all adult patients for obesity and offer intensive counseling and behavioral interventions to promote sustained weight loss for obese adults.⁴⁶ **SOR B** Evidence, however, was insufficient to recommend for or against the use of moderate- or low-intensity counseling together with behavioral interventions to promote sustained weight loss in obese adults or use of counseling of any intensity and behavioral interventions to promote sustained weight loss in overweight adults.

PROGNOSIS

Obesity increases the risk in adults for the following:^{13,47}

- Chronic health diseases such as coronary heart disease, type 2 DM, stroke, osteoarthritis, liver disease, and gallbladder disease.
- Cancers (i.e., endometrial, breast, colon, gallbladder).
- Cardiovascular risk factors such as hypertension and dyslipidemia.
- Sleep apnea and respiratory problems.
- Gynecologic problems (e.g., abnormal menses, infertility).

Overweight adolescents are also more susceptible than their leaner peers to hypertension, type 2 DM, dyslipidemia, lung problems (e.g., asthma, obstructive sleep apnea), orthopedic problems (e.g., genu varum, slipped capital femoral epiphysis), and nonalcoholic steatohepatitis.^{48,49} Obese adolescents may also suffer from depression and low self-esteem.⁴⁹ In addition, more than half of obese adolescents remain overweight as young adults.⁴⁹

Among pregnant women, obesity increases the risk for prenatal complications (gestational diabetes and hypertensive disorders),⁵⁰ intrapartum complications (cesarean section, induced preterm birth),⁵¹ and stillbirth (OR 2.8; 95% CI, 1.5 to 5.3) and neonatal death (OR 2.6; 95% CI, 1.2 to 5.8) compared with women of normal weight.⁵² In addition, women whose gestational weight gain is above the recommendations retain an additional 3 kg after 3 years and 4.7 kg on average after 15 or more years postpartum.⁵³

Based on one metaanalysis, intentional weight loss did not confer benefit on all-cause mortality but may provide a small benefit for individuals classified as unhealthy (those with obesity-related risk factors).⁵⁴

FOLLOW-UP

- The NHLBI recommends frequent contacts between the patient and provider to promote and monitor weight loss and weight maintenance therapies.¹³ **SOR C** Although these programs can be conducted by a practitioner without specialization in weight loss, various health professionals with expertise are available and are often helpful.
- For children, health providers should calculate and plot BMI (or weight percentile) yearly and watch for excessive weight gain compared with linear growth, identify and track patients at risk of obesity based on risk factors, encourage and support breastfeeding, routinely promote healthy diets and levels of physical activity, and monitor changes in obesity-associated risk factors.⁴⁹

PATIENT EDUCATION

- Advise patients to strive for a healthy lifestyle with a diet that is high in fruits and vegetables and to pursue daily physical activity. Maintaining normal weight and treating obstructive sleep apnea and diabetes may help prevent NAFLD.
- Weight loss can improve cardiovascular risk factors. Commercial weight-reduction programs may be most helpful.¹⁹ The addition of cognitive-behavioral strategies may enhance weight loss.²³

- For patients who are obese and fail to achieve their weight loss goals through diet and exercise alone, pharmacologic therapy can be considered, but pharmacologic therapy adds cost, can be associated with adverse effects, lacks long-term safety data, and weight loss may be temporary.
- Surgery is also an option for carefully selected patients with clinically severe obesity (BMI 40 or 35 with comorbid conditions) when less-invasive methods of weight loss have failed and the patient is at high risk for obesity-associated morbidity or mortality.

225 OSTEOPOROSIS AND OSTEOPENIA

Mindy Smith, MD, MS

PATIENT STORY

An 83-year-old woman accompanied by her 56-year-old daughter presents to the office with severe upper back pain over the past 2 days. Her medical problems include hypothyroidism, for which she is on replacement medication, and mild hypertension, which is controlled with a diuretic. She has known osteopenia and was taking calcium and vitamin D but had not tolerated a bisphosphonate. Physical examination reveals moderate thoracic kyphosis and tenderness over several lower thoracic vertebrae. A plain radiograph demonstrates a vertebral compression fractures (**Figure 225-1A**). The daughter asks about management options for pain and prevention of future fractures and also about screening for herself. As there was a suggestion of multiple compression fractures a CT was ordered to better visualize the fractures (**Figure 225-1B**).

INTRODUCTION

- Osteoporosis is a skeletal disorder characterized by low bone mineral density (BMD) ≤ 2.5 standard deviations (SD) of the mean for a gender-matched young white adult and compromised bone strength predisposing a person to fracture from minimal trauma.
- Osteopenia is defined as a BMD measurement of between 1.0 and 2.5 SD below the gender-matched young white adult mean. The World Health Organization also defines osteoporosis as a history of fragility fractures and osteopenia.¹

EPIDEMIOLOGY

- Approximately 12 million Americans older than age 50 years are have osteopenia.²
- Half of all postmenopausal women will have an osteoporosis-related fracture in their lifetime; 25% will experience a vertebral deformity and 15% will suffer a hip fracture.²
- Low BMD at the femoral neck (T-score of -2.5 or below) is found in 21% of postmenopausal white women, 16% of postmenopausal Mexican American women, and 10% of postmenopausal African American women.³
- About 1 in 5 older men are at risk of an osteoporosis-related fracture.²
- Vertebral fractures can cause severe pain and lead to 150,000 hospital admissions per year in the United States.
- Following a hip fracture, more than 30% of men and approximately 17% of women die within 1 year and more than half are unable to return to independent living.³

FIGURE 225-1 Osteoporosis-related thoracic vertebral compression fractures in an 83-year-old woman with kyphosis. **A.** Lower thoracic vertebral compression fractures seen on the lateral plain radiograph. **B.** Same fractures visualized more clearly on a lateral CT of the spine. (Courtesy of Rebecca Loredó-Hernández, MD.)

FIGURE 225-2 Normal trabecular bone (*left*) compared with trabecular bone in a patient with osteoporosis (*right*). The loss of mass in osteoporosis makes these bones more susceptible to breakage. (Printed with permission from Barrett KE, Barman SM, Boitano S, et al. *Ganong's Review of Medical Physiology*, 23rd ed. Philadelphia, McGraw-Hill Medical; 2009.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Primary osteoporosis is either a result of aging changes or menopause.
 - Usually affects those older than age 70 years.
 - Proportionate loss of cortical and trabecular bone density (**Figure 225-2**). Bone mass peaks at approximately age 30 years and declines thereafter. This bone loss can lead to an increase in vertebral, hip, and radius fractures.
 - In the 15 years following menopause, there is a disproportionate loss of trabecular bone. This can lead to an increase in fractures of the vertebrae, distal forearm, and ankle.
- Secondary osteoporosis is a result of medical conditions or medications (**Table 225-1**). Long-term oral prednisone used to treat a number of autoimmune diseases is a major contributing cause of secondary osteoporosis (**Figure 225-3**).

RISK FACTORS

- See **Table 225-1**.
- Previous low-trauma fracture.⁴ Other risk factors for an osteoporosis-related fracture include advanced age, low BMD, low body mass index (BMI), and starred items in **Table 225-1**.³
- There are many validated clinical decision rules that can help identify patients who are at higher-than-average risk of fracture.^{5,6}

TABLE 225-1 Factors Associated with Osteoporosis**Genetic factors**

White or Asian ethnicity
 Family history of osteoporosis*
 Low body weight (<127 pounds)*
 Late menarche or early menopause

Nutritional factors

Low intake of calcium or vitamin D
 High animal protein intake
 Low protein intake

Medical disorders

Endocrine disorders (e.g., hyperthyroidism, hyperparathyroidism, diabetes mellitus type 1, Cushing disease, hypogonadism)
 Hematologic disorders (e.g., multiple myeloma, anemia (hemolytic, pernicious), lymphoma, leukemia)
 GI disorders (e.g., malabsorption syndromes, chronic liver disease)
 Renal disorders (e.g., chronic renal failure)
 Rheumatologic disorders (e.g., rheumatoid arthritis, ankylosing spondylitis)
 Other disorders (e.g., anorexia, osteogenesis imperfecta)

Medications (commonly used)

Systemic corticosteroids*, antiepileptic drugs, proton pump inhibitors, chemotherapy, diuretics producing calciuria, GnRH agonist or antagonist, heparin, extended tetracycline use

Lifestyle factors

Sedentary
 Excessive exercise
 Current smoking or alcohol use (>2 U/day)*

Abbreviations: GnRH, Gonadotropin-releasing hormone.

*Also risk factors for osteoporosis-related fractures.

Sources: Kaplan-Machlis B, Bors KP, Brown SR. Osteoporosis. In: Smith MA, Shimp LA, eds. *Twenty Common Problems in Women's Health Care*. New York, NY: McGraw Hill; 2000; Osteoporosis. In: Ebell MH, Ferenchik G, Smith MA, et al, eds. *Essential Evidence Plus*. Hoboken, NJ: John Wiley; 2009; Watts NB, Bilezikian JP, Camacho PM, et al. American Association of Clinical Endocrinologists medical guidelines for clinical practice for the prevention and treatment of postmenopausal osteoporosis: 2010 edition. *Endocr Pract*. 2010;16(Suppl 3):1-37.

An extensively validated online tool developed by the World Health Organization, the Fracture Risk Assessment (FRAX) (<http://www.shef.ac.uk/FRAX/>), can be used to estimate 10-year risk for fractures for women and men based on easily obtainable clinical information, such as age, BMI, parental fracture history, and tobacco and alcohol use.

DIAGNOSIS**CLINICAL FEATURES**

- Height loss (>1 cm or >0.8 inch) can alert the clinician to osteoporosis.
- Kyphosis and cervical lordosis (dowager's hump).
- Acute pain is often the first symptom from a fracture, usually of the vertebrae (vertebral body collapse), hip or forearm, especially occurring after minor trauma. Pain may also be elicited from palpation over spinous processes and paraspinous muscle spasm may be noted.
- Osteoporosis may be identified on x-ray done for another purpose.

TYPICAL DISTRIBUTION

- Fractures caused by menopausal osteoporosis typically occur in thoracic vertebrae, distal forearm, and ankle; occasionally there is loss of teeth.
- Fractures caused by senile osteoporosis are in the vertebrae, hip, and radius.

FIGURE 225-3 Wedge compression fracture of T11 vertebra in a postmenopausal woman on long-term prednisone for dermatomyositis. The patient presented with acute back pain. (Courtesy of Richard P. Usatine, MD.)

LABORATORY TESTING

- Laboratory testing is recommended for women with osteoporosis to identify secondary causes including a complete blood cell count (for anemia or malignancy), serum chemistry (calcium, phosphorus, total protein, albumin, liver enzymes, alkaline phosphatase, creatinine, and electrolytes), 24-hour urine collection (calcium, sodium, and creatinine excretion to identify calcium malabsorption or hypercalciuria), and serum 25-hydroxyvitamin D.³
- Other laboratory tests may be indicated for patients with suspected secondary causes (e.g., serum thyrotropin, erythrocyte sedimentation rate, testosterone, acid–base studies).^{3,4}
- Central dual-energy x-ray absorptiometry (DEXA) measurement of BMD is the accepted gold standard for diagnosis (T-score less than or equal to -2.5 in the spine, femoral neck or hip in the absence of fracture) (Figures 225-4 and 225-5).
- Additional imaging with X-ray can confirm osteoporosis-related fracture (Figures 225-1 and 225-3).
- The presence of a hip or vertebral fracture in the absence of other bone conditions can also be considered osteoporosis.³ Two types of

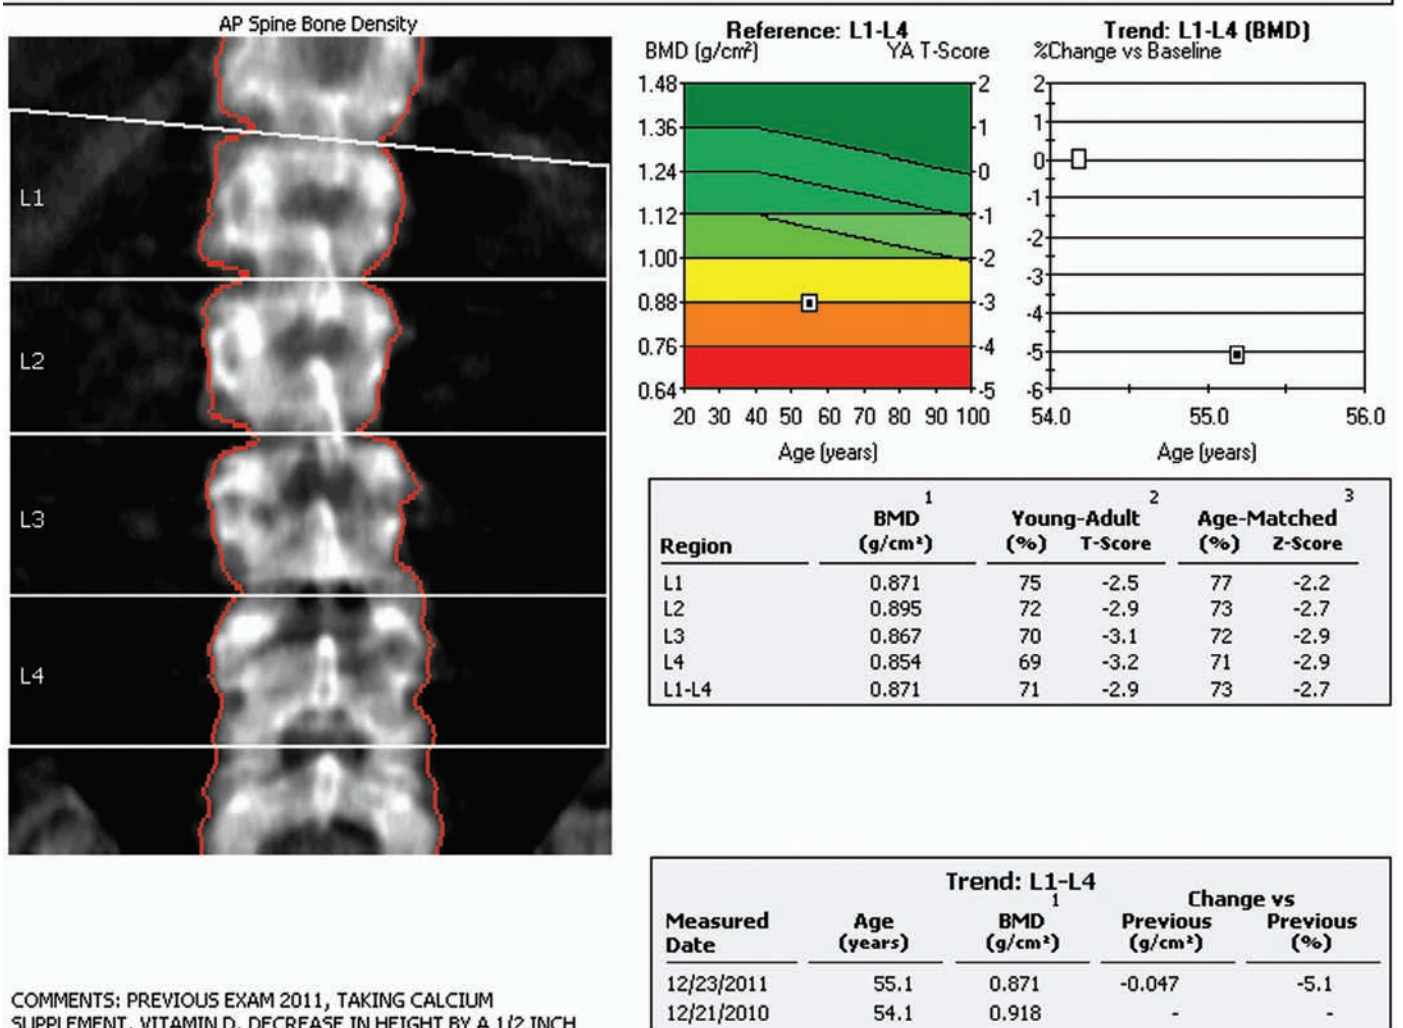

FIGURE 225-4 Dual-energy x-ray absorptiometry bone density scan showing osteoporosis in the vertebral spine showing 5% loss of vertebral bone density in 1 year. (Courtesy of Richard P. Usatine, MD.)

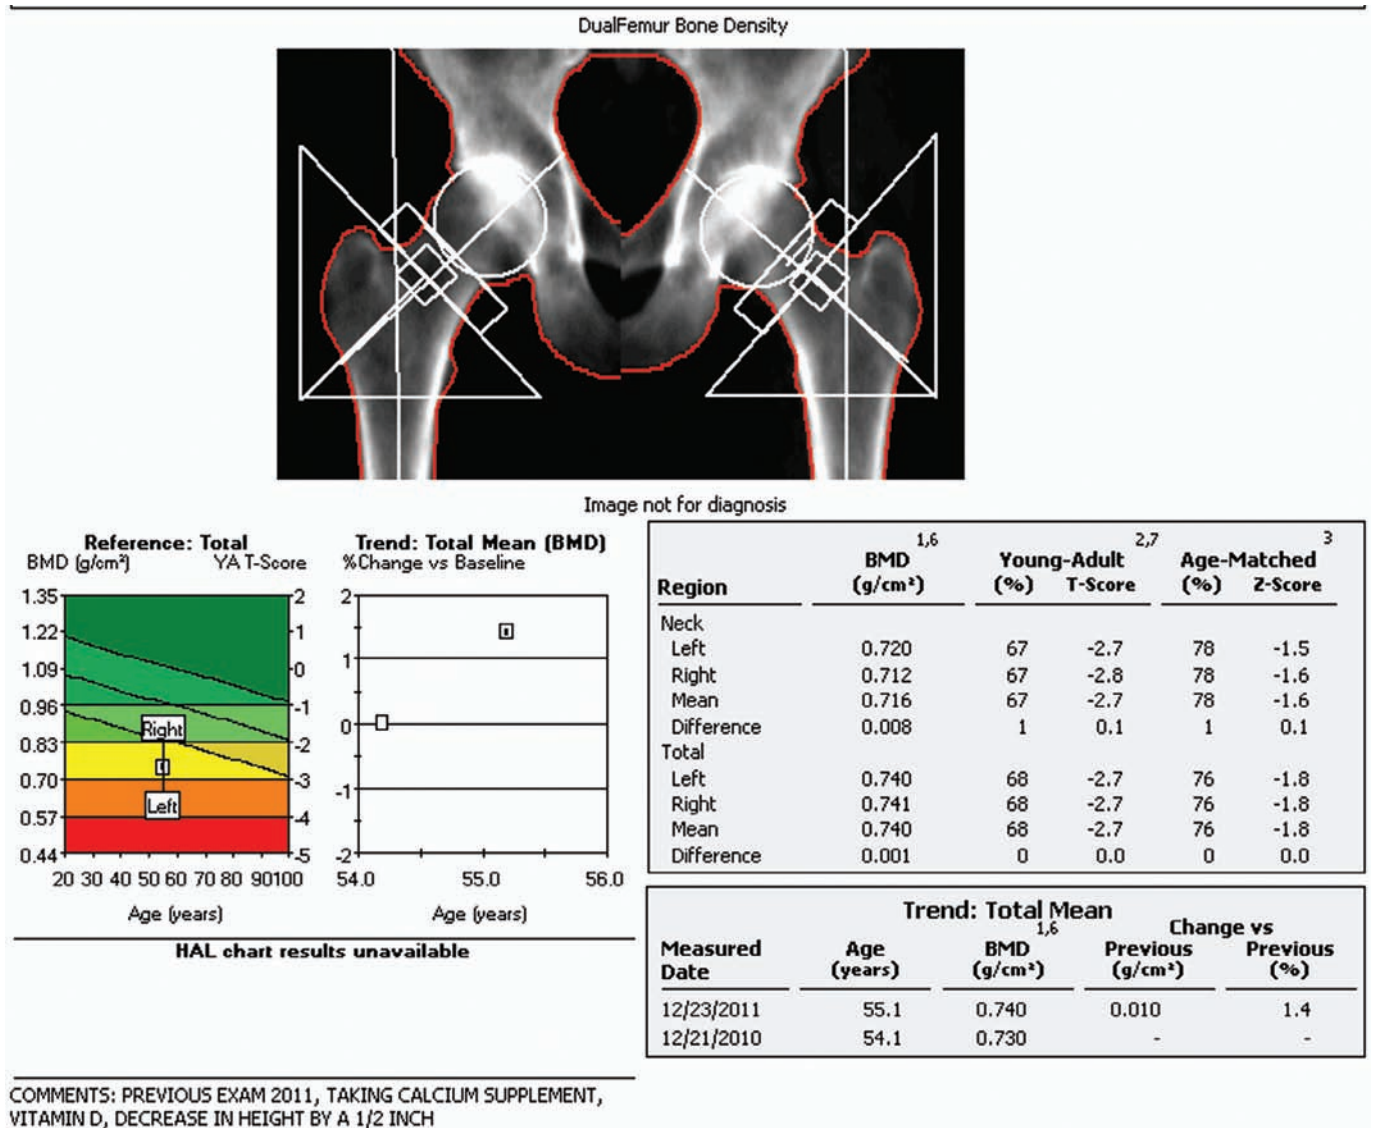

FIGURE 225-5 Dual-energy x-ray absorptiometry bone density scan showing osteoporosis of the hips with 2% gain of bone density in 1 year. (Courtesy of Richard P. Usatine, MD.)

hip fractures related to osteoporosis are femoral neck fractures (Figure 225-6) and intertrochanteric fractures.

DIFFERENTIAL DIAGNOSIS

Thoracic kyphosis of recent onset in adults can also be caused by:

- Degenerative arthritis of the spine—Pain and swelling in other joints, morning stiffness.
- Ankylosing spondylitis—Male gender, night pain, and limited motion in sacroiliac joints, uveitis.
- Tuberculosis (TB) and other infections of the spine—History of TB, positive cultures, X-ray showing joint destruction (Chapter 54, Tuberculosis).
- Cancer—History of cancer, imaging distinguishes.

FIGURE 225-6 Femoral neck fracture (arrow) in an elderly woman with osteoporosis. The woman fell on her left hip when coming out of the shower. (Courtesy of Rebecca Loredo-Hernandez, MD.)

MANAGEMENT

NONPHARMACOLOGIC

- Identify and treat secondary causes (see **Table 225-1**).
- Dietary advice includes adequate calcium, vitamin D, and protein intake.³ **SOR B**
- Recommend regular weight-bearing exercise.³ Institute for Clinical Systems Improvement (ICSI) notes that 3 components of an exercise program are needed for strong bone health: impact exercise (e.g., jogging, brisk walking, stair climbing), strengthening exercise with weights, and balance training such as Tai Chi or dancing.⁴
- Encourage smoking cessation and moderate alcohol use (<3 drinks per day).³ **SOR B**
- Hip protectors may reduce hip fractures in the nursing home.⁷ **SOR B**
- Address other risk factors for falling (e.g., low vision, gait disturbance, use of sedatives) and consider referral for physical or occupational therapy, if indicated.

MEDICATIONS

- Calcium (1200 mg/day from diet plus supplement) and vitamin D (at least 800 IU/day).^{8,9} **SOR A** One study found that a single large dose of vitamin D (100,000 IU given orally every 4 months) over 5 years reduced fractures in elderly British women (NNT = 20).¹⁰
- Women with osteoporosis or previous hip or spine fractures should receive medication therapy, beginning with a bisphosphonate.^{3,4} Women should also be considered for medication if they have a T-score of between -1.0 and -2.5, if FRAX major osteoporotic fracture probability is equal to or greater than 20%, or hip fracture probability is equal to or greater than 3%.³
- First-line agents include alendronate, risedronate, and zoledronic acid. **SOR A** Based on a Cochrane review of 11 studies, use of alendronate prevented hip (absolute risk reduction [ARR] 1%), vertebral (ARR 6%), and nonvertebral fractures (ARR 2%).¹¹ Potential side effects of bisphosphonates include rare atypical femoral shaft fracture (0.13% in the subsequent year for women with at least 5 years of treatment)¹² and jaw osteonecrosis (0.7 per 100,000 patient-years with oral bisphosphonate therapy).¹³
- Other drug therapies approved by the U.S. Food and Drug Administration to reduce fractures include parathyroid hormone (PTH, teriparatide [e.g., Forteo]), raloxifene (a selective estrogen receptor modulator [SERM]), and estrogen (women only). The ICSI recommends PTH as a first-line agent for patients with the highest fracture risk. Second-line agents recommended by American Association of Clinical Endocrinologists (AACE) are ibandronate and raloxifene.³ Choice of second-line medications should be based on the patient's clinical situation, preferences, and the tradeoff between benefits and harms. AACE recommends against combination therapy. **SOR B**
- The first-line agents listed above for treatment of osteoporosis have been approved for use in men as well as women; however, data are limited for men, especially for fracture reduction. In a randomized controlled trial (RCT) of 265 men on glucocorticoid therapy, both risedronate and zoledronic acid prevented bone loss in the prevention population while zoledronic acid increased BMD slightly

more than risedronate (4.7% vs. 3.3% lumbar spine and 1.8% vs. 0.2% total hip, respectively) in the treatment group.¹⁴

- Denosumab is a human monoclonal antibody that inhibits osteoclast mediated bone resorption; denosumab was shown to reduce new vertebral fractures in women with multiple and/or severe prevalent vertebral fractures (ARR 9.1%) and hip fractures in subjects age 75 years or older (ARR 1.4%). Both denosumab and zoledronic acid appear to reduce fracture risk in men with castration-resistant prostate cancer metastatic to bone and denosumab and toremifene (a SERM) reduced osteoporotic fracture risk in men on androgen-deprivation treatment.¹⁵ Denosumab has not been compared with bisphosphonates or other interventions. AACE considers this a first-line agent but it is very expensive.³ **SOR A** Risks of treatment include endocarditis, cancer, and skin rash.
- Nasal calcitonin may preserve BMD and reduce new vertebral fractures; this drug also has an analgesic effect for some women with painful acute vertebral fractures.¹⁶ AACE recommends calcitonin as a last line of therapy for treatment of osteoporosis.³

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Limited data support use of phytoestrogens, synthetic isoflavones such as ipriflavone or natural progesterone cream for prevention or treatment of osteoporosis. A 2-year multicenter, randomized trial of ipriflavone showed some effect on total body BMD but no significant effect on regional bone density at common fracture sites.¹⁷

REFERRAL

- AACE recommends referral of patients to a clinical endocrinologist if a patient with a normal BMD sustains a low-trauma fracture, has recurrent fractures or continued bone loss despite therapy, has unexpectedly severe osteoporosis or unusual features, or has a complicating condition (e.g., renal failure).³ **SOR C**

PREVENTION AND SCREENING

- The AACE guideline recommends adequate calcium and vitamin D intake to reduce bone loss.³ **SOR A** Maintaining an active lifestyle **SOR B**, smoking cessation **SOR B**, limiting alcohol intake **SOR B**, and limiting caffeine intake **SOR C** are also recommended.
- The United States Preventive Services Task Force (USPSTF) and AACE recommend screening for osteoporosis for women 65 years of age and older and for younger women whose fracture risk is the same as or greater than that of a 65-year-old white woman who has no additional risk factors (9.3% risk over 10 years).²
- Screening should be done with DEXA of the hip or lumbar spine or quantitative ultrasonography of the calcaneus; appropriate cutoffs for diagnosis and treatment using ultrasound, however, have not been established. Other guidelines have similar risk-based recommendations, although the age of initial assessment (all adults, adults age 50 years, or postmenopausal women) differs and the groups do not recommend use of ultrasound for screening.¹⁸

- Bisphosphonate therapy should be considered in patients starting glucocorticoid therapy planned for over 3 months and those on chronic glucocorticoid therapy if their T-score is less than -1.0 .¹⁹

FOLLOW-UP

- Repeat DEXA (same machine if possible) every 1 to 2 years until findings are stable and then continue with follow-up DEXA every 2 years or less (**Figures 225-4 and 225-5**).^{3,4}
- Consider discontinuation of a bisphosphonates after 4 to 5 years of stability or after 10 years of stability for high-risk patients.³ Reinstitution treatment if BMD declines substantially, bone turnover markers increase, or a fracture occurs.

PATIENT EDUCATION

- Encourage home-based fall prevention by removing throw rugs, reducing clutter in high traffic areas, increasing lighting, use of safety step stools and safety hand rails in the bathroom, and walking aids.
- Encourage healthy lifestyle and diet.

226 GOITROUS HYPOTHYROIDISM

Mindy A. Smith, MD, MS

PATIENT STORY

A 55-year-old woman presented with a several-month history of fatigue and weight gain. She reported that she felt puffy and swollen. She had difficulty buttoning the top button of her blouse because her neck was so large, but she reported no neck pain. Review of systems was positive for constipation, dry skin, and cold intolerance. On physical examination, a large goiter was found (**Figure 226-1**). Laboratory testing revealed an elevated thyroid-stimulating hormone (TSH) and a low free thyroxine (FT₄) level confirming hypothyroidism. The patient was started on levothyroxine.

INTRODUCTION

- Goiter is a spectrum of changes in the thyroid gland ranging from diffuse enlargement to nodular enlargement depending on the cause. In the United States, the most common etiology of goiter with normal thyroid function or transient dysfunction is thyroiditis.
- Hypothyroidism is a condition caused by lack of thyroid hormone and usually develops as a result of thyroid failure from intrinsic thyroid disease. The most common cause of goitrous hypothyroidism is chronic lymphocytic (Hashimoto) thyroiditis.
- Subclinical thyroid disease refers to a patient with no or minimal thyroid-related symptoms but abnormal laboratory values (elevated TSH and thyroxine level within the normal range).

EPIDEMIOLOGY

- Worldwide, goiter is the most common endocrine disorder with rates of 4% to 15% in areas of adequate iodine intake and more than 90% where there is iodine deficiency.¹ Endemic goiter is defined as goiter that affects more than 5% of the population (**Figures 226-2** and **226-3**).
- Most goiters are not associated with thyroid dysfunction.
- The prevalence of goitrous hypothyroidism varies from 0.7% to 4% of the population.
- Subclinical hypothyroidism is present in 3% to 10% of population groups and in 10% to 18% of elderly persons.^{2,3}
- The female-to-male ratio of goiter is 3:1, and 6:1 for goitrous hypothyroidism.
- The annual incidence of autoimmune hypothyroidism is 4 in 1000 women and 1 in 1000 men, with a mean age at diagnosis of 60 years.⁴

FIGURE 226-1 Goiter that extends approximately 2 cm forward when viewed from the patient's side. (Courtesy of Dan Stulberg, MD.)

FIGURE 226-2 Massive goiter in an Ethiopian woman who lives in an endemic area for goiters. Many adults have large goiters in Ethiopia where there is little iodine in their diets. (Courtesy of Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

Contributing factors for goiter are:

- Iodine deficiency or excess (**Figures 226-2 and 226-3**).
- TSH stimulation.
- Drugs, including lithium, amiodarone, and α -interferon.
- Autoimmunity/heredity.

Hypothyroidism may be caused by disease of the thyroid gland itself (e.g., Hashimoto thyroiditis), radioiodine thyroid ablation, thyroidectomy, high-dose head and neck radiation therapy, and medications (as above), or, rarely, by pituitary or hypothalamic disorders (e.g., tumors, inflammatory conditions, infiltrative diseases, infections, pituitary surgery, pituitary radiation therapy, and head trauma).²

- Hashimoto thyroiditis is caused by thyroid peroxidase (TPO) antibodies.
- Human leukocyte antigen-D related (HLA-DR) and cytotoxic T-lymphocyte antigen 4 (CTLA-4) are the best-documented genetic risk factors for this disorder.⁴
- There is marked lymphocytic infiltration of the thyroid in Hashimoto thyroiditis; the infiltrate is composed of activated CD4+ and CD8+ T cells, as well as B cells.
- Thyroid destruction in Hashimoto thyroiditis is believed to be primarily mediated by CD8+ cytotoxic T cells.

RISK FACTORS

Risk factors for hypothyroidism include:²

- Symptoms of thyroid hormone deficiency.
- Goiter.
- Personal or family history of thyroid disease.
- Personal treatment of thyroid disease.
- History of autoimmune disease, especially diabetes mellitus.
- High-dose head and neck radiation therapy.

Myxedema coma usually occurs in elderly patients with untreated or inadequately treated hypothyroidism who develop a precipitating event, such as myocardial infarction, stroke, sepsis, or prolonged cold exposure.²

DIAGNOSIS

CLINICAL FEATURES

The history can be the key to the diagnosis:

- A painful neck mass is usually a form of thyroiditis.
- Large goiters are easily visible before palpating the neck (**Figures 226-1 to 226-5**).
- Asymmetric goiters can shift the trachea away from the midline (**Figure 226-6**).

FIGURE 226-3 Goiter developing in a 12-year-old girl in an endemic area for goiters. (Courtesy of Richard P. Usatine, MD.)

Common signs and symptoms of hypothyroidism are:

- Fatigue and/or weakness.
- Dry and cool skin.
- Diffuse hair loss or thinning of the lateral eyebrows.
- Difficulty concentrating.
- Puffy face/hands/feet from myxedema (**Figure 226-7**).
- Bradycardia.
- Delayed deep tendon reflex relaxation.
- Weight gain despite poor appetite.
- Constipation.
- The most useful signs for diagnosing hypothyroidism are puffiness (likelihood ratio positive [LR+] 16.2) and delayed ankle reflex (LR+ 11.8).⁵

Clues to a central cause of hypothyroidism include a history of pituitary/hypothalamic surgery or radiation, headache, visual field defects, or ophthalmoplegia.²

Physical examination maneuvers that help detect goiter are:⁶

- Neck extension.
- Observation from the side.
- Palpation by locating the isthmus first.
- Having the patient swallow.
- Myxedema coma

LABORATORY STUDIES

Laboratory tests include an erythrocyte sedimentation rate (ESR) if thyroiditis is suspected, and TSH (elevated in hypothyroidism and subclinical disease) and FT₄ levels (low in hypothyroidism).

- In acute granulomatous thyroiditis, ESR is greater than 50 (LR+ 95) and the TSH and FT₄ are usually normal.
- In primary hypothyroidism, the TSH is greater than 10 mIU/L (LR+ 16) and FT₄ is less than 8 (LR+ 11).
- The presence of antibodies to TPO and thyroglobulin help establish the diagnosis of Hashimoto thyroiditis but is unnecessary for treatment. TPO antibodies will be positive in 90% to 95% of patients.⁴
- In pituitary causes of hypothyroidism (central hypothyroidism), the TSH may be normal or elevated but FT₄ will be low.²
- In the future, reference limits may need to change as TSH distribution and reference limits have been shown to shift to higher concentrations with age and are unique for different racial/ethnic groups.⁷

DIFFERENTIAL DIAGNOSIS

Goiter presenting as a painful neck mass is most commonly caused by subacute granulomatous (de Quervain) thyroiditis (likely viral) or hemorrhage into a thyroid cyst or adenoma. Other causes include the following:

- Painful Hashimoto thyroiditis—Hypothyroidism with the presence of antibodies helps to confirm this diagnosis.

FIGURE 226-4 A. A 36-year-old woman with large goiter. B. The resected goitrous thyroid gland. (Courtesy of Frank Miller, MD.)

FIGURE 226-5 Massive multinodular goiter before surgery. (Courtesy of Frank Miller, MD.)

- Infected thyroglossal duct or branchial cleft cyst—Mass palpates as cystic and may be fluctuant; focal (e.g., erythema and warmth) and systemic symptoms of infection (e.g., fever) may be present. Even a noninfected thyroglossal duct cyst can be confused for an enlarged thyroid (**Figure 226-8**).
- Acute suppurative thyroiditis (microbial)—Focal (e.g., erythema and warmth) and systemic symptoms of infection (e.g., fever) are usually present.
- Thyroid carcinoma—Hard mass within thyroid gland (**Figure 226-9**).

Painless goiter and hypothyroidism are most often caused by Hashimoto thyroiditis, but may also be caused by the following:

- Environmental goitrogens (e.g., excess iodine, foods such as cassava, cabbage, and soybeans).
- Iodine deficiency.
- Pharmacologic inhibition (rare)—Drugs include lithium, amiodarone, and interferon- α .

Painless goiter and hyperthyroidism may be caused by the following:

- Graves disease (common, 0.5% to 2.5% of the population)—Symptoms of nervousness, fatigue, weight loss, heat intolerance, palpitations, and exophthalmus (Chapter 227, Graves Disease and Goiter).
- Postpartum thyroiditis (2% to 16% within 3 to 6 months of delivery)—Recent delivery.
- Toxic nodular goiter (uncommon)—Usually in the elderly; thyroid gland feels nodular (**Figure 226-4**) and thyroid scan shows multiple foci of increased uptake.

MANAGEMENT

NONPHARMACOLOGIC

- For nonendemic goiter, identify and remove goitrogens.

MEDICATIONS

Patients with endemic goiter should be provided with iodine.

For nonendemic goiter, also consider the following:

- TSH suppression with levothyroxine (1 to 2.2 mg/kg per day) (variable but limited effect on goiter size and can cause hyperthyroidism).⁸ **SOR B**
- Radioactive iodine treatment if enough functioning tissue is present. **SOR C**

Treat patients with acute microbial thyroiditis with antibiotics against the most common pathogens (i.e., *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*). Alternative agents, used for 7 to 10 days, include: **SOR C**

- Amoxicillin/clavulanate (500 mg 3 times daily),
- A first- or second-generation cephalosporin (e.g., cephalexin 500 mg 4 times daily), and
- Penicillinase-resistant penicillin (e.g., dicloxacillin 500 mg 4 times daily).

FIGURE 226-6 Asymmetric multinodular goiter causing trachea to deviate from the midline prior to resection. (Courtesy of Frank Miller, MD.)

FIGURE 226-7 Myxedema of the face with puffiness around the eye. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

In patients with subacute thyroiditis:

- Oral corticosteroids can reduce pain and swelling. **SOR C**
- Symptoms of hyperthyroidism can be treated with β -blockers or calcium channel blockers.⁹ **SOR B**
- Symptoms of hypothyroidism can be treated with levothyroxine.⁸ **SOR B**

Patients with Hashimoto thyroiditis and low FT4 are treated with levothyroxine as follows:

- Younger patients start with 50 to 100 mcg/day increasing by 25 to 50 mcg/day at 6- to 8-week intervals until the TSH is normal (approximately 1.6 mcg/kg per day of levothyroxine).^{2,8} **SOR B**
- Older patients or those with cardiac disease start with 25 mcg/day and increase by 12.5 to 25 mcg/day every 6 to 8 weeks to normalize the TSH (approximately 1 mcg/kg per day of levothyroxine). **SOR C**
- Dosing in the evening appears to normalize the laboratory values more effectively, but in one study, did not influence symptoms or quality of life.^{2,10}

A Cochrane review of 12 small randomized controlled trials (RCTs) determined that treatment of subclinical hypothyroidism did not improve survival or decrease cardiovascular morbidity.¹¹

- Patients with subclinical hypothyroidism should be considered for treatment if they have symptoms of thyroid deficiency, are at high likelihood of progression to hypothyroidism (e.g., TSH >10 mIU/L), or are pregnant.^{2,3}
- For patients with TSH levels of 5 to 10 mIU/L, other factors to consider in a treatment decision include presence of goiter, bipolar disorder or depression, infertility or ovulatory dysfunction, presence of antithyroid antibodies, young age, patient preference, and possibly hyperlipidemia.³
- A dose of 50 to 75 mcg/day is usually sufficient for those with subclinical hypothyroidism. **SOR C**

REFERRAL

- Large goiters that impinge upon the trachea or do not respond to medications may be treated with surgery (**Figure 226-4**).
- Subtotal thyroidectomy can be considered for nodular goiters but recurrence rates can be high.¹² **SOR A**
- Consultation with an endocrinologist may be helpful if the diagnosis is uncertain and for patients with central hypothyroidism, severe hypothyroidism (i.e., myxedema coma), or coexisting cardiovascular disease.²
- Patients with myxedema coma should be hospitalized in an intensive care unit; without treatment, mortality approaches 100%.

PREVENTION AND SCREENING

- There is insufficient evidence to support screening for hypothyroidism in pregnant and nonpregnant patients¹³; however, pregnant women with subclinical hypothyroidism are more likely to have placental abruption (three-fold increase) and preterm delivery

FIGURE 226-8 Thyroglossal duct cyst in the midline superior to the thyroid. (Courtesy of Frank Miller, MD.)

FIGURE 226-9 A 93-year-old woman with thyroid cancer that went untreated for 3 years. Two large firm masses are visible in the neck. (Courtesy of Dustin Williams, MD.)

(two-fold increase) and their infants are at higher risk for intraventricular hemorrhage and respiratory distress syndrome.¹⁴ Authors of a literature review found a single intervention trial demonstrating a decrease in preterm delivery among thyroid antibody-positive women treated with levothyroxine.¹⁵

- One expert panel recommended TSH testing in women with symptoms of thyroid dysfunction, personal or family history of thyroid disease, an abnormal thyroid gland on palpation, or type 1 diabetes mellitus or other autoimmune disorders.¹⁶ In support of this approach, a clinical trial of universal screening versus case finding did not demonstrate a difference in adverse outcomes; however, treatment of women with thyroid dysfunction identified by screening a low-risk group was associated with a lower rate of adverse outcomes.¹⁷

PROGNOSIS

- In the most extensive community survey on goiter (Whickham, England), goiter was present in 15.5% of the population.¹ At the 20-year follow-up, 20% of women and 5% of men no longer had goiter and 4% of women and no men had acquired a goiter.
- Suppression of TSH with levothyroxine effectively reduces the goiter of Hashimoto thyroiditis and should be continued indefinitely. In one study, withdrawal of medication after 1 year resulted in only 11.4% remaining euthyroid.¹⁸
- Large goiter, TSH greater than 10 mU/L, and a family history of thyroid disease are associated with failure to recover normal thyroid function and treatment should continue indefinitely.
- In patients with subclinical hypothyroidism, progression to clinically overt hypothyroidism is 2.6% each year if TPO antibodies are absent, and 4.3% if they are present.¹⁹

FOLLOW-UP

- TSH should be rechecked approximately 6 to 8 weeks after initiation of levothyroxine therapy and again in 4 to 6 months if normal, and annually thereafter unless otherwise clinically indicated.²⁰ **SOR C**
- Although the need for thyroid replacement is lifelong, dose requirements may change over time. Thyroxine dose may need to be increased during pregnancy (20% to 40%), with use of estrogens, or in situations of weight gain, malabsorption, *Helicobacter pylori*-related gastritis and atrophic gastritis and with use of some medications. Requirements may decrease with increased age, androgen use, reactivation of Graves disease, or the development of autonomous thyroid nodules.²
- There is some evidence that use of ultrasound can help predict progression to overt hypothyroidism in patients with subclinical hypothyroidism²¹; in one study, patients with TPO antibodies and/or ultrasound abnormalities had a greater progression to overt disease than those without either finding (31.2% vs. 9.5% at 3 years).²²
- The frequency of other autoimmune disease is increased in patients with Hashimoto thyroiditis (14.3% in one study), including rheumatoid

arthritis, pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo, and increased monitoring should be considered.²³

227 GRAVES' DISEASE AND GOITER

Mindy A. Smith, MD, MS

PATIENT STORY

A 32-year-old woman presents with fatigue and “eye strain” (**Figure 227-1**). She had been working as a secretary and noticed difficulty focusing her eyes. She said she was anxious and was having difficulty writing. She reported that her sister was taking medication for “thyroid trouble.” A low thyroid-stimulating hormone (TSH) and an elevated free thyroxin level (T_4) were found on laboratory testing, and the patient was diagnosed with Graves disease (GD). Her thyroid scan showed an enlarged thyroid with increased uptake (**Figure 227-2**). The patient chose radioactive iodine (RAI) as her treatment and her symptoms resolved. One year later she required levothyroxine treatment.

INTRODUCTION

GD is an autoimmune thyroid disorder characterized by circulating antibodies that stimulate the TSH receptor and resulting in hyperthyroidism.¹

SYNONYMS

Thyrotoxicosis (clinical state resulting from inappropriately high thyroid hormone levels); hyperthyroidism (thyrotoxicosis caused by elevated synthesis and secretion of thyroid hormone).

EPIDEMIOLOGY

- GD is a common disorder affecting 0.5% to 1.2% of the population.
- There is a female-to-male ratio of 5 to 10:1.
- Among patients with hyperthyroidism, 60% to 80% have GD; younger patients (younger than age 64 years) with hyperthyroidism are more likely to have GD than are older patients with hyperthyroidism.
- Graves ophthalmopathy (see “Clinical Features” below) occurs in more than 80% of patients within 18 months of diagnosis of GD. The ophthalmopathy is clinically apparent in 30% to 50% of patients.²
- Goiter is present in 90% of patients younger than age 50 years (vs. 75% in older patients with GD).¹
- Untreated hyperthyroidism can lead to osteoporosis, atrial fibrillation, cardiomyopathy, and congestive heart failure; thyrotoxicosis (thyroid storm) has an associated mortality rate of 20% to 50%.³

ETIOLOGY AND PATHOPHYSIOLOGY

- The hyperthyroidism of GD results from circulating immunoglobulin (Ig) G antibodies that stimulate the TSH receptor.² These

FIGURE 227-1 This patient displays the following common findings of Graves disease: Lid retraction and mild proptosis (exophthalmus), particularly evident on the left eye, and goiter. (Courtesy of Dan Stulberg, MD.)

FIGURE 227-2 Nuclear scan of the thyroid in Graves disease showing increased uptake (61%). (Courtesy of Michael Freckleton, MD.)

antibodies are synthesized in the thyroid gland, bone marrow, and lymph nodes. Activation of the TSH receptor stimulates follicular hypertrophy and hyperplasia causing thyroid enlargement (goiter) and an increase in thyroid hormone production with an increased fraction of triiodothyronine (T_3) relative to T_4 (from approximately 20% to up to 30%).²

- The etiology is seen as a combination of genetic (human leukocyte antigen-D related [HLA-DR] and cytotoxic T-lymphocyte antigen 4 [CTLA-4] polymorphisms) and environmental factors, including physical and emotional stress (e.g., infection, childbirth, life events).² In addition, insulin-like growth factor-1 receptor (IGF-1R)-bearing fibroblasts and B-cells exhibiting the IGF-1R(+) phenotype may be involved in the connective tissue manifestations.⁴ Siblings have higher incidence of both GD and Hashimoto thyroiditis (Chapter 226, Goitrous Hypothyroidism).
- The ophthalmopathy is believed to result from an autoimmune response directed toward an antigen shared by the thyroid and the eye's orbit. There is infiltration of the extraocular muscles by activated T cells, which release cytokines, activating fibroblasts (fibrosis can lead to diplopia) and increasing the synthesis of glycosaminoglycans (water trapping causes swelling).²

RISK FACTORS

- Family history of thyroid disease, especially in maternal relatives.
- Smoking (a strong risk factor for Graves ophthalmopathy).

DIAGNOSIS

There are several guidelines available for the diagnosis and management of thyroid disease in provider resources on page 1360.

CLINICAL FEATURES

Symptoms depend on the severity of thyrotoxicosis, duration of disease, and age (findings are more subtle in the elderly). More than half of patients diagnosed with GD have these common symptoms:

- Nervousness.
- Fatigue.
- Weight loss.
- Heat intolerance.
- Palpitations.

Signs of disease include:

- Tachycardia (atrial fibrillation is common in patients >50 years of age).²
- Goiter—Listening over the goiter with a stethoscope may reveal a thyroid bruit (**Figure 227-3**).
- Resting tremor.
- Hyperreflexia
- Flushing and temporal wasting (**Figure 227-4**).

FIGURE 227-3 This 37-year-old woman has Graves disease and a loud bruit over her enlarged hyperactive thyroid gland. She was thyrotoxic at this time. (Courtesy of Richard P. Usatine, MD.)

FIGURE 227-4 Visible flushed skin and temporal wasting in this thyrotoxic woman with new-onset Graves disease. (Courtesy of Richard P. Usatine, MD.)

- Skin and nail changes include:
 - Warm, erythematous, moist skin (from increased peripheral circulation).
 - Palmer erythema.
 - Pretibial myxedema—Occurring in a small percentage of patients (0.5% to 4%), it consists of nonpitting scaly thickening and induration of the skin usually on the anterior shin and dorsa of the feet (**Figures 227-5** and **227-6**).⁵ It can also appear as a few well-demarcated pink, flesh-colored, or purple-brown papules or nodules.
 - Nails are soft and shiny and may develop onycholysis (distal separation of the nail plate from the underlying nail bed).
- Eye involvement may occur before hyperthyroidism (in 20% of patients) and gradually progresses with only mild discomfort (a gritty sensation with increased tearing is the earliest manifestation). The eye findings in GD^{1,2} are:
 - Lid retraction (drawing back of the eyelid allowing more sclera to be visible) (**Figures 227-1** and **227-7**).
 - Frank proptosis (displacement of the eye in the anterior direction); occurs in one-third (**Figures 227-1** and **227-7**).
 - It is possible to have unilateral eye involvement with Graves ophthalmopathy (**Figure 227-8**).
 - Extraocular muscle dysfunction (e.g., diplopia).
 - Corneal exposure keratitis or ulcer.
 - Periorbital edema, chemosis, and scleral injection.

FIGURE 227-5 Early bilateral pretibial myxedema in a patient with Graves eye disease. These asymmetrical erythematous plaques and nodules are firm and nonpitting. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

LABORATORY TESTING AND IMAGING

- With typical symptoms, you can confirm the diagnosis of GD with a low or undetectable sensitive assay for TSH and an elevated free T₄ level.
- The presence of TSH receptor antibodies (present in 70% to 100% of patients at diagnosis) has a positive and negative likelihood ratio of 247 and 0.01, respectively.⁶ These antibodies are not usually required for diagnosis.
- If the clinical picture is uncertain or there is thyroid nodularity, obtain a RAI scan and uptake.⁷ Elevated uptake (>30%) and a homogeneous pattern on scan are diagnostic (**Figure 227-2**).

DIFFERENTIAL DIAGNOSIS

Other causes of hyperthyroidism:

- Autonomous functioning nodule—This is an uncommon cause of thyrotoxicosis (present in 1.6% to 9% of patients with hyperthyroidism),⁸ and most nodules do not cause hyperthyroidism. These present as a discrete swelling in an otherwise normal thyroid gland, and thyroid scan would show a discrete nodule.
- Toxic multinodular goiter—More common cause of hyperthyroidism in the elderly; thyroid scan shows multiple foci of increased uptake.
- Thyrotropin-secreting pituitary adenoma (rare)—Adenomas may cause visual disturbance (in the absence of exophthalmus), and other hormonal stimulation may occur (e.g., elevated serum prolactin).
- Thyroiditis—May be painless or painful, short duration, low uptake on RAI scan.
- Exogenous thyroid hormone ingestion—History of overdosage of prescribed or acquired thyroid medication.

FIGURE 227-6 Pretibial myxedema in a patient with Graves ophthalmopathy. Hair follicles are prominent, giving a peau d'orange appearance. (Courtesy of the University of Texas Health Sciences Center, Division of Dermatology.)

The differential diagnoses for the eye findings include the following:

- Metastatic disease to the extraocular muscles.
- Pseudotumor—This condition's rapid onset and pain differentiate it from Graves ophthalmopathy.

MANAGEMENT

- Three options are available to treat the hyperthyroidism: antithyroid drugs, RAI therapy, and surgery, as discussed below.^{1,2} **SOR A**

NONPHARMACOLOGIC

- Supportive measures for eye symptoms include dark glasses, artificial tears, propping up the head and taping the eyelids closed at night.

MEDICATIONS

- Symptoms of hyperthyroidism can be controlled with β -adrenergic blockers (e.g., propranolol, 10 to 40 mg bid–qid) or calcium channel blockers (e.g., diltiazem, 30 to 90 mg bid). **SOR B** Authors of a recent guideline recommend β -adrenergic blockage in elderly patients with symptomatic disease, those who are thyrotoxic with cardiovascular disease or a resting heart rate greater than 90 beats/min, and prior to RAI treatment in patients with GD at risk for complications of extreme hyperthyroidism (e.g., highly symptomatic).⁷
- Antithyroid drugs (methimazole 10 to 20 mg/day or propylthiouracil [PTU], 100 to 200 mg every 8 hours). Potential side effects of these medications include rash, joint pain, liver inflammation, and, rarely, agranulocytosis.² Baseline liver enzymes and complete blood count (CBC) (including white blood cells [WBCs] and differential) is recommended.⁷ Methimazole is preferred except in patients during the first trimester of pregnancy, those being treated for thyroid storm, or for those who have reactions to methimazole.⁷
- The drug dose may be reduced after the patient is euthyroid (typically PTU 50 to 100 mg/day and methimazole 2.5 to 10 mg/day).
- Antithyroid drugs are preferred during pregnancy and can be considered in patients with mild disease, small goiter, and lower antibody levels. Pretreatment with methimazole prior to RAI is suggested for patients with GD who are at high risk for complications of extreme hyperthyroidism.⁷ They are also used more commonly as primary treatment in Europe and Asia.
- The optimal duration of titrated antithyroid drug therapy is 12 to 18 months to minimize relapse.^{7,9} **SOR A**
- In a randomized controlled trial (RCT) of 159 patients with mild Graves orbitopathy who were given selenium (100 mcg twice daily), pentoxifylline (600 mg twice daily), or placebo (twice daily) orally for 6 months, selenium significantly improved quality of life, reduced ocular involvement, and slowed progression of the disease compared to the other treatments.¹⁰
- Patients with severe (and possibly moderate) Graves orbitopathy are usually treated with a 12-week course of high-dose intravenous glucocorticoid pulses (total <8 g of methylprednisolone); approximately 80% of patients respond to this regimen.^{11,12} Liver failure is a serious but rare side effect.

FIGURE 227-7 Bilateral exophthalmos that has been present for 5 years since patient was diagnosed with Graves disease. Although the radioactive iodine returned her thyroid function to normal, the exophthalmos continues to bother the patient. (Courtesy of Richard P. Usatine, MD.)

FIGURE 227-8 Woman with unilateral Graves ophthalmopathy and vitiligo. There is a strong association between autoimmune thyroid diseases and vitiligo. (Courtesy of Richard P. Usatine, MD.)

RADIOTHERAPY

- RAI—It is the most commonly prescribed treatment in the United States, but is contraindicated in pregnancy or with breastfeeding and should be used with caution in patients with cardiovascular disease.
- RAI may also be used after initial treatment with antithyroid drugs; these drugs should be discontinued for 3 to 7 days before treatment.²
- The half-life of iodine-131 is about 1 week; however, it is recommended that women not attempt pregnancy for 6 to 12 months after RAI treatment.
- RAI may cause painful thyroid inflammation for a few weeks in approximately 1% of patients; this condition can be treated with nonsteroidal antiinflammatory agents, β -blockers, and possibly steroids.³ Approximately 5% of patients with toxic nodular goiter treated with RAI develop GD.³
- In addition, radiation-induced thyroiditis can aggravate ophthalmopathy. This side effect can be minimized by early levothyroxine replacement and prednisone (60 to 80 mg/day starting at the time of RAI treatment and tapering, after 2 to 4 weeks, over the next 3 to 12 months).¹³ One author believed that moderate to severe ophthalmopathy was a contraindication for RAI.³

SURGICAL TREATMENT

- Near-total to total thyroidectomy by a high-volume thyroid surgeon is recommended for patients with GD.⁷
- Indications for surgery are very large goiters, presence of suspicious nodules, pregnant women requiring high doses of antithyroid drugs, and allergy or failure of other therapies.
- In most cases for patients with GD, pretreatment with methimazole until euthyroid is recommended prior to surgery and levothyroxine is started following surgery.⁷
- Following surgery, small remnants of thyroid tissue (<4 g) result in rates of hypothyroidism of greater than 50% and large remnants (>8 g) have higher rates of recurrent hyperthyroidism (15%).
- With respect to the eye findings, most symptoms except for proptosis improve with control of the hyperthyroidism. In one study, 64% of the patients spontaneously improved, 22% stabilized, and 14% progressed.¹³

REFERRAL

- Patients with significant eye symptoms or clinical findings should be referred to an ophthalmologist.
- Treatment options for the persistent severe ophthalmopathy include high-dose systemic steroids (40 to 80 mg/day), orbital radiotherapy, and orbital decompression surgery.¹⁴ **SOR B**

PROGNOSIS

- With use of antithyroid medications, symptoms improve in 3 to 4 weeks; weight gain (about 4.5 kg) often occurs as metabolism normalizes.² Remission rates following antithyroid drugs vary from 37% to 70% and occur within 6 to 8 weeks.

- Following RAI, 50% to 75% of patients become euthyroid after 5 to 8 weeks, but 50% to 90% of patients with GD eventually become hypothyroid (10% to 20% in year 1 and 5% per year afterward). Retreatment with radioiodine may be needed in 14% of patients with GD, 10% to 30% of patients with toxic adenoma, and 6% to 18% of patients with toxic nodular goiter.³
- In a RCT comparing GD treatments, relapse rates were higher among patients who received antithyroid drugs (approximately 40% [range: 34% (elderly) to 42% (young)]) versus patients following RAI (21%) and surgery (5% [3% (young) to 8% (elderly)]).¹⁵

FOLLOW-UP

- The goals of therapy are to resolve hyperthyroid symptoms and to restore the euthyroid state. Close follow-up is needed in the initial treatment period; medications for symptoms of hyperthyroidism may be withdrawn slowly following treatment.
 - Antithyroid drug dosages may be reduced after the patient is euthyroid (typically PTU 50 to 100 mg/day and methimazole 2.5 to 10 mg/day), but drugs should be continued for 12 to 18 months to minimize relapse. **SOR A**
 - Following treatment with RAI, most patients eventually become hypothyroid (20% within the first year) and so periodic monitoring of thyroid function is important. Follow-up within the first 1 to 2 months (free T₄ and T₃) is recommended and then at 4 to 6 weeks if hyperthyroidism continues; consider retreatment with RAI if there is minimal response at 3 months or hyperthyroidism persists at 6 months.⁷
 - Following surgery, patients may become hypothyroid or have a recurrence of hyperthyroidism, depending on the size of the remnant remaining; patients should be monitored with periodic blood tests and for symptoms. For those with GD following surgery and levothyroxine, a TSH is recommended at 6 to 8 weeks postoperation.⁷
 - An in-office exophthalmometer can be used to track changes in eye prominence over time.²
 - Patients with GD are at high risk for development of other autoimmune disease; in one cross-sectional study in the United Kingdom of patients attending a thyroid clinic, the frequency of another autoimmune disorder (e.g., rheumatoid arthritis [3.15%], pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo) was 9.67% in patients with GD.¹⁶
- should be made aware of symptoms to watch for and to report any recurrent symptoms.
- Following RAI, patients should avoid intimate contact (including kissing) and contact with children for 5 days; avoid contact with pregnant women for 10 days (maintain distance of approximately 6 feet); limit close contact with other adults to 2 hours for 5 days; sit while voiding and flush twice with the lid closed; not share toothbrushes, utensils, dishes, towels, or clothes, and wash these separately.³
 - Ophthalmopathy usually runs its own course independent of the thyroid function. Additional treatment may be needed in consultation with an ophthalmologist.
 - Smoking cessation may have a beneficial effect on the course of ophthalmopathy.
 - Siblings and children should be made aware of their increased risk of developing thyroid disease or associated disorders and should monitor themselves for symptoms.

PATIENT EDUCATION

- Patients should be told that the goals of therapy are to resolve the symptoms of thyroid excess and to restore the thyroid function to normal.
- The treatment choices should be discussed, as each has advantages and disadvantages; treatment should be individualized.
- Regardless of the therapy chosen, long-term follow-up is needed to monitor thyroid status; there is a high risk of becoming hypothyroid in the future or to relapse again into hyperthyroidism. Patients

228 ACROMEGALY

Mindy A Smith, MD, MS

PATIENT'S STORY

A 60-year-old man presents to his family physician with severe headache and weakness (**Figure 228-1**). He also noted enlargement of his hands (**Figure 228-2**), which made him remove his wedding ring when it became too tight, and feet (his shoe size had increased). He said his voice seemed to be deeper and his hands feel doughy and sweaty. Laboratory testing reveals an elevated insulin-like growth factor (IGF)-I, and there is a failure of growth hormone (GH) suppression following an oral glucose load confirming the diagnosis of acromegaly. Computed tomography (CT) scan of the head demonstrates a pituitary adenoma.

INTRODUCTION

Acromegaly is a condition of excessive linear and organ growth usually caused by autonomous GH hypersecretion from a pituitary tumor.

EPIDEMIOLOGY

- Rare (5/1,000,000 adults)¹
- Most typically caused by a pituitary somatotrope macroadenoma. It may also be caused by growth hormone-releasing hormone (GHRH) excess from lesions of the pancreas, lung, or ovaries, or from a chest or abdominal carcinoid tumor.
- The disorder is usually sporadic, but may be familial (<5%) and has been associated with other endocrine tumors (e.g., multiple endocrine neoplasia type I).¹
- In a Spanish multicenter epidemiologic study, the reported mean age at diagnosis was 45 years.²
- The occurrence of GH hypersecretion in children and adolescents, prior to epiphyseal closure, causes gigantism.

ETIOLOGY AND PATHOPHYSIOLOGY

- The clinical signs and symptoms of acromegaly result from GH excess that stimulates linear and organ growth (through IGF-I), soft-tissue swelling, and chondrocyte action.
- Acromegaly is also associated with insulin resistance and an increased risk of cardiovascular disease; the latter appears to be a result of pressure-related arterial and left ventricular stiffening rather than atherosclerotic disease.³
- An increased risk for several cancers among these patients may be a result of the proliferative and antiapoptotic activity associated with increased circulating levels of IGF-I.

FIGURE 228-1 A 60-year-old man with acromegaly. Note the coarse facial features and moderate prognathism (protrusion of the lower jaw). (Courtesy of Richard P. Usatine, MD.)

DIAGNOSIS

The diagnosis of acromegaly is established by documenting autonomous GH hypersecretion and by pituitary imaging.

CLINICAL FEATURES

The clinical manifestations of acromegaly are often subtle and may not be noticed for many years. Gigantism occurs if excessive GH exposure occurs *before* closure of the epiphyses; acromegaly develops *after* closure of the epiphyses. Clinical features of acromegaly include¹:

- Soft-tissue swelling resulting in hand and foot enlargement (**Figure 228-2**).
- Kyphoscoliosis and skeletal hyperostosis.
- Coarse facial features and a large fleshy nose (**Figures 228-1 and 228-3**).
- Frontal bossing.
- Jaw malocclusion and overbite.
- Hyperhidrosis and oily skin.
- Other common features are deep voice (soft-tissue swelling of vocal cords), arthropathy, carpal tunnel syndrome, kyphosis, proximal muscle weakness, and fatigue; patients may complain of headache and visual field defects (expanding tumor), paresthesias, and sexual dysfunction.¹
- Associated medical conditions include sleep apnea (60%), coronary heart disease (20% to 90% depending on duration and associated hypertension), and diabetes mellitus (25%). There also appears to be an increase in intracranial aneurysms.⁴
- In one study (N = 55), approximately two-thirds of women had anovulatory cycles; some believed related to elevated hormone levels.⁵

LABORATORY AND IMAGING

- An elevated total serum IGF-I concentration (age and gender matched) is extremely useful in the diagnosis of acromegaly.⁶ Lack of standardization and normative data, however, have hampered diagnosis and monitoring.
- Failure of GH suppression to less than 1 mcg/L within 1 to 2 hours of an oral glucose load (75 g) can confirm the diagnosis, although 20% of patients exhibit a paradoxical increase in GH. Failure to suppress GH levels may also be seen in patients with diabetes, renal or hepatic failure, and obesity, and in those receiving estrogen replacement and in pregnant women.¹
- A single measure of GH is not helpful because of its pulsatile secretion.
- Another associated laboratory abnormality is elevated prolactin (30% of patients).

MANAGEMENT

The Acromegaly Consensus Group recommends a team approach, including an experienced surgeon, endocrinologist with pituitary expertise, and a physician with radiotherapy experience.⁷ Treatment is usually surgical followed by medication (usually a somatostatin

FIGURE 228-2 The man in **Figure 228-1** with acromegaly producing hands that are large and doughy with widened fingers. (Courtesy of Richard P. Usatine, MD.)

receptor ligand [SRL]) if the disease is not controlled. If initial medical treatment (following dose titration) fails to normalize GH and IGF-I, patients with tumor mass on magnetic resonance imaging (MRI) may consider radiation therapy while those without a mass effect may be tried on combination medical therapy.⁷

MEDICATIONS

There are 3 types of medications used in the treatment of patients with acromegaly: SRLs, a GH receptor antagonist, and a dopamine agonist. Although GH reduction may alleviate symptoms, attempts to normalize levels of both GH and its target growth factor (i.e., IGF-I) should be made because persistent secretion of either pose significant long-term health risks.

- There is insufficient evidence to support presurgical treatment with SRLs.⁷
- Somatostatin analogs are first-line therapy for those with nonsurgically resectable tumors; after surgery if normalization of GH and IGF-I does not occur; or during radiation treatment until control is achieved by that therapy (can take several years).
 - Long-acting somatostatin depot formulations, octreotide LAR and lanreotide Autogel, are available and appear equivalent. Patients should be treated with the same dose for 3 months before reassessment and dose titration if needed.⁷
 - Side effects are injection pain, sinus bradycardia, and symptoms related to suppression of GI motility and secretion (nausea, abdominal pain, diarrhea, and flatulence); gallstones or sludge occur in 30%, but few develop cholecystitis.¹
- Subcutaneous pegvisomant is the available GH receptor antagonist for acromegaly. It is indicated for patients with persistent IGF-I elevations despite other treatment, as an adjunct to SRLs, or possibly as monotherapy; supporting data are lacking.⁷
 - Side effects include injection site pain and lipohypertrophy. Elevated liver enzymes are seen in approximately 5% to 25% of patients (usually transient) and should be monitored.
- Of the dopamine agonists, only cabergoline is effective (limited) at suppressing GH hypersecretion.⁷
 - Considered for patients preferring oral medication, patients following surgery with markedly elevated prolactin along with elevated GH and IGF-I, and as an adjunct to SRLs when failed response to maximum dose.⁷
 - Common side effects are GI (nausea, constipation), psychiatric and central nervous system (sleep disturbance, vertigo, depression), and cardiovascular (hypertension, peripheral edema); cardiac valve abnormalities have been reported in patients with Parkinson disease (who usually use high doses).

PROCEDURES

- Surgical resection (adenomectomy via transsphenoidal approach) is the cornerstone of treatment for intrasellar microadenomas, noninvasive macroadenomas, and when the tumor is causing compression symptoms.⁷
- Radiation therapy, conventional and stereotactic procedures, is also effective in decreasing GH levels but takes 10 to 15 years to work and carries a risk of hypopituitarism (>50%). It is considered

FIGURE 228-3 A. A 26-year-old attractive woman prior to acromegaly changes. B. Facial changes 20 years later in the same woman. Note the coarse facial features with large nose, lips, and chin. Protrusion of the lower jaw is visible. (Courtesy of Vernon Burke, DMD.)

third-line therapy.⁷ Radiation has been used in an attempt to discontinue medical therapy.

- Five-year remission rates from gamma knife radiotherapy (after surgical debulking) are between 29% and 60%.⁷
- Conventional radiotherapy has potential risks of second tumors (approximately 1% intracranial) and cerebrovascular events, but long-term data are lacking.⁷

PROGNOSIS

- After surgical resection, 70% to 95% of patients with microadenomas and 40% to 68% of patients with macroadenomas have normalization of IGF-I.^{6,7}
 - Irradiation of adenomas results in attenuation of IGF-I secretion in more than 60% of subjects after 10 to 15 years.⁷
 - Less than half of patients (44%) receiving somatostatin analogs achieve normal IGF-I levels, and a third achieve normal GH levels.⁷
- An MRI following surgery demonstrating a hypointense MRI signal in the remaining tumor may be useful in predicting good response to subsequent somatostatin analog treatment.⁸
- In the past, patients with acromegaly had a 10-year reduction in life span because of cardiac (heart failure, arrhythmia), cerebrovascular, metabolic (diabetes, osteoporosis), and respiratory (airway obstruction from macroglossia and hypertrophied mucosal tissues, sleep apnea) disease; radiotherapy may also increase the mortality rate.¹ Both IGF-I and GH levels correlate with mortality and normalizing these levels (IGF-I to age/sex standards and GH <2.5 ng/mL) appear to normalize the life span.⁷
- Successful pregnancy appears to occur in women with acromegaly,⁵ although one case series found cases of gestation diabetes and gestational hypertension in women with uncontrolled disease; symptomatic (e.g., visual field defect, headache) enlargement of GH-secreting pituitary macroadenomas occurred in a few women.⁹

FOLLOW-UP

- Identification and treatment of comorbidities should be pursued. An initial colonoscopy and echocardiogram is recommended.⁷
- The Acromegaly Consensus Group defines optimal disease control (i.e., posttreatment remission of acromegaly) as IGF-I level (determined by a reliable standardized assay) in the age-adjusted normal range, and a GH level less than 1 g/L from a random GH measurement, using an ultrasensitive assay.⁶ In patients who are controlled, monitor levels every 6 months.
- Based on a cohort study of patients hospitalized for acromegaly (Denmark 1977–1993; Sweden 1965–1993) linked to tumor registry data for up to 28 years of follow-up, individuals with acromegaly have higher rates of small intestine, colon, rectal, kidney, and bone cancer.¹⁰ The researchers also found that these patients had elevated rates for cancers of the brain and thyroid that may be related to pituitary irradiation.
- Monitoring treatment success postoperatively or following radiation therapy includes:

- Measurement of GH and IGF-I levels. The consensus group suggest that optimal disease control (i.e., posttreatment remission of acromegaly) is now defined as IGF-I level (determined by a reliable standardized assay) in the age-adjusted normal range and a GH level less than 1 g/L from a random GH measurement.⁶
- Postoperative magnetic resonance imaging (MRI) 3 to 4 months postsurgery and 3 to 6 months following medical therapy, and yearly for those who remain uncontrolled. There is no consensus on frequency of continued MRI once remission is achieved.⁷
- Full pituitary function should be measured 3 months after surgery and periodically for those receiving radiotherapy.⁷

PATIENT EDUCATION

- Patients should be advised that untreated, one's life span is decreased by an average of 10 years. Survival improves greatly if GH and IGF-I can be normalized.
- Patients should consider increased surveillance for colorectal cancer and encouraged to actively manage comorbid conditions.

229 HEADACHE

Heidi Chumley, MD

PATIENT STORY

A 35-year-old woman presented to the office to discuss her migraines. She has episodic unilateral throbbing headaches accompanied by nausea, photophobia, and phonophobia. She used to have a migraine about every 3 months, but is now having one almost every 2 weeks. As this frequency interferes with her life, prophylactic therapy is discussed. She accepts and her migraine frequency decreases dramatically.

INTRODUCTION

More than 77% of adults experience headaches during their lifetime. Headaches are either primary or secondary and the presence or absence of red flags is useful to distinguish dangerous causes of secondary headaches. The most common primary headaches are tension, migraine, and chronic daily headaches. Medication overuse can complicate headache therapy. Treatment and prognosis is dependent on type of headache.

EPIDEMIOLOGY

- Lifetime prevalence estimated to be greater than 77% in adults.¹
- Fifty-three percent of adults (61% of women and 45% of men), and 53% of children have had a headache in the past year.¹ Elderly adults have a lower rate of headaches with 36% reporting a headache in the past year.
- Episodic tension-type headache (TTH) prevalence is 62.6% in adults and 15.9% in children.¹
- Chronic (>15 days per month) TTH has a prevalence of 3.3% in adults and 0.9% in children.¹
- Migraine has a prevalence of 14.7% in adults (8% in men, 17.6% in women) and 9.2% in children.¹
- Chronic daily headache has lifetime prevalence of 4% to 5%.²
- Medication overuse contributes to daily headache in approximately 1% of adults in the general population.¹
- Cluster headache has a lifetime prevalence of 0.2% to 0.3%.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- TTH etiology is uncertain, but likely caused by activation of peripheral afferent neurons in head and neck muscles.³
- Migraine headache is thought to be caused by central sensory processing dysfunction, which is genetically influenced.⁴ Nociceptive input from the meningeal vessels is abnormally modulated in the dorsal raphe nucleus, locus coeruleus, and nucleus raphe magnus. This activation can be seen on positron emission tomography (PET) scan during an acute attack (**Figure 229-1**).

FIGURE 229-1 Imaging has helped clarify the etiology of migraine disorder. This positron emission tomography image shows activation in the dorsolateral pons, which includes the noradrenergic locus coeruleus, an area that modulates nociceptive input from the meningeal vessels. (With permission from Longo D, Fauci A, Kasper D, Hauser S, Jameson J, Loscalzo J, eds. *Harrison's Principles of Internal Medicine*, 18th ed. New York, NY: McGraw-Hill; 2011:116, Figure 14-2B.)

- Cluster headache is caused by trigeminal activation with hypothalamic involvement, but the inciting mechanism is unknown.⁵

RISK FACTORS

- For migraines—Family history.
- For medication overuse headache—Regular use of any medication used to treat acute headaches, most commonly simple analgesics and triptans.

DIAGNOSIS

CLINICAL FEATURES

- Red flags for dangerous secondary cause—Sudden onset; persistent headache with nausea, vomiting; worsening pattern; history of cancer, HIV, or systemic illness (fever, rash, etc); focal neurologic signs or seizures; vision changes; papilledema; headache worsened by Valsalva, exertion, or position changes; new headache during pregnancy or postpartum; new headache after age 55 years.^{2,3,6}
- Episodic TTH—At least 10 episodes of bilateral, mild to moderate, pressure (nonpulsating) type pain without nausea or vomiting, not aggravated by exertion, and rare photophobia or phonophobia, occurring less than 15 days per month.⁷
- Migraine headache—At least 5 episodes of unilateral, pulsating, moderate-to-severe headache lasting 4 to 72 hours, aggravated by physical activity, accompanied by nausea or emesis or photophobia and phonophobia.⁷
- Chronic daily headache (CDH)—A primary headache 15 or more days per month, for 4 or more hours per day, for 3 months.² Four types of CDH:
 - Chronic migraine—Episodic migraines increase in frequency while associated symptoms decrease; resembles tension headache with occasional typical migraine; often accompanied by medication overuse.²
 - Chronic TTH—Bilateral, nonpulsating, without nausea. Photophobia or phonophobia can be present.²
 - New daily persistent headache—Abrupt onset of daily headache in patient without a history of a headache disorder; patient often remembers exactly where and when the headaches started.²
 - Hemicrania continua—Chronic unilateral pain with exacerbations, often associated with ipsilateral autonomic features.²
- Medication overuse headache—Accompanies one of the CDHs; acute medications, such as triptans or opiates are taken more than 10 days a month, or analgesics more than 15 days a month, for more than 3 months.⁷
- Cluster headache—The most common type of trigeminal autonomic cephalalgias; can be episodic or chronic; sharp stabbing unilateral pain in trigeminal distribution, lasting 15 minutes to 3 hours, with ipsilateral autonomic features² (**Figure 229-2**).
- Sinus headache—Purulent nasal discharge, co-onset of sinusitis, headache localized to facial and cranial areas.

FIGURE 229-2 Lacrimation, ptosis, and lid edema seen in cluster headache. (Courtesy of The International Headache Society, <http://ihs-classification.org/en/>. Copyright www.ihs-classification.org; Copyright (2012) Prof. Hartmut Göbel, Germany, www.schmerzlinik.de.)

TYPICAL DISTRIBUTION

- Tension headaches are typically bilateral (**Figure 229-3**).
- Migraine and cluster headaches are typically unilateral.

LABORATORY TESTING

- Generally not indicated.
- May be used when a secondary cause, such as infection is suspected.

IMAGING

- Generally not indicated.
- MRI when red flags are present.

DIFFERENTIAL DIAGNOSIS

- Common primary headaches include episodic TTH, migraine, and chronic daily headache.
- Secondary causes of headache are uncommon and include systemic illnesses/infections, brain masses, subarachnoid hemorrhage (**Figure 229-4**), or increased intracranial pressure.
- Medication overuse headache is predominately seen with a primary headache, but may also accompany a secondary headache.

MANAGEMENT

Episodic TTH:

- Acute therapy.
 - Aspirin 500 to 1000 mg is the most effective treatment for acute episode. NSAIDs are more effective than acetaminophen.³
 - Avoid opiates.
 - Limit acute medications to less than 3 times a week to reduce the risk of medication overuse headache.³
- Consider preventive therapy if headaches occur once a week.
 - Amitriptyline 75 to 150 mg a day is the most effective medication.³
 - Biofeedback may be effective.³
 - Acupuncture may be helpful.³

Migraine headache:

- Use a stepped approach to treat acute migraine episodes.
 - Start with simple analgesics. Aspirin and ibuprofen are often effective.⁸
 - Add an antiemetic or try butorphanol nasal spray or an oral opiate combination.⁸
 - Reserve migraine-specific agents such as triptans for patients who fail the above therapies.⁸
- Consider prophylaxis for patients whose migraines have a negative impact on their lives or to decrease risk of developing medication overuse headache when frequency requires use of simple analgesics more than 15 days a month or use of opioids, triptans, or combination analgesics more than 10 days a month.
 - Amitriptyline (before bedtime starting with 10 or 25 mg and titrate up as needed and tolerated), divalproex sodium 500 to

FIGURE 229-3 Woman with daily tension-type headache. This is a primary headache. (Courtesy of Wikimedia Commons and Shanghai killer whale at <http://commons.wikimedia.org/wiki/File:Tension-headache.jpg>)

FIGURE 229-4 Sudden onset of a thunderclap headache prompted imaging that showed diffuse subarachnoid hemorrhage with associated ventricular hemorrhage. Top arrow indicates blood in interhemispheric fissure. Bottom arrow indicates blood in lateral ventricle. (Courtesy of James Anderson, MD, Department of Radiology, Oregon Health & Science University.)

1500 mg daily, topiramate 100 mg daily, venlafaxine 150 mg daily, and multiple β -blockers have each demonstrated 50% reduction in migraine frequency.⁹

- Riboflavin 400 mg daily, coenzyme Q10 300 mg daily, butterbur 50 mg twice daily have each demonstrated 50% reduction in migraine frequency.⁹
- Magnesium citrate 600 mg daily also reduces migraine frequency and has an A rating in pregnancy.⁹
- Cognitive behavioral therapy, biofeedback, stress management, and lifestyle modification may also be useful.⁸
- Acupuncture may provide additional benefit.¹⁰

CDH:

- Tricyclic antidepressants significantly reduce the number of days with TTH compared to placebo.¹¹ Amitriptyline taken before bedtime starting with 10 or 25 mg and titrate up as needed and tolerated.
- Acupuncture may be beneficial in chronic TTHs.¹²

Cluster headache:

- Acute episode:
 - Inhaled high-flow oxygen 10 to 15 L per minute.⁵
 - Sumatriptan 6 mg subcutaneously; contraindicated in pregnancy, lactation, coronary artery disease, stroke, peripheral artery disease.⁵
- Several agents may be effective for prophylactic therapy including verapamil or topiramate.⁵
- Refer refractory patients for evaluations for other medical or surgical therapies.

Medication overuse headaches:

- Educate patients that chronic medication use is contributing to their daily headaches.¹³
- Abruptly stop (when safe) or taper the overused medication.¹³
- Inpatient withdrawal is recommended for patients overusing opiates, benzodiazepines, or barbiturates.¹³
- Start prophylactic therapy with topiramate 100 to 200 mg daily prior to initiating withdrawal or as soon as possible after withdrawal has been initiated.¹³

REFERRAL

- Refer patients when the diagnosis is unclear or response to therapy is inadequate.
- Consider referral for medication overuse headaches as these are difficult to treat.

PREVENTION

- Closely monitor use of medications for acute episodes. Advise patients to limit simple analgesics to less than 15 days per month and triptans, opiates, and combination medications to less than 10 days per month.
- Appropriately prescribe preventive therapies to reduce frequency of headaches and avoid development of CDHs.

PROGNOSIS

- Tension headaches—Favorable; 45% of adults with frequent episodic or chronic TTHs experienced remission before 3 years.³
- Cluster headaches—Unknown; ranges from total remission to chronic form.⁵

FOLLOW-UP

- Dangerous causes of secondary headaches require immediate evaluation and management.
- Frequency of follow-up for primary headaches is determined by type and severity of headache and response to therapy.

PATIENT EDUCATION

Advise patients to limit frequency of acute medications to less than 2 to 3 times a week to reduce the risk of medication overuse headache.

PATIENT RESOURCES

230 CEREBRAL VASCULAR ACCIDENT

Heidi Chumley, MD

PATIENT STORY

A 65-year-old hypertensive black man presented to the emergency department with onset of right face, arm, and hand paralysis, and difficulty communicating. Rapid diagnostic testing using MRI revealed an ischemic infarct in the left middle cerebral artery (**Figure 230-1**). He was evaluated by a stroke response team and was found to be a candidate for tissue plasminogen activator (TPA). After the stroke, he was treated with aspirin, antihypertensives, and cholesterol-lowering medication. He recovered 80% of his neurologic deficit over the next 3 months. **Figure 230-2** is a noncontrast CT image of this patient 2 weeks later.

INTRODUCTION

Cerebral vascular accidents or strokes are common, especially in older populations. Most strokes are ischemic or hemorrhagic. Risk factors include hypertension, smoking, diabetes mellitus, and atrial fibrillation. Thirty-day mortality for a first stroke is greater than 20%.

SYNONYMS

Stroke.

EPIDEMIOLOGY

- Cerebral vascular accidents (CVAs) affect approximately 700,000 people per year in the United States, most being older than age 65 years.¹
- Ischemic (66%) and hemorrhagic (10%) strokes account for most strokes.¹
- Prevalence of stroke and mortality are higher in blacks than in whites. Prevalence is 753 versus 424 per 100,000 and mortality is 95.8 versus 73.7 per 100,000 for black and white men, respectively.¹

ETIOLOGY AND PATHOPHYSIOLOGY

- CVAs are typically classified into cardioembolic (15% to 22%), large vessel (10% to 12%), small vessel (15% to 18%), other known cause (2% to 4%), and undetermined cause (46% to 51%).²
- Ischemic CVAs occur when atherosclerosis progresses to a plaque, which ruptures acutely. Each step of this process is mediated by inflammation.³

FIGURE 230-1 Acute left middle cerebral artery infarct on MRI of a 65-year-old hypertensive man. The MRI demonstrates increased signal intensity (arrows). Abnormalities in MRI occur before those seen on CT during ischemic strokes. (Courtesy of Chen MYM, Pope TL, Ott DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:338.)

FIGURE 230-2 Noncontrast CT image of a subacute left middle cerebral artery infarct (arrows). This was done 2 weeks after the stroke in the same patient as previous figure. CT findings occur later than MRI findings in ischemic strokes. (Courtesy of Chen MYM, Pope TL, Ott DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:338.)

- Hemorrhagic CVAs occur when vessels bleed into the brain, usually as the result of elevated blood pressure.
- Other known causes of CVAs include inflammatory disorders (giant cell arteritis, systemic lupus erythematosus [SLE], polyarteritis nodosa, granulomatous angiitis, syphilis, and AIDS), fibromuscular dysplasia, drugs (cocaine, amphetamines, and heroin), hematologic disorders (thrombocytopenia, polycythemia, and sickle cell), and hypercoagulable states.

RISK FACTORS

- Hypertension (HTN)—The predominant risk factor for more than 50% of all strokes. Prehypertension (blood pressure in the range of 130 to 139/85 to 89) carries a hazard ratio of 2.5 for women and 1.6 for men.⁴
- Cigarette smoking carries a hazard ratio of 1.62 for ischemic stroke and 2.56 for hemorrhagic stroke.⁵
- Type 2 diabetes mellitus (DM) increases the risk of having a stroke six-fold.⁴
- Black patients at ages 45 and 65 are 2.9 and 1.66 times more likely to have a stroke compared to white patients.⁶
- Atrial fibrillation increases the risk of stroke. The CHADS2 (congestive heart failure [CHF], HTN, age >75, DM, stroke) scoring system (see below) separates patients into low risk (stroke rate 1% to 1.5% per year), moderate risk (2.5%), high risk (4%), and very high risk (7%).⁴
- Body mass index (BMI) greater than 30 carries a hazard ratio of 1.45 for ischemic stroke but does not increase the risk of hemorrhagic stroke.⁵

DIAGNOSIS

Diagnosis of CVA must be made expediently to minimize mortality and morbidity.

CLINICAL FEATURES

- History of risk factors, including older age, HTN, cigarette smoking, type 2 DM, or previous transient ischemic attack (TIA) or stroke.
- Acute onset of neurologic signs and symptoms based on the site of the CVA (see “Typical Distribution” below).

TYPICAL DISTRIBUTION

TIA or stroke can occur in any area of the brain; common areas with typical symptoms include the following:

- Middle cerebral artery is the most common ischemic site (**Figure 230-3**):
 - Superior branch occlusion causes contralateral hemiparesis and sensory deficit in face, hand, and arm, and an expressive aphasia if the lesion is in the dominant hemisphere.
 - Inferior branch occlusion causes a homonymous hemianopia, impairment of contralateral graphesthesia and stereognosis, anosognosia and neglect of the contralateral side, and a receptive aphasia if the lesion is in the dominant hemisphere.

FIGURE 230-3 CT image of right middle cerebral artery infarct; the hypodense (darker) area (arrows) indicates the infarct. The midline structures are shifted to the left. (Courtesy of Chen MYM, Pope TL, Ott DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:335.)

- Internal carotid artery (approximately 20% of ischemic strokes) occlusion causes contralateral hemiplegia, hemisensory deficit, and homonymous hemianopia; aphasia is also present with dominant hemisphere involvement.
- Posterior cerebral artery occlusion causes a homonymous hemianopia affecting the contralateral visual field.

LABORATORY TESTING (INCLUDE ANCILLARY TESTING)

These tests may be helpful in the context of an acute stroke, particularly when the cause of the stroke is not immediately evident:

- Complete blood count (CBC) for thrombocytosis or polycythemia.
- Erythrocyte sedimentation rate (ESR) for diseases such as giant cell arteritis or SLE.
- Testing for syphilis using a treponemal enzyme immunoassay (EIA), with positive results confirmed by a nontreponemal test (Venereal Disease Research Laboratory [VDRL]).
- Serum glucose to eliminate hypoglycemia as the cause of the neurologic symptoms.

IMAGING

CT or MRI can distinguish ischemic from hemorrhagic and localize the lesion (**Figure 230-4**).

FIGURE 230-4 Hemorrhagic stroke. CT image demonstrates bleeding in the right basal ganglia (*large black arrow*) and into the ventricles (*small black arrows*). Blood appears white on the CT scan. The *white arrows* illustrate midline shift. (Courtesy of Chen MYM, Pope TL, Ott DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:337.)

DIFFERENTIAL DIAGNOSIS

Other causes of acute neurologic dysfunction include the following:

- TIA—This precursor to a CVA can appear identical; however, no lesion is seen on imaging, and symptoms resolve within 48 hours.
- Multiple sclerosis—Multiple anatomically distinct neurologic signs and symptoms that occur over time and resolve; vision is often affected. MRI findings should help to distinguish multiple sclerosis from CVA.
- Brain mass—More common presentation is headache or seizure; however, may present with focal neurologic signs based on location. CT or MRI will help to diagnose a brain mass and differentiate this from stroke.
- Migraines—Throbbing, unilateral headache with photophobia, and nausea; hemiparesis or aphasia may be part of the aura.
- Vertigo from benign positional vertigo or acute labyrinthitis—Can mimic a CVA in the posterior circulation; however, symptoms such as dysarthria, dysphagia, and diplopia are typically absent.
- Hypoglycemia—Confused state is similar to large stroke syndromes but is easily differentiated by a blood glucose measurement.

MANAGEMENT

ACUTE STROKE (WITHIN THE FIRST 3 HOURS)

- Rapidly evaluate or consult specialists to identify candidates for TPA. Odds for a favorable 3-month outcome for TPA compared to no TPA are 2.8 (95% confidence interval [CI], 1.8 to 4.5) for 0 to 90 minutes, 1.6 (95% CI, 1.1 to 2.2) for 91 to 180 minutes.⁷ **SOR A**

- Favorable outcomes at 90 days poststroke have also been demonstrated when TPA is given up to 4.5 hours after the onset of symptoms.⁸ **SOR B**
- Currently, only 3% of patients who meet the criteria receive TPA.⁴
- Preliminary studies cautioned about using TPA in community settings; recent studies, however, indicate several options to improve outcomes, including telephone consultation with a regional stroke center.⁹
- Acutely elevated blood pressure should not be aggressively treated in most cases.

After stabilization, treat ischemic strokes with antithrombotic, antihypertensives, statins, and lifestyle changes.

- Prescribe 81-mg or 325-mg aspirin for secondary stroke prevention in patients with prior ischemic stroke or TIA (relative risk [RR] reduction 28%; number needed to treat [NNT] to prevent 1 stroke per year = 77).⁴ **SOR A**
- Lower blood pressure (RR reduction 28%; NNT to prevent 1 stroke per year = 51).⁴ Current data demonstrate that thiazide-type diuretic and angiotensin-converting enzyme inhibitor (ACEI) (or angiotensin receptor blocker [ARB]) may provide additional risk reduction beyond blood pressure (BP) control and should be used first. ACEI and ARB may not be as effective as monotherapy in black populations.⁴ **SOR A**
- Lower low-density lipoprotein (LDL) cholesterol to less than 100 mg/dL for patients with a prior stroke or who are at high risk of stroke using a statin (RR reduction 25%; NNT to prevent 1 stroke per year = 57).⁴ **SOR A**
- Assist patients to stop smoking (RR reduction 33%; NNT to prevent 1 stroke per year = 43).⁴ **SOR A**
- Advise patients to adopt a healthy lifestyle by eating more fruits and vegetables, losing weight, and maintaining a physical exercise program. **SOR B**

Consider the following to further decrease morbidity and mortality:

- Avoid indwelling urinary catheters to reduce the risk of urinary tract infection.
- Encourage early ambulation to reduce the risk of a deep venous thrombosis.
- Use antiembolism stockings to reduce the risk of a deep venous thrombosis.
- Consider a swallowing study to identify patients at risk of aspiration.

SPECIAL SITUATIONS

- Hemorrhagic stroke:
 - Acutely—Do not aggressively lower BP. Some authorities recommend lowering BP only when mean arterial pressure (MAP) is more than 130 mm Hg ($\text{MAP} = [(2 \times \text{diastolic BP}) + \text{systolic BP}] / 3$).
 - After the hemorrhagic stroke is over, treat BP aggressively; modest decreases (12/5 mm Hg) from one of many classes of hypertensive drugs lower recurrent stroke risk by 50% to 75%.⁴

- Nonvalvular atrial fibrillation (AF)—Use the CHADS2 scoring system to identify patients with AF who can be managed with aspirin or should be anticoagulated with coumadin.⁴
- The CHADS/CHADS2 scoring table is shown below:²

C: Congestive heart failure	= 1 point
H: HTN (or treated HTN)	= 1 point
A: Age >75 years	= 1 point
D: Diabetes	= 1 point
S: Prior TIA or stroke	= 2 points

- For 0 to 1 point, use aspirin; 2 points, weigh risk of bleeding, adequacy of follow-up versus benefit; 3 or greater, use warfarin if at all possible.
- Patients with symptomatic carotid stenosis: Refer for carotid endarterectomy patients with 70% to 99% carotid stenosis (without near-occlusion) with ipsilateral focal neurologic signs (absolute risk reduction [ARR] 16.0%).¹⁰ Consider referring symptomatic patients with moderate stenosis of 50% to 69% (ARR 4.6%).¹⁰ **SOR A**
- Patients with asymptomatic carotid artery stenosis greater than 60%. Consider referral for carotid endarterectomy in patients younger than the age of 75 years (NNT = 20 to prevent 1 stroke in 5 years).⁴

PREVENTION

- Address modifiable risk factors: Control HTN, high cholesterol and DM; stop smoking; and maintain a healthy body weight.
- The United States Preventive Services Task Force (USPSTF) recommends the use of aspirin for women ages 55 to 79 when the potential benefit of reduction in ischemic strokes outweighs the potential harm of an increase in GI hemorrhage.¹¹
- The USPSTK found the evidence insufficient to recommend for or against the use of aspirin for stroke reduction in men.¹¹

PROGNOSIS

CVA prognosis varies based on size and location of ischemia or hemorrhage, time to TPA administration (for ischemic stroke), and availability of aggressive poststroke rehabilitation.

- The 30-day mortality rate after a first or second stroke is 22% and 41%, respectively.⁴
- Five-year observed survival is 40% to 68% for stroke.¹²

FOLLOW-UP

- Patients with symptoms of an acute stroke should be hospitalized, evaluated immediately for appropriateness of TPA and treatment of reversible causes, and managed, if possible, in a stroke unit or using the “best practices” associated with these units.
- After a stroke and rehabilitation, patients should be followed at regular intervals to evaluate risk reduction strategies.

PATIENT EDUCATION

Educate patients who have had a stroke about the high risk of having a second stroke, the high morbidity and mortality associated with a recurrent stroke, and the need for lifestyle modifications and medications to reduce this risk.

PATIENT RESOURCES

231 SUBDURAL HEMATOMA

Heidi Chumley, MD

PATIENT STORY

A 34-year-old driver was hit from behind at approximately 25 mph. He hit his head, but did not lose consciousness and did not seek care. Approximately 12 hours later, he developed a headache and confusion, and was taken to the emergency department by a family member. He was found to have an acute subdural hematoma (**Figure 231-1**). He was hospitalized, and a neurosurgeon was consulted for surgical management.

INTRODUCTION

Subdural hematomas (SHs) can occur at any age, but are most common in infants and older adults. Most SHs are caused by trauma. Symptoms are generally nonspecific such as irritability or poor feeding in infants and confusion or headaches in adults. Treatment is prompt consultation with a neurosurgeon.

EPIDEMIOLOGY

- SHs occur at all ages. In adults, SHs are more common in men.¹
- Eight percent of asymptomatic newborns can have an SH.²
- Twenty-four of 100,000 infants ages 0 to 1 year in United Kingdom population studies.³
- Less than 1 in 100,000 adults per year have a traumatic SH.¹
- Forty-two of 100,000 hospitalizations for adult patients.⁴
- Cost is \$1.6 billion per year in 2007 dollars.⁴
- Mortality rates in treated older adults are approximately 8% for patients younger than age 65 years and 33% for patients older than age 65 years.⁵

ETIOLOGY AND PATHOPHYSIOLOGY

- Most SHs are caused by trauma, either accidental or intentional, from a direct injury to the head or shaking injury in an infant.
- Falls, motor vehicle accidents, and assault are the most common causes of traumatic SH.¹
- SHs have been reported from chronic jarring from rapid walking in older patients and can occur during a nontraumatic birth.
- Motion of the brain within the skull causes a shearing force to the cortical surface and interhemispheric bridging veins.³
- This force tears the weakest bridging veins as they cross the subdural space, resulting in an acute SH as seen in **Figure 231-1**.³
- Three days to 3 weeks after the injury, the body breaks down the blood in an SH; water is drawn into the collection causing hemodilution, which appears less white and more gray on noncontrast CT.³
- If the hematoma fails to resolve, the collection has an even higher content of water and appears darker on a noncontrast CT; it may

FIGURE 231-1 CT scan of an acute subdural hematoma (arrow) seen as a hyperdense clot with an irregular border. There is a midline shift from the mass effect of the accumulated blood. (Courtesy of Kasper DL, Braunwald E, Fauci AS, Hauser SL, Longo DL, Jameson JL. *Harrison's Principles of Internal Medicine*, 16th ed. New York, NY: McGraw-Hill; 2005:2450.)

have fresh bleeding or may calcify (chronic SH; **Figure 231-2**).³ This is often of the same color as brain parenchyma on noncontrast CT.

- Nontraumatic causes reported in the literature include spontaneous bleeding because of bleeding disorders or anticoagulation, meningitis, and complications of neurologic procedures, including spinal anesthesia.

RISK FACTORS

Increased mortality is seen in patients:

- Older than 80 years of age.⁴
- With lower income.⁴
- With acquired clotting abnormalities.^{4,6}
- Who experienced trauma.⁴
- With a higher APACHE (Acute physiology, Age, and Chronic Health Evaluation) III score on presentation.⁶

DIAGNOSIS

The clinical features are often nonspecific, making the diagnosis difficult in the absence of known trauma.

- Infants may present with drowsiness, irritability, poor tone, poor feeding, or new seizures.³
- Older adults may present with headaches, confusion, subtle changes in mental status, gait disturbances, hemiparesis, or other focal neurologic signs.⁷

TYPICAL DISTRIBUTION

SHs by definition occur in the subdural space, most commonly seen in the parietal region.

IMAGING

Acute SHs are seen easily on a noncontrast CT scan (**Figure 231-1**). Subacute and chronic SHs (**Figure 231-2**) can be similar in color to the brain parenchyma and may be easier to see on a contrast CT or an MRI.

DIFFERENTIAL DIAGNOSIS

Other causes of nonspecific symptoms seen with SH can be differentiated by neuroimaging and include the following:

- Infections such as sepsis or meningitis—Fever, elevated white blood cells, positive blood cultures, and cerebral spinal fluid consistent with meningitis.
- Hemorrhagic (**Figure 231-3**) or ischemic stroke or transient ischemic attacks—Consider risk factors for stroke such as hypertension, diabetes, atrial fibrillation, and smoking (see Chapter 230, Cerebral Vascular Accident).
- Dementia or depression—Less acute onset, advanced age, and other symptoms consistent with depression.
- Primary or metastatic brain neoplasms—History of cancer and risk factors for cancer.

FIGURE 231-2 CT scan of chronic bilateral subdural hematomas. As subdural hematomas age, these become isodense gray and then hypodense (darker gray to black) compared to the brain. Some resolving blood is still visible on the left (arrows). (Courtesy of Kasper DL, Braunwald E, Fauci, AS, Hauser SL, Longo DL, Jameson JL. *Harrison's Principles of Internal Medicine*, 16th ed. New York, NY: McGraw-Hill; 2005:2450.)

FIGURE 231-3 Hemorrhagic stroke seen on CT. The CT image demonstrates bleeding in the right basal ganglia (large black arrow) into the ventricles (small black arrows) with midline shift (white arrows). (Courtesy of Chen MYM, Pope TL Jr., Ott, DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:337.)

Other causes of intracranial bleeding can also be differentiated by neuroimaging and include the following:

- Epidural hematoma (**Figure 231-4**)—Well-defined biconvex bright white density that resembles the shape of the lens of the eye.
- Subarachnoid hemorrhage (**Figure 231-5**)—Bright white blood outlines cerebral sulci.
- Hemorrhage in brain parenchyma—Bright white lesion apart from dura.

MANAGEMENT

Most SHs are managed surgically, and there is little evidence about conservative management.

- Determine the Glasgow Coma Scale in patients with serious head trauma and consider airway protection in patients with a score less than 12.
- Obtain an urgent noncontrast CT scan on any patient suspected of having an SH.
- If the noncontrast CT scan is nonrevealing, obtain a contrast CT or MRI, particularly if the traumatic event occurred 2 to 3 days prior.
- Emergently refer patients with an SH and deteriorating neurologic status or evidence of brain edema or midline shift to a hospital with neurosurgeons.
- Consult a neurosurgeon expediently in patients with an SH and stable focal neurologic signs.
- Consider neurosurgical consultation in asymptomatic patient or patients with only a headache and a small acute SH without brain edema or midline shift. These patients may be followed by serial CT scans without surgical treatment, but this should be done in consultation with experts in CT interpretation and management of SHs.⁷ **SOR C**
- Evaluate any infant with an SH for child abuse or neglect.³ **SOR C**

PREVENTION

- Follow safety measures that reduce motor vehicle accidents, and falls in the elderly.
- Use recommended protective gear for sports and recreational activities and follow guidelines for return to play after a head injury.
- Carefully evaluate the risks and benefits of chronic use of antiplatelet and anticoagulation medications.

PROGNOSIS

- In-hospital mortality for acute SH is 12%.^{4,5}
- In-hospital mortality for traumatic SH is 26%.¹
- Best predictor of in-hospital mortality is neurologic status on admission.⁸

FIGURE 231-4 This head CT demonstrates an epidural hematoma, with the typical biconvex appearance (arrows). Note how the biconvex appearance resembles the lens of an eye. (Courtesy of Chen MYM, Pope TL Jr, Ott, DJ. *Basic Radiology*. New York, NY: McGraw-Hill; 2004:346.)

FIGURE 231-5 A subarachnoid hemorrhage appears as areas of high density (more white like bone rather than the darker gray of brain tissue) in the subarachnoid space (arrows). (Courtesy of Aminoff MJ, Greenberg DA, Simon RP. *Clinical Neurology*, 6th ed. New York, NY: McGraw-Hill; 2005:77.)

- In patients older than age 65 years, the mortality rate for chronic SH remains elevated until 1 year after diagnosis independent of treatment.⁸

FOLLOW-UP

- Follow-up is determined by severity of SH and type of treatment.
- Ideally, follow-up is conducted jointly between the neurosurgeon and primary care physician to ensure resolution of the SH and maximal return of function, especially in elderly patients.

PATIENT EDUCATION

- Advise patients to seek medical care immediately for head trauma, which can cause several emergencies including an SH.
- Discuss with parents or guardians the need for a thorough evaluation for child abuse and neglect in infants with an SH.

232 NORMAL PRESSURE HYDROCEPHALUS

Heidi Chumley, MD

PATIENT STORY

A 68-year-old man presented with a gradual onset of difficulty with his gait, increased urinary incontinence, and difficulty with his memory during the past several months. His gait was wide-based and slow, with decreased step height and length. His Mini Mental State Examination was consistent with impaired cognition. As part of his workup, he had a noncontrast head CT, which demonstrated dilated ventricles (**Figure 232-1**) without extensive cortical atrophy. He had normal cell counts and opening pressure on a spinal tap. He was diagnosed with normal pressure hydrocephalus (NPH) and referred to a neurosurgeon to be evaluated for a ventricular shunt. The patient had the shunt placed (**Figure 232-2**). His gait and urinary incontinence improved. Unfortunately, his cognitive impairments did not improve as is often the case.

INTRODUCTION

NPH can be idiopathic or secondary to meningitis, subarachnoid hemorrhage, or head trauma, and is caused by impaired reabsorption of spinal fluid. Patients present with gait abnormalities, urinary incontinence, and/or cognitive impairment. Diagnosis is confirmed by radiographic evidence and a normal opening pressure on lumbar puncture.

EPIDEMIOLOGY

- Prevalence—1 in 250 in those older than age 65 years; determined in a door-to-door survey in Germany.¹
- Incidence—1 to 2/100,000 population per year; determined by number of surgeries in Sweden.²
- Most common between the ages of 60 to 70 years.
- Five percent of dementias are caused by NPH.³

ETIOLOGY AND PATHOPHYSIOLOGY

- Cerebral spinal fluid (CSF) is produced by the choroid plexus, circulates through the ventricles, exits into the subarachnoid space, and is reabsorbed by the arachnoid granulations at the top of the brain.³
- NPH is thought to be due to impaired reabsorption and can be idiopathic or secondary to meningitis, subarachnoid hemorrhage, or head trauma.

FIGURE 232-1 Noncontrast CT demonstrates enlarged lateral ventricles (white arrows) without significant cerebral atrophy. (Courtesy of Reginald Dusing, MD.)

FIGURE 232-2 Noncontrast CT shows ventricular shunt (red arrow) in place. Lateral ventricles remain enlarged after shunting (white arrows). (Courtesy of Reginald Dusing, MD.)

DIAGNOSIS

NPH is a clinical diagnosis based on signs and symptoms, CSF studies, radiographic imaging, and a clinical response to ventriculoperitoneal (VP) shunting.

CLINICAL FEATURES

Classic triad is gait disturbance, urinary incontinence, and cognitive impairment:

- Gait disturbances typically occur first—Wide-based stance; slow, shuffling steps; difficulty with initiation.³
- Urinary incontinence usually with urgency; abnormal detrusor contractions on urodynamic studies.³
- Cognitive impairment—Difficulty with attention and concentration (digit span, arithmetic) with sparing of orientation and general memory.⁴

LABORATORY TESTING

- CSF had normal cell counts and opening pressure less than 200 mm Hg.³
- High-volume spinal tap (removal of 30 to 66 cc of CSF) or prolonged CSF drainage (3 to 5 days via an indwelling catheter) followed by clinical improvement can be helpful in selecting patients more likely to respond to VP shunting.⁵
- Continuous monitoring of intracranial pressure demonstrates characteristic waves of NPH; however, this is done only in specialized centers.

IMAGING

- Enlarged ventricles without substantial cerebral atrophy can be seen on CT or MRI.
- Cisternography, a nuclear medicine test, can demonstrate impaired clearing of CSF from the lateral ventricles at 48 hours (**Figure 232-3**), which is useful in predicting which patients respond to shunting⁶

DIFFERENTIAL DIAGNOSIS

- Alzheimer disease—Impaired orientation and memory, which are often spared in NPH; cortical atrophy.
- Parkinson disease—Tremor and rigidity in addition to bradykinesia and gait disturbances; normal neuroimaging.
- Chronic alcoholism—History of alcohol use, memory and learning difficulties; cortical atrophy.
- Multiinfarct dementia, atherosclerotic disease, subdural hematomas, and tumors—Identifiable on neuroimaging.
- Intracranial infections or carcinomatous meningitis—Abnormal CSF findings.

FIGURE 232-3 Lateral view on cisternography demonstrates increased uptake in the lateral ventricle (*red arrow*). In this nuclear medicine study, indium is injected into the cerebral spinal fluid at the lower lumbar spine and a scan is done 48 hours later. Normally, the indium-tagged spinal fluid has been reabsorbed at 48 hours, and the lateral ventricle does not have increased uptake. (Courtesy of Reginald Dusing, MD.)

- Hypothyroidism—Has other symptoms such as fatigue, weakness, dry and cool skin, diffuse hair loss, cold intolerance, constipation, and difficulty concentrating. The thyroid-stimulating hormone (TSH) is elevated and there is no urinary incontinence (see Chapter 226, Goitrous Hypothyroidism).

MANAGEMENT

Refer to a neurosurgeon to evaluate for VP shunting (Figure 232-2).

- VP shunting is the only known effective treatment (Figure 232-2). In larger retrospective studies, 39% to 75% of patients demonstrated improvement by 24 months.^{5,7}
- The risks of VP shunting can be substantial; moderate to severe complications occurred in 28% of patients in one study⁷; more recent reviews report a 6% complication rate.⁸
- Repetitive lumbar punctures may be considered in patients who cannot undergo surgery.⁹

PROGNOSIS

- In one study, patients demonstrated improvements in gait (81.1%), urinary incontinence (55.9%), and dementia (64.4%) after surgery. Surgical complications occurred in approximately 6% of patients.⁸
- Favorable prognostic factors include—Gait abnormality as the presenting or dominant symptom, symptoms less than 6 months prior to treatment, and an identified cause (i.e., because of head trauma).¹⁰
- Poor prognostic factors include—Dementia preceding gait abnormality or dementia for more than 2 years.¹⁰

FOLLOW-UP

Long-term multidisciplinary follow-up can facilitate gait and bladder retraining and early recognition of signs of shunt malfunction including vomiting, headache, fever, or seizures.

PATIENT EDUCATION

Advise patients that improvements from VP shunting:

- Do not occur for all patients.
- Appear slowly over several months.
- May last several years.
- Are more likely to involve gait disturbances rather than cognitive deficits.

Advise patients to inform any healthcare provider they see about their VP shunt.

233 BELL'S PALSY

Heidi Chumley, MD

PATIENT STORY

Five years ago, a young woman awoke with the inability to move the left side of her face. She was pregnant at that time. On examination it was found that she had absent brow furrowing, weak eye closure, and dropping of her mouth angle (**Figure 233-1**). She was diagnosed with Bell's palsy and was provided eye lubricants and guidance on keeping her left eye moist. Her physician discussed the available evidence about treatment with steroids. She chose not to take the steroids because of her pregnancy.

INTRODUCTION

Bell's palsy is an idiopathic paralysis of the facial nerve resulting in loss of brow furrowing, weak eye closure, and dropped angle of mouth. Treatment is oral steroids as soon after the onset of symptoms as possible. Most patients have a full recovery within 6 months.

SYNONYMS

Idiopathic facial paralysis.

EPIDEMIOLOGY

- In a Canadian study, incidence was 13.1 to 15.2/100,000 adults.¹
- In a study of United States military members, the incidence was 42.77/100,000, with higher incidence in females, blacks, and Hispanics; arid climate and cold months were independent predictors of risk with adjusted relative risk ratios of 1.34 and 1.31, respectively.²
- Women who develop Bell's palsy in pregnancy have a 5-fold increased risk over national average of preeclampsia or gestational hypertension.³
- Seventy percent of cases of acute peripheral facial nerve palsy are idiopathic (Bell's palsy); 30% have known etiologic factors such as trauma, diabetes mellitus, polyneuritis, tumors, or infections such as herpes zoster, leprosy (**Figure 233-2**) or *Borrelia*.⁴

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology of Bell's palsy is currently unknown and under debate; the prevailing theory suggests a viral etiology from the herpes family.
- The facial nerve becomes inflamed, resulting in nerve compression.
- Compression of the facial nerve compromises muscles of facial expression, taste fibers to the anterior tongue, pain fibers, and secretory fibers to the salivary and lacrimal glands.

FIGURE 233-1 Bell's palsy with loss of brow furrowing and dropped angle of the mouth on the affected left side of her face demonstrated during a request to smile and raise her eyebrows. The Bell's palsy has been present for 5 years and the patient is being evaluated by ear, nose, and throat (ENT) for surgery to restore facial movement. (Courtesy of Richard P. Usatine, MD.)

FIGURE 233-2 Bell's palsy secondary to leprosy. The hypopigmented patches on his back are further signs of the leprosy. (Courtesy of Richard P. Usatine, MD.)

- This is a lower motor neuron lesion; the upper and lower portions of the face are affected (**Figure 233-1**). In upper motor neuron lesions (e.g., cortical stroke), the upper third of the face is spared, while the lower two-thirds are affected as a result of the bilateral innervation of the orbicularis, frontalis, and corrugator muscles, which allows sparing of upper face movement.

DIAGNOSIS

CLINICAL FEATURES

- Weakness of all facial muscles on the affected side—Loss of brow furrowing, weak eye closure, and dropped angle of mouth.
- Postauricular pain.
- Dry eyes.
- Involuntary tearing.
- Hyperacusis.
- Altered tastes.

LABORATORY TESTING

Laboratory testing is not usually indicated:

- Herpes virus titers are not usually helpful.
- Consider serologic tests for Lyme disease in endemic areas.
- Consider testing for diabetes mellitus in patients with risk factors.

IMAGING

- Consider MRI to look for a space-occupying lesion with atypical presentations.

DIFFERENTIAL DIAGNOSIS

- Upper motor neuron diseases including stroke—Normal brow furrowing, eye closure, and blinking.
- Space-occupying lesion—Symptoms are dependent on the location of the mass; consider with an isolated facial nerve palsy that does not affect all three branches of the facial nerve.
- Lyme disease—Occurs in endemic area with skin rash, joint inflammation, and flu-like symptoms. Bell's palsy is the most common neurologic manifestation of Lyme disease (see Chapter 218, Lyme Disease).
- Suppurative ear disease—Ear pain, abnormal tympanic membrane, and more common in children.
- Facial nerve damage from microvascular disease—Most commonly in diabetes mellitus.
- Facial nerve damage from trauma—History of trauma differentiates this from Bell's palsy that is idiopathic or from an infectious etiology.
- Isolated third nerve palsy—Manifestations include diplopia and drooping of the upper eyelid (ptosis) (**Figure 233-3**). The affected eye may deviate out and down in straight-ahead gaze; adduction is slow and cannot proceed past the midline. Upward gaze is

FIGURE 233-3 Ptosis from an isolated third nerve palsy in a patient with diabetes. Note the symmetry of the facial creases, which would be absent in Bell's palsy. This patient would also have abnormal eye movements. The eye would deviate down and out, adduction would not pass the midline, and upward gaze would be impaired. (Courtesy of Richard P. Usatine, MD.)

impaired. When downward gaze is attempted, the superior oblique muscle causes the eye to adduct. The pupil may be normal or dilated; its response to direct or consensual light may be sluggish or absent (efferent defect). Pupil dilation (mydriasis) may be an early sign.

MANAGEMENT

NONPHARMACOLOGIC

- Provide eye protection with artificial tears, lubricants, or closing of the eyelid. **SOR C**

MEDICATIONS

- New data and a Cochrane systematic review supports treating patients with systemic corticosteroids. Steroids significantly decrease a patient's risk for incomplete recovery from 33% to 23%, risk ratio 0.71.⁵ **SOR A**
 - Dosing of steroids in the studies analyzed within the Cochrane review varied from oral methylprednisolone 1 mg/kg daily for 10 days, and then gradually withdrawn for another 3 to 5 days to prednisone given as a single dose of 60 mg daily for 5 days, followed by a dose reduced by 10 mg, per day, with a total treatment of 10 days. One trial used high-dose prednisolone given intravenously.
- A Cochrane systematic review does not support using antiviral medications. There is no significant benefit from acyclovir or valacyclovir when compared to placebo. Antivirals are less likely than steroids to produce complete recovery.⁶ **SOR A**

COMPLEMENTARY AND ALTERNATIVE THERAPY

Acupuncture has been studied; the data, however, is inadequate to determine the efficacy.⁷

REFERRAL

- In longstanding facial paralysis, consider referral to an ear, nose, and throat (ENT) surgeon or plastic surgeon with experience in treating Bell's palsy with surgery. It is possible to restore some facial movement with specialized surgical procedures including regional muscle transfer and microvascular free tissue transfer.⁸ **SOR C**

PROGNOSIS

Seventy-seven percent of patients treated with systemic steroids have complete recovery of facial motor function in 6 months.

FOLLOW-UP

Consider seeing patients in 2 to 3 weeks to evaluate recovery and to reconsider diagnosis if there has been no recovery, particularly in children.

PATIENT EDUCATION

- Most patients recover spontaneously. Steroid treatment improves a patient's chance of complete recovery.
- Ninety-five percent of children recover; 70% recover within 3 weeks.

234 NEUROFIBROMATOSIS

Heidi Chumley, MD

PATIENT STORY

A 44-year-old Hispanic man has neurofibromatosis type 1 (NF-1). He has typical features of NF-1, including eight café-au-lait spots, axillary freckling, and neurofibromas all over his body (**Figures 234-1 to 234-4**). He states that he is used to having the NF and it does not currently affect his work or life. He is happily married but never had children. No intervention is necessary at this time other than recommending yearly visits to his family physician and ophthalmologist.

INTRODUCTION

NF-1 is a common autosomal dominant disorder that predisposes to tumor formation. Café-au-lait spots are often the first clinical sign. Other clinical signs include neurofibromas, axillary or inguinal freckling, optic gliomas, Lisch nodules, and sphenoid bone dysplasia. Treatment at present is early recognition and monitoring for complications such as cognitive dysfunction, scoliosis or other orthopedic problems, tumor pressure on vital structures, or malignant transformation.

EPIDEMIOLOGY

- NF-1 is relatively common—Birth incidence is 1 in 3000 and prevalence in the general population is 1 in 5000.¹
- Autosomal-dominant inheritance; however, up to 50% of cases are sporadic.¹
- Diagnosis is typically made during childhood.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mutations in the NF-1 gene (on the long arm of chromosome 17) result in loss of function of neurofibromin, which helps keep protooncogene ras (which increases tumorigenesis) in an inactive form.
- Loss of neurofibromin results in increased protooncogene ras activity in neurocutaneous tissues, leading to tumorigenesis.¹

RISK FACTORS

A first-degree relative with NF-1.

DIAGNOSIS

For a diagnosis of NF-1, patients need to have at least 2 of the following:²

1. Two or more neurofibromas (**Figures 234-1 to 234-6**) or one or more plexiform neurofibromas (**Figure 234-7**).

FIGURE 234-1 A 44-year-old Hispanic man with neurofibromatosis type 1 showing all the typical findings including neurofibromas, café-au-lait spots, and axillary freckling. (Courtesy of Richard P. Usatine, MD.)

FIGURE 234-2 Close-up of neurofibromas on the back of the man in **Figure 234-1**. These are soft and round. (Courtesy of Richard P. Usatine, MD.)

- Six or more café-au-lait spots, 0.5 cm or larger before puberty and 1.5 cm or larger after puberty (**Figures 234-3** and **234-4**).
- Axillary or inguinal freckling (**Figures 234-1** and **234-4**).
- Optic glioma.
- Two or more Lisch nodules (melanotic iris hamartomas) (**Figure 234-8**).
- Dysplasia of the sphenoid bone or dysplasia/thinning of long bone cortex.
- A first-degree relative with NF-1.

CLINICAL FEATURES

History and physical:

- Ninety-five percent have café-au-lait macules, mostly before the age of 1 year.
- Ninety percent have axillary or inguinal freckling (**Figures 234-1** and **234-4**).
- Eighty-one percent have cognitive dysfunction manifest as learning disorder, attention deficit hyperactivity disorder, or mild cognitive impairment.³
- Nerve sheath, intracranial, or spinal tumors.
- Cutaneous or subcutaneous neurofibromas (**Figures 234-1** to **234-6**).
- Other bony pathology, including dysplasia of the sphenoid or long bones, scoliosis, or short stature.
- Eye abnormalities, including Lisch nodules or early glaucoma (**Figure 234-7**).

LABORATORY TESTING

- Genetic testing for couples considering having children.

IMAGING

- Although not typically used for diagnosis, imaging may be needed if tumor compression of vital structures is suspected.

DIFFERENTIAL DIAGNOSIS

NF-1 is the predominant cause of café-au-lait spots, which can also be seen in the following cases:

- Normal childhood—13% to 27% of children younger than 10 years of age have at least 1 spot.
- Neurofibromatosis type 2 (NF-2)—Vestibular schwannomas, family history of NF-2, meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities, or juvenile cortical cataracts.
- Tuberous sclerosis—Angiofibromas (skin-colored telangiectatic papules most commonly in the nasolabial folds, cheek, or chin; **Figure 234-9**) and hypopigmented ovoid or ash leaf-shaped macules.
- McCune-Albright syndrome—Fibrous dysplasia of bone and endocrine gland hyperactivity.
- Fanconi anemia—Decreased production of all blood cells, short stature, upper limb anomalies, genital changes, skeletal anomalies,

FIGURE 234-3 Large café-au-lait spot on the back of the man in **Figure 234-1**. Café-au-lait spots are ovoid hyperpigmented macules, 10 to 40 mm in diameter, with smooth borders. (Courtesy of Richard P. Usatine, MD.)

FIGURE 234-4 Close-up of axillary freckling (Crow sign) with large café-au-lait spot on arm. (Courtesy of Richard P. Usatine, MD.)

FIGURE 234-5 A man with neurofibromatosis covered with neurofibromas. (Courtesy of Jack Resneck, Sr., MD.)

eye/eyelid anomalies, kidney malformations, ear anomalies/deafness, and GI/cardiopulmonary malformations.

- Segmental NF—Cutaneous neurofibromas limited to specific dermatome(s); very rare.
- Bloom syndrome—Growth delay and short stature, increased risk of cancer, telangiectatic erythema on the face, cheilitis, narrow face, prominent nose, large ears, and long limbs.
- Ataxia telangiectasia—Progressive neurologic impairment, cerebellar ataxia, immunodeficiency, impaired organ maturation, ocular and cutaneous telangiectasia, and a predisposition to malignancy.
- Proteus syndrome—Very rare condition with hamartomatous and multisystem involvement. Joseph Merrick (also known as “the elephant man”) is now, in retrospect, thought by clinical experts to have had Proteus syndrome and not NF.

MANAGEMENT

Management focuses on early recognition and treatment of manifestations.

- Evaluate children twice a year and adults annually. **SOR C**
- Screen for cognitive impairment and refer early for intervention. **SOR C**
- Screen for scoliosis and treat accordingly.
- Refer patients annually for ophthalmologic evaluation.
- Consider treatment or referral for treatment of café-au-lait spots if desired by the patient. Topical vitamin D₃ analogs (calcipotriene [Dovonex]) and laser therapy independently may improve the appearance of café-au-lait spots.^{4,5} **SOR B** One small study suggests that intense pulsed light–radio frequency (IPL-RF) in combination with topical application of vitamin D₃ ointment may lighten small-pigmented lesions in patients with NF-1.⁶ **SOR B** Although calcipotriene is approved for use in psoriasis, it can be prescribed off-label to patients disturbed by their hyperpigmented macules.^{4,6} **SOR B**
- Examine other undiagnosed first-degree relatives. **SOR C**
- Surgical excision of tumors is required for tumors pressing on vital structures (i.e., spinal cord impingement) or when characteristics such as rapid enlargement are worrisome for malignant transformation.

PROGNOSIS

- Clinical manifestations are variable leading to difficulty in prognosis.
- There is a 10% lifetime risk of developing a malignant peripheral nerve sheath tumor.

FOLLOW-UP

- Primary care evaluation biannually for children; annually for adults, including monitoring of blood pressure.

FIGURE 234-6 Neurofibromatosis in a 62-year-old black woman. Note how large some of the neurofibromas can become. (Courtesy of Richard P. Usatine, MD.)

FIGURE 234-7 Plexiform neurofibroma on the thenar eminence feels like a bag of worms in this man with neurofibromatosis. It is a benign tumor of the peripheral nerve sheath and is most often asymptomatic. (Courtesy of Richard P. Usatine, MD.)

FIGURE 234-8 Lisch nodules (melanotic hamartomas of the iris) are clear yellow-to-brown, dome-shaped elevations that project from the surface of this blue iris. These hamartomas are the most common type of ocular involvement in neurofibromatosis type 1 and do not affect vision. (Courtesy of Paul Comeau.)

- Ophthalmologic examination annually for children and adults for early detection of optic gliomas and glaucoma. Neurofibromas and plexiform neuromas can occur on the eyelids. Neurofibromas on the eyelids usually are not a problem (**Figure 234-10**) but a plexiform neuroma can present with ptosis and need surgical intervention.
- Genetic counseling for patients with NF-1 considering having children.

PATIENT RESOURCES

- Neurofibromatosis, Inc. has a variety of patient education materials, information about local support groups, ongoing clinical trials, and camp New Friends for children with NF—<http://www.nfinc.org>.
- The National Institute of Neurological Diseases and Stroke has patient information at its *Neurofibromatosis Information Page*—<http://www.ninds.nih.gov/disorders/NF/NF.htm>.

PROVIDER RESOURCE

- Neurofibromatosis, Inc. has a variety of resources including NF specialists by location—<http://www.nfinc.org>.

SUBSTANCE ABUSE

Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1447–1450 for further information.

235 SUBSTANCE ABUSE DISORDER

Richard P. Usatine, MD
Heidi Chumley, MD
Kelli Hejl, MA

PATIENT STORY

A 21-year-old mother and her 4 children are being seen in a free clinic within a homeless shelter for various health reasons (**Figure 235-1**). The woman is currently clean and sober, but has a long history of cocaine use and addiction (**Figure 235-2**). Her children span the ages of 3 months to 5 years. She was recently living with her mother after the birth of her youngest child, but was kicked out of her mother's home when she went out to use cocaine once again. The patient gave written consent to the photograph and when she was shown the image on the digital camera she noted how depressed she looked. She asked for us to tell the viewers of this photograph that these can be the consequences of drug abuse—being depressed, homeless, and a single mom.

INTRODUCTION

Addiction occurs when substance use has altered brain function to an extent that an individual loses a degree of control over his or her behaviors. Addiction is an epigenetic phenomenon. Many genes influence the brain functions that affect behavior and genetic variants. These genes differ in their susceptibility to environmental conditions, which trigger the changes in brain circuitry, and contribute to the development of addiction. Addiction must be recognized and treated as a chronic illness with an interprofessional team and social support.

EPIDEMIOLOGY

- An estimated 69.6 million Americans age 12 years or older were current users of a tobacco product in 2010. This represents 27.4% of the population in that age range. In addition, 58.3 million persons (23% of the population) were current cigarette smokers, 13.2 million (5.2%) smoked cigars, 8.9 million (3.5%) used smokeless tobacco, and 2.2 million (0.8%) smoked tobacco in pipes.¹
- An estimated 22.6 million Americans age 12 years or older were current illicit drug users in 2010. This represents 8.9% of the population in that age range.¹
- Marijuana was the most commonly used illicit drug (17.4 million users) (**Figures 235-3** and **235-4**). It was used by 76.8% of current illicit drug users. Among current illicit drug users, 60.1% used only marijuana, 16.7% used marijuana and another illicit drug, and the remaining 23.2% used only an illicit drug other than marijuana.¹
- There were 1.5 million persons who were current cocaine users in 2010.¹

FIGURE 235-1 A cocaine-addicted mother with her children in a homeless shelter. Her drug addiction resulted in their homelessness. (Courtesy of Richard P. Usatine, MD.)

FIGURE 235-2 Purified cocaine. (Courtesy of DEA.)

- There were 353,000 persons who were current methamphetamine users in 2010 (**Figure 235-5**).¹
- Hallucinogens were used by 1.2 million persons (0.5%) in 2010, including 695,000 (0.3%) who had used Ecstasy (**Figure 235-6**).¹
- In 2010, 140,000 persons used heroin for the first time (**Figure 235-7**).¹
- There were 9 million people age 12 years or older (3.6%) who were current users of illicit drugs other than marijuana in 2010. Most (7 million, 2.7%) used psychotherapeutic drugs (including prescription drugs) nonmedically. Of these, 5.1 million used pain relievers, 2.2 million used tranquilizers, 1.1 million used stimulants and 374,000 used sedatives.¹
- Among persons who used pain relievers nonmedically in the past 12 months, 55% reported that the source of the drug was from a friend or relative for free. Another 17.3% reported that they got the drug from a physician. Only 4.4% obtained the pain relievers from a drug dealer or other stranger, and only 0.4% reported buying the drug on the Internet.¹

FIGURE 235-3 Home-grown marijuana plant. (Courtesy of DEA.)

ASSOCIATION WITH CIGARETTE AND ALCOHOL USE

- In 2010, the rate of current illicit drug use was 8.5 times higher among youths age 12 to 17 years who smoked cigarettes in the past month (52.9%) than it was among youths who did not smoke cigarettes in the past month (6.2%).¹
- Past month illicit drug use was also associated with the level of past month alcohol use. Among youths age 12 to 17 years in 2010 who were heavy drinkers (i.e., drank 5 or more drinks on the same occasion [i.e., at the same time or within a couple of hours] on each of 5 or more days in the past 30 days), 70.6% were also current illicit drug users, which was higher than among nondrinkers (5.1%).¹

FIGURE 235-4 Marijuana ready to be smoked. (Courtesy of DEA.)

ETIOLOGY AND PATHOPHYSIOLOGY

- “Drug addiction is a brain disease. Although initial drug use might be voluntary, drugs of abuse have been shown to alter gene expression and brain circuitry, which in turn affect human behavior. Once addiction develops, these brain changes interfere with an individual’s ability to make voluntary decisions, leading to compulsive drug craving, seeking and use.”²
- Addiction is a polygenic disorder. Many genes have direct or indirect influences on neurotransmitters, drug metabolic pathways and behavioral patterns. For example, variants of receptors for dopamine or opiates influences perceived reward.³
- Epigenetic mechanisms, external influences that trigger changes in gene expression, are believed to play a role through modulation of reward and emotion.³ As such, both genetics and environment/learned behaviors can increase a person’s risk for substance abuse.
- Family, twin, and adoption studies convincingly demonstrate that genes play an important role in the development of alcohol dependence, with heritability estimates in the range of 50% to 60% for both men and women. Important genes include those involved in alcohol metabolism, and those involved in γ -aminobutyric acid

FIGURE 235-5 Methamphetamine ice with pipe. (Courtesy of DEA.)

(GABA), endogenous opioid, dopaminergic, cholinergic, and serotonergic transmission.⁴

- Several drinking behaviors, including alcohol dependence, history of blackouts, age at first drunkenness, and level of response to alcohol are associated with single-nucleotide polymorphisms (SNPs) within 1 of 4 GABA receptor genes on chromosome 5q.⁵
- Comorbid mental health issues and chronic pain disorders are highly prevalent among persons with substance abuse disorders. Commonly, a person begins using drugs to self-treat feelings of depression and symptoms of pain.
- The medical consequences of addiction are far reaching and very costly to society. Cardiovascular disease, stroke, cancer, HIV/AIDS, hepatitis, and lung disease can all be increased by drug abuse. Some of these effects occur when drugs are used at high doses or after prolonged use. Some consequences occur after just 1 use.²
- Classes of substances that are frequently abused and involved in addiction include:
 - Depressants—Alcohol, sedatives, hypnotics, opioids, and anxiolytics.
 - Stimulants—Cocaine, amphetamines, and nicotine.
 - Hallucinogens—Cannabis, phencyclidine (PCP), and lysergic acid diethylamide (LSD).
 - Toxic inhalants.
- The onset of drug effects is approximately:
 - Seven to 10 seconds for inhaling or smoking.
 - Fifteen to 30 seconds for intravenous injection.
 - Three to 5 minutes for intramuscular or subcutaneous injection.
 - Three to 5 minutes for intranasal use (snorting).

RISK FACTORS

- Family history.
- Personal history of prior addiction.

DIAGNOSIS

It helps to make the distinction between substance abuse and substance dependence to understand how to provide help for the patient.

DSM-IV CRITERIA FOR SUBSTANCE ABUSE⁶

Substance abuse is defined by the *Diagnostic and Statistical Manual of Mental Disorders, 4th edition* (DSM-IV) as a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by 1 (or more) of the following, occurring within a 12-month period:

- Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home (such as repeated absences or poor work performance related to substance use; substance-related absences, suspensions, or expulsions from school; or neglect of children or household).
- Recurrent substance use in situations in which it is physically hazardous (such as driving an automobile or operating a machine when impaired by substance use).

FIGURE 235-6 Ecstasy tablets used at raves where people dance all night long and some collapse in dehydration. (Courtesy of DEA.)

FIGURE 235-7 Black tar heroin for injection. (Courtesy of DEA.)

- Recurrent substance-related legal problems (such as arrests for substance-related disorderly conduct).
- Continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance (e.g., arguments with spouse about consequences of intoxication and physical fights).

DSM-IV CRITERIA FOR SUBSTANCE DEPENDENCE⁶

A maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by 3 (or more) of the following, occurring at any time in the same 12-month period:

- Substance is often taken in larger amounts or over a longer period than intended.
- Persistent desire or unsuccessful efforts to cut down or control substance use.
- A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple physicians or driving long distances), to use the substance (e.g., chain smoking), or to recover from its effects.
- Important social, occupational, or recreational activities are given up or reduced because of substance abuse.
- Continued substance use despite knowledge of having a persistent or recurrent psychological or physical problem that is caused or exacerbated by use of the substance.

Tolerance, as defined by either:

- Need for markedly increased amounts of the substance in order to achieve intoxication or desired effect; or
- Markedly diminished effect with continued use of the same amount.

Withdrawal, as manifested by either:

- Characteristic withdrawal syndrome for the substance; or
- The same (or closely related) substance is taken to relieve or avoid withdrawal symptoms.

CLINICAL FEATURES VISIBLE WITH SUBSTANCE ABUSE

- With intoxication, the following signs may be visible:
 - Via stimulants—Dilated pupils and increase in blood pressure, respiratory rate, pulse, and body temperature.
 - Via depressants—Decrease in blood pressure, respiratory rate, pulse, and body temperature. Opioids produce pinpoint pupils. Alcohol intoxication produces dilated pupils.
 - Withdrawal develops with decline of substance in the central nervous system (CNS). Withdrawal reactions vary by the substance used. Alcohol withdrawal is one of the most deadly and dangerous types of withdrawal.

LABORATORY TESTING

- All injection-drug users and persons engaged in high-risk sexual activities should be screened for HIV (with consent), hepatitis B and hepatitis C, and syphilis (rapid plasma reagin [RPR]).
- Women should have Papanicolaou (Pap) smears performed and be screened for chlamydia and gonorrhea based on age, risk factors and previous history of screening.

- Men or women who have multiple sex partners or use sex to obtain drugs are at high risk for sexually transmitted diseases (STDs) and should be tested.
- Homeless, HIV-positive, and previously incarcerated patients should be screened for tuberculosis using a purified protein derivative (PPD) test.
- ECG is warranted if there are any cardiac symptoms or if the physical examination reveals signs of cardiac disease.
- Urine screen for common drugs of abuse may reveal other drugs not admitted to in the history. Most laboratories can differentiate prescription from nonprescription drugs (i.e., opiates) upon request. Substances have different physiologic half-lives in the body and show up for varying amounts of time in the urine. Marijuana has a long excretion half-life and may be detectable for 1 month after its use. Other substances may last for only days.

DIFFERENTIAL DIAGNOSIS

Substance abuse disorders coexist with and complicate the course and treatment of numerous psychiatric conditions.

- Mood/anxiety disorders—Especially depression, bipolar affective disorder, panic disorder, and generalized anxiety disorder. Persons with addictions can develop the symptoms of these disorders from the drugs of abuse. However, mood and anxiety disorders can predate the use of drugs, and some of the motivation for drug use can stem from the desire to self-treat these psychological conditions. It is best to evaluate persons when they are off the drugs whenever possible.
- Schizophrenia—Although drugs can cause temporary psychosis and paranoia, if these symptoms persist after the drugs are stopped for some time, consider schizophrenia and other causes of psychosis.
- Personality disorders—These are a complicated set of disorders that can coexist and be confused with substance abuse disorder. An addict may appear to have an antisocial personality disorder when committing crimes to get money for expensive drugs. It is best to not use this diagnosis unless the behaviors continue when the person is off the drugs.

MANAGEMENT

- Recognize addiction (referred to as dependence in the DSM-IV criteria). One simple mnemonic device is the “three C’s of addiction”:
 - Compulsion to use.
 - Lack of Control.
 - Continued use despite adverse consequences.
- Use the “5 A’s”—Ask, Advice, Assess, Assist, and Arrange—to help smokers who are willing to quit. This model can be applied to any substance of abuse.⁷
- Offer counseling and pharmacotherapy to aid your patients to quit smoking.
- Use the CAGE⁷ questionnaire when asking about alcohol use:
 - Cut down (Have you ever felt you should *cut* down on your drinking?).

- Annoyed (Have people *annoyed* you by criticizing your drinking?).
- Guilty (Have you ever felt bad or *guilty* about your drinking?).
- Eye opener (Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (eye-opener)?).

Interpreting the results: 1 positive suggests at risk, 2 positives suggest abuse, and 3 or 4 positives suggest dependence. This is just a screening tool, and further evaluation is always needed.

- Recommend the 12-step programs to your patients. These have been very effective for millions of people worldwide.
- Refer to substance abuse programs. Such programs include hospital- and community-based programs. Some programs include detoxification and others require the patient to have gone through detoxification before starting the program. There are residential treatment units, outpatient programs, and ongoing self-help programs. Learn about the programs in your community and work with them.
- When prescribing opioid analgesics for chronic pain consider the outcomes in 4 domains, or the “4 A’s.” Is the patient:
 - Receiving adequate Analgesia?
 - Experiencing improvements in Activities of daily life?
 - Experiencing any Adverse effects?
 - Demonstrating Aberrant medication-taking behaviors that may be linked to addiction?⁸
- When patients are exhibiting aberrant drug-taking behaviors, consider the following:
 - They may have an addiction.
 - They may not be getting adequate pain relief taking the drug as prescribed.
 - They may have a comorbid mental illness.
 - They may intend to distribute pain medications illegally.⁹
- Help your patients acknowledge that they have a problem and offer them help in a nonjudgmental manner.
- Enlist family members to help whenever the patient gives your permission to do so.
- Demonstrate genuine concern and care; suspend judgment and you will have a higher chance of succeeding to help your patients overcome addiction.
- Advanced brain imaging and genetic tests are helping us to understand the physiologic basis of addiction and will ultimately provide us with better treatments for the medical disease of addiction.

PERSONS IN RECOVERY

- Be careful how you prescribe medications to persons in recovery. A “simple” prescription for hydrocodone (Vicodin) postoperatively can start a recovered person down the road of active addiction.
- Avoid giving opioids and benzodiazepines whenever there are good alternatives. Use NSAIDs for pain if possible. Use selective serotonin reuptake inhibitors (SSRIs), other antidepressants, or buspirone for anxiety if a medication is needed.
- If an opioid is needed, work with the patient to monitor the amount and manner of use. Involving a third person or sponsor to help meter out the dose may prevent relapse.
- Be upfront and honest about a shared goal to avoid relapse.

FOLLOW-UP

- Follow-up is critical to the treatment of all types of substance abuse. Substance abuse is a chronic condition (similar to hypertension or diabetes mellitus) and requires ongoing intervention to maintain sobriety.
- The frequency and intensity of follow-up depends on the substance, the addiction, and the patient.
- Do not give up on patients who relapse because it often takes more than 1 attempt before long-term cessation can be achieved.

PATIENT EDUCATION

Explain to patients that addiction is a disease and not a failing of their moral character. Inform patients about the existing treatment programs in their community and offer them names and phone numbers so that they may get help. If your patient is not ready for help today, give the numbers and names for tomorrow. Speak about the value of 12-step programs because these are effective and everyone can afford a 12-step program (they are free). There are 12-step programs in the community for everyone, including nonsmokers and agnostics.

PATIENT RESOURCES

- Alcoholics Anonymous (AA)—meetings and the Big Book are free. The Big Book is online for free in three languages. <http://www.alcoholics-anonymous.org/>.
- Narcotics Anonymous (NA)—meetings are free. The “Basic Text” costs \$10; it is similar to the AA big book, but the language is more up to date and readable. <http://www.na.org/index.htm>.
- Cocaine Anonymous (CA)—meetings are free. Their first book “Hope, Faith and Courage: Stories from the Fellowship of Cocaine Anonymous” was published in 1994 and sells for \$10. <http://www.ca.org/>.
- Crystal Meth Anonymous (12-step meetings). <http://www.crystallmeth.org/>.

236 TOBACCO ADDICTION

Carlos Roberto Jaén, MD, PhD, MS

PATIENT STORY

A 55-year-old woman presents for follow-up of hypertension. She has been smoking 1.5 packs of cigarettes per day since her late teens and reports that she is now ready to stop smoking. She realizes that smoking is bad for her health and does not like how smoking causes more wrinkles on the face (**Figure 236-1**). She has tried unsuccessfully to stop smoking on 3 different occasions using nicotine replacement therapy (patches and gum) and bupropion. She has no history of a psychiatric or seizure disorder. She would like to try stopping smoking using varenicline. She is also willing to return for 4 follow-up sessions at weekly intervals. She agrees to call a stop smoking telephone helpline (1-800-QUIT NOW) for counseling help. The patient tolerates the varenicline well and is able to stop successfully without any adverse effects. Two years after treatment she continues to be abstinent and very glad of this outcome. The clinician used elements of the “5 A’s” model for treating tobacco use and dependence to successfully help this patient quit smoking. (**Table 236-1**)

INTRODUCTION

Half of all deaths (more than 440,000) in the United States are attributed to tobacco addiction, including those caused by passive smoking. Tobacco addiction is a chronic disease, often developed during adolescence and early adulthood, that requires ongoing assessment and repeated intervention. There are effective treatments that can significantly increase rates of long-term abstinence. There are also effective preventive interventions that can prevent the initiation of tobacco use and reduce its prevalence among youth.

SYNONYMS

Tobacco use and dependence, tobacco use disorder, nicotine addiction, tobacco dependence.

EPIDEMIOLOGY

- Among adults who become daily smokers, nearly all first use of cigarettes occurs by 18 years of age (88%), with 99% of first use by 26 years of age.¹
- Almost 1 in 4 high school seniors is a current (in the past 30 days) cigarette smoker, compared with 1 in 3 young adults and 1 in 5 adults. Approximately 1 in 10 high school senior males is a current smokeless tobacco user, and approximately 1 in 5 high school senior males is a current cigar smoker.¹
- Significant disparities in tobacco use remain among young people nationwide. The prevalence of cigarette smoking is highest among American Indians and Alaska Natives, followed by whites and Hispanics, and then Asians and blacks. The prevalence of cigarette smoking is also higher among lower socioeconomic status youth.¹

FIGURE 236-1 55-year-old woman with premature wrinkling from years of heavy smoking. Note the numerous lines around her mouth and lips. (Courtesy of Richard P. Usatine, MD.)

- The latest data show the use of smokeless tobacco is increasing among white high school males, and cigar smoking may be increasing among black high school females.¹
- Concurrent use of multiple tobacco products is prevalent among youth. Among those who use tobacco, nearly one-third of high school females and more than one-half of high school males report using more than 1 tobacco product in the last 30 days.¹
- Persons with psychiatric diagnoses have much higher rates of smoking than the general population.²
- Persons with mental illness and/or substance abuse consume 44% of all cigarettes sold in the United States, despite being only 22% of the population.²

ETIOLOGY AND PATHOPHYSIOLOGY

- The evidence on the mechanisms by which smoking causes disease indicates that there is no risk-free level of exposure to tobacco smoke.³
- Inhaling the complex chemical mixture of combustion compounds in tobacco smoke causes adverse health outcomes, particularly cancer and cardiovascular and pulmonary diseases, through mechanisms that include DNA damage, inflammation, and oxidative stress.³
- There is sufficient evidence to infer that a causal relationship exists between active smoking and (a) impaired lung growth during childhood and adolescence; (b) early onset of decline in lung function during late adolescence and early adulthood; (c) respiratory signs and symptoms in children and adolescents, including coughing, phlegm, wheezing, and dyspnea; and (d) asthma-related symptoms (e.g., wheezing) in childhood and adolescence.¹
- The evidence is suggestive but not sufficient to conclude that smoking by adolescents and young adults is *not* associated with significant weight loss, contrary to young people's belief.¹
- Through multiple defined mechanisms, the risk and severity of many adverse health outcomes caused by smoking are directly related to the duration and level of exposure to tobacco smoke.³
- Sustained use and long-term exposures to tobacco smoke are caused by the powerfully addicting effects of tobacco products, which are mediated by diverse actions of nicotine and perhaps other compounds, at multiple types of nicotinic receptors in the brain.³
- Nicotine stimulates the release of multiple neurotransmitters, including dopamine, norepinephrine, acetylcholine, glutamate, serotonin, β -endorphin, and γ -aminobutyric acid.⁴
- Low levels of exposure, including exposures to secondhand tobacco smoke, lead to a rapid and sharp increase in endothelial dysfunction and inflammation, which are implicated in acute cardiovascular events and thrombosis.³
- There is insufficient evidence that product modification strategies to lower emissions of specific toxicants in tobacco smoke reduce risk for the major adverse health outcomes.³

RISK FACTORS

Given their developmental stage, adolescents and young adults are uniquely susceptible to social and environmental influences to use tobacco.

TABLE 236-1 The "5 A's" Model for Treating Tobacco Use and Dependence

Ask about tobacco use.	Identify and document tobacco use status for every patient at every visit.
Advise to quit.	In a clear, strong, and personalized manner, urge every tobacco user to quit.
Assess willingness to make a quit attempt.	Is the tobacco user willing to make a quit attempt at this time?
Assist in quit attempt.	For the patient willing to make a quit attempt, offer medication and provide or refer for counseling or additional treatment to help the patient quit. For patients unwilling to quit at the time, provide interventions designed to increase future quit attempts.
Arrange followup.	For the patient willing to make a quit attempt, arrange for followup contacts, beginning within the first week after the quit date. For patients unwilling to make a quit attempt at the time, address tobacco dependence and willingness to quit at next clinic visit.

From: Treating Tobacco Use and Dependence: 2008 Update. US Department of Health and Human Services; 2008. http://www.ahrq.gov/clinic/tobacco/treating_tobacco_use08.pdf

- Socioeconomic factors and educational attainment influence the development of youth smoking behavior. The adolescents most likely to begin to use tobacco and progress to regular use are those who have lower academic achievement.¹
- The evidence is sufficient to conclude that there is a causal relationship between peer group social influences and the initiation and maintenance of smoking behaviors during adolescence.¹
- Affective processes play an important role in youth smoking behavior, with a strong association between youth smoking and negative affect.¹
- The evidence is suggestive that tobacco use is a heritable trait, more so for regular use than for onset. The expression of genetic risk for smoking among young people may be moderated by small-group and larger social–environmental factors.¹

DIAGNOSIS

CLINICAL FEATURES

- History—Most tobacco users express a desire to stop using tobacco but report repeated failures in their attempts. All patients should be asked if they use tobacco and should have their tobacco use status documented on a regular basis. Evidence shows that clinic screening systems, such as expanding the vital signs to include tobacco use status, or the use of other reminder systems, such as chart stickers or computer prompts, significantly increase rates of clinician intervention.⁵ **SOR A**
- Physical—Individuals with tobacco addiction may easily be detected by:
 - Distinctive odor of tobacco smoke.
 - Smoker’s cough.
 - Raspy or hoarse voice (see Chapter 36, The Larynx [Hoarseness])
 - Pack of cigarettes in the front pocket of the shirt.
 - Wrinkles in excess of what would be expected for their age (**Figure 236-2**).
- *Smoker’s face* is described as:
 - “Lines or wrinkles on the face, typically radiating at right angles from the upper and lower lips or corners of the eyes, deep lines on the cheeks, or numerous shallow lines on the cheeks and lower jaw.” (**Figure 236-2**.)
 - “A subtle gauntness of the facial features with prominence of the underlying bony contours.”⁶
- The oral cavity of smokers often shows signs of prolonged exposure to tobacco in the form:
 - Yellow and brown teeth (**Figures 236-3 to 236-5**).
 - Angular cheilitis (**Figure 236-3**) (see Chapter 32, Angular Cheilitis).
 - Gingivitis and periodontitis (**Figure 236-4**) (see Chapter 39, Gingivitis and Periodontal Disease).
- There may be other serious conditions within the oral cavity such as:
 - Leukoplakia—A pre-malignant condition (**Figure 236-5**) (see Chapter 42, Leukoplakia).
 - Nicotine stomatitis (**Figure 236-6**).

FIGURE 236-2 Smoker’s face described as “one or more of the following: (a) lines or wrinkles on the face, typically radiating at right angles from the upper and lower lips or corners of the eyes, deep lines on the cheeks, or numerous shallow lines on the cheeks and lower jaw. (b) A subtle gauntness of the facial features with prominence of the underlying bony contours.”⁶ (Courtesy of Usatine R, Moy R, Tobinick E, Siegel D. *Skin Surgery: A Practical Guide*. St. Louis, MO: Mosby; 1998.)

FIGURE 236-3 Angular cheilitis and tobacco staining of the tongue from chewing tobacco. (Courtesy of Richard P. Usatine, MD.)

FIGURE 236-4 Tobacco staining teeth and periodontitis from smoking tobacco. (Courtesy of Richard P. Usatine, MD.)

- Squamous cell carcinoma (**Figures 236-7 and 236-8**) (see Chapter 43, Oral Cancer).
- Withdrawal symptoms—Symptoms associated with tobacco addiction withdrawal include a dysphoric or depressed mood, insomnia, irritability, frustration or anger, anxiety, difficulty concentrating, restlessness, decreased heart rate, and increased appetite or weight gain.⁷ None of the withdrawal symptoms are life-threatening, as they can be with other drugs like alcohol and opiates. Their intensity peaks during the first week and most last no more than 2 to 4 weeks following abstinence.⁸
- Complications—Continuing use of tobacco causes multiple cancers and the development and/or exacerbation of multiple chronic diseases as summarized in **Figure 236-9**.
- Emphysema may significantly impair lung function and lead to death (see Chapter 56, Chronic Obstructive Pulmonary Disease). Centrilobular emphysema occurs with carbon deposits in the destroyed lung tissue.

LABORATORY TESTING

- Some specialized assessments of individual and environmental attributes provide information for tailoring treatment and may predict quitting success. Specialized assessments refer to the use of formal instruments (e.g., questionnaires, clinical interviews, or physiologic indices such as carbon monoxide, serum nicotine/cotinine levels, and/or pulmonary function) that may be associated with cessation outcome. In addition, clinicians may find other assessments relevant to medication use and specific populations when selecting treatment. The use of biochemical confirmation (use of biologic samples, such as expired air, saliva, urine, or blood, to measure tobacco-related compounds, such as nicotine, cotinine, and carboxyhemoglobin) is particularly useful to verify abstinence during pregnancy treatment where reports of deception have been documented.⁵ Variables targeted by specialized assessments that predict treatment success include:
 - High motivation;
 - Readiness to change in the next month;
 - Moderate to high self-efficacy (confidence in his or her ability to stop using tobacco successfully); and
 - Supportive social network.
- Variables associated with lower abstinence rates include:
 - High nicotine dependence;
 - Psychiatric comorbidity and substance use (particularly elevated depressive symptoms, schizophrenia, and current alcohol abuse);
 - High stress level; and
 - Exposure to other smokers.⁵

IMAGING

There are currently no practical clinical applications for imaging studies that are helpful when treating individuals with tobacco addiction. Experimentally several MRI, functional MRI, and positron emission tomography (PET) scan studies provide helpful clues as to mechanisms of actions of tobacco addiction.³

FIGURE 236-5 Leukoplakia on the buccal mucosa and gingiva in a tobacco smoker. Although much of the leukoplakia is on the bite line, the risk of squamous cell carcinoma of the oral cavity must be assessed with appropriate biopsies. (Courtesy of Richard P. Usatine, MD.)

FIGURE 236-6 Nicotine stomatitis over the hard palate from smoking tobacco. (From Rizzolo D, Chiodo TA. Lesion on the hard palate. *J Fam Pract*, 2008;57(1):33-35. Reproduced with permission from Frontline Medical Communications.)

MANAGEMENT

The combination of counseling and medication is more effective for smoking cessation than either medication or counseling alone. Therefore, whenever feasible and appropriate, both counseling and medication should be provided to patients trying to stop smoking.⁵ **SOR A**

NONPHARMACOLOGIC
(COUNSELING INTERVENTIONS)

- Minimal interventions lasting less than 3 minutes increase overall tobacco abstinence rates. Every tobacco user should be offered at least a minimal intervention, whether or not he or she is referred to an intensive intervention.⁵ **SOR A**
- Two types of counseling and behavioral therapies result in higher abstinence rates: (a) providing smokers with practical counseling (problem-solving skills/skills training), and (b) providing support and encouragement as part of treatment. These types of counseling elements should be included in smoking cessation interventions.⁵ **SOR B**
- There is a strong dose–response relationship between the session length of person-to-person contact and successful treatment outcomes. Intensive interventions are more effective than less-intensive interventions and should be used whenever possible.⁵ **SOR A**
- Proactive telephone counseling, group counseling, and individual counseling formats are effective and should be used in smoking cessation interventions.⁵ **SOR A**
- Person-to-person treatment delivered for 4 or more sessions appears especially effective in increasing abstinence rates. Therefore, if feasible, clinicians should strive to meet 4 or more times with individuals quitting tobacco use.⁵ **SOR A**
- Motivational interviewing for smokers not willing to make an attempt to stop tobacco use:
 - Motivational intervention techniques appear to be effective in increasing a patient’s likelihood of making a future quit attempt. Therefore, clinicians should use motivational techniques to encourage smokers who are not currently willing to quit to consider making a quit attempt in the future.⁵ **SOR B**
 - The four general principles that underlie motivational intervention are: (a) *express empathy*, (b) *develop discrepancy*, (c) *roll with resistance*, and (d) *support self-efficacy* (Table 236–2). Motivational intervention researchers have found that having patients use their own words to commit to change is more effective than clinician exhortations, lectures, or arguments for quitting, which tend to increase rather than lessen patient resistance to change.⁵

MEDICATIONS

Clinicians should encourage all patients attempting to quit to use effective medications for tobacco dependence treatment, except where contraindicated or for specific populations for which there is insufficient evidence of effectiveness (e.g., pregnant women, smokeless tobacco users, light smokers, and adolescents).⁵ **SOR A**

- In the United States, there are 7 FDA-approved medications for treating tobacco use and these first-line medications should be recommended: bupropion SR (Zyban), nicotine gum, nicotine inhaler, nicotine

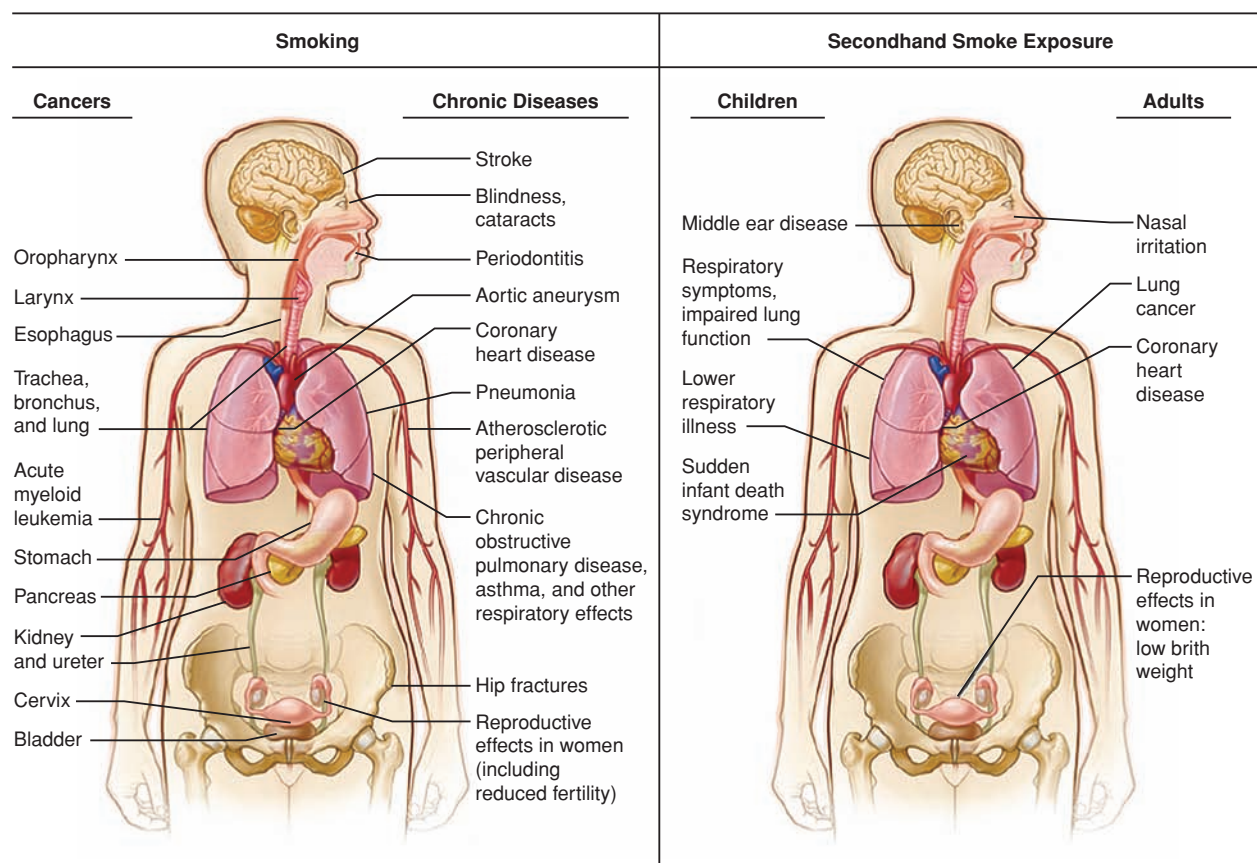

FIGURE 236-7 Squamous cell carcinoma of buccal mucosa in a man that used chewing tobacco along with smoking. (Courtesy of Richard P. Usatine, MD.)

FIGURE 236-8 Squamous cell carcinoma of the lip inner lip in a cigar smoker. (Courtesy of Gerald Ferritti, DDS.)

Source: USDHHS 2004, 2006.

FIGURE 236-9 Health consequences causally linked to smoking and second hand smoking. (From U.S. Department of Health and Human Services. *How Tobacco Smoke Causes Disease: The Biology and Behavioral Basis for Smoking-Attributable Disease: A Report of the Surgeon General*. Atlanta, GA: U.S. Department of Health and Human Services, Centers for Disease Control and Prevention, National Center for Chronic Disease Prevention and Health Promotion, Office on Smoking and Health; 2010.)

lozenge, nicotine nasal spray, nicotine patch, and varenicline (Chantix). Dosing guidelines for these 7 meds are found in **Table 236-3**.

- The clinician should consider the first-line medications shown to be more effective than the nicotine patch alone: 2 mg/day varenicline or the combination of long-term nicotine patch use + ad libitum nicotine replacement therapy (NRT).⁵
- Certain combinations of first-line medications have been shown to be effective smoking cessation treatments. Therefore, clinicians should consider using these combinations of medications with their patients who are willing to quit. Effective combination medications are:
 - Long-term (>14 weeks) nicotine patch + other NRT (gum and spray).
 - The nicotine patch + the nicotine inhaler.
 - The nicotine patch + bupropion SR.⁵ **SOR A**
- There is a strong relationship between the number of sessions of counseling combined with medication and the likelihood of successful smoking cessation. Therefore, to the extent possible, clinicians should provide multiple counseling sessions, in addition to medication, to their patients who are trying to quit smoking.⁵ **SOR A**

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Acupuncture—A metaanalysis of 5 studies did not show effectiveness of acupuncture as a tobacco use treatment. There is also lack

TABLE 236-2 Motivational Interviewing Strategies

Express empathy.	<ul style="list-style-type: none"> • Use open-ended questions to explore: <ul style="list-style-type: none"> ◦ The importance of addressing smoking or other tobacco use (e.g., “How important do you think it is for you to quit smoking?”) ◦ Concerns and benefits of quitting (e.g., “What might happen if you quit?”) • Use reflective listening to seek shared understanding: <ul style="list-style-type: none"> ◦ Reflect words or meaning (e.g., “So you think smoking helps you to maintain your weight”). ◦ Summarize (e.g., “What I have heard so far is that smoking is something you enjoy. On the other hand, your boyfriend hates your smoking, and you are worried you might develop a serious disease.”). • Normalize feelings and concerns (e.g., “Many people worry about managing without cigarettes.”). • Support the patient’s autonomy and right to choose or reject change (e.g., “I hear you saying you are not ready to quit smoking right now. I’m here to help you when you are ready.”).
Develop discrepancy.	<ul style="list-style-type: none"> • Highlight the discrepancy between the patient’s present behavior and expressed priorities, values, and goals (e.g., “It sounds like you are very devoted to your family. How do you think your smoking is affecting your children?”). • Reinforce and support “change talk” and “commitment” language: <ul style="list-style-type: none"> ◦ “So, you realize how smoking is affecting your breathing and making it hard to keep up with your kids.” ◦ “It’s great that you are going to quit when you get through this busy time at work.” • Build and deepen commitment to change: <ul style="list-style-type: none"> ◦ “There are effective treatments that will ease the pain of quitting, including counseling and many medication options.” ◦ “We would like to help you avoid a stroke like the one your father had.”
Roll with resistance.	<ul style="list-style-type: none"> • Back off and use reflection when the patient expresses resistance: <ul style="list-style-type: none"> ◦ “Sounds like you are feeling pressured about your smoking.” • Express empathy: <ul style="list-style-type: none"> ◦ “You are worried about how you would manage withdrawal symptoms.” • Ask permission to provide information: <ul style="list-style-type: none"> ◦ “Would you like to hear about some strategies that can help you address that concern when you quit?”
Support self-efficacy.	<ul style="list-style-type: none"> • Help the patient to identify and build on past successes: <ul style="list-style-type: none"> ◦ “So you were fairly successful the last time you tried to quit.” • Offer options for achievable small steps toward change: <ul style="list-style-type: none"> ◦ Call the quitline (1-800-QUIT-NOW) for advice and information. ◦ Read about quitting benefits and strategies. ◦ Change smoking patterns (e.g., no smoking in the home). ◦ Ask the patient to share his or her ideas about quitting strategies.

From: Treating Tobacco Use and Dependence: 2008 Update. US Department of Health and Human Services; 2008. [http:// www.ahrq.gov/clinic/tobacco/treating_tobacco_use08.pdf](http://www.ahrq.gov/clinic/tobacco/treating_tobacco_use08.pdf)

of scientific evidence for the effectiveness of electrostimulation or laser acupuncture for the treatment of tobacco addiction.⁵

- Hypnotherapy—There is insufficient evidence to recommend hypnotherapy as an effective treatment for tobacco addiction.⁵
- Novel tobacco products—There is insufficient evidence to determine whether novel tobacco products reduce individual and population health risks. The evidence indicates that changing cigarette designs over the last 5 decades, including filtered, low-tar, and “light” variations, have not reduced overall disease risk among smokers and may have hindered prevention and cessation efforts. The overall health of the public could be harmed if the introduction of novel tobacco products encourages tobacco use among people who would otherwise be unlikely to use a tobacco

product or delays cessation among persons who would otherwise quit using tobacco altogether.³

REFERRAL

For patients who are unsuccessful with therapies available in primary care, it is reasonable to refer them to a tobacco-cessation specialist. These specialists typically provide intensive tobacco interventions. Specialists are not defined by their professional affiliation or by the field in which they trained. Rather, specialists view tobacco dependence treatment as a primary professional role. Specialists possess the skills, knowledge, and training to provide effective interventions across a range of intensities, and often are affiliated with programs offering intensive treatment interventions or services.

¹Marketed by GlaxoSmithKline.

²Marketed by Pfizer.

³The U.S. Clinical Practice Guideline states that pregnant smokers should be encouraged to quit without medication based on insufficient evidence of effectiveness and theoretical concerns with safety. Pregnant smokers should be offered behavioral counseling interventions that exceed minimal advice to quit.

⁴In July 2009, the FDA mandated that the prescribing information for all bupropion- and varenicline-containing products include a black-boxed warning highlighting the risk of serious neuropsychiatric symptoms, including changes in behavior, hostility, agitation, depressed mood, suicidal thoughts and behavior, and attempted suicide. Clinicians should advise patients to stop taking varenicline or bupropion SR and contact a healthcare provider immediately if they experience agitation, depressed mood, and any changes in behavior that are not typical of nicotine withdrawal, or if they experience suicidal thoughts or behavior. If treatment is stopped due to neuropsychiatric symptoms, patients should be monitored until the symptoms resolve.

⁵Average wholesale price from Medi-Span Electronic Drug File. Indianapolis, IN: Wolters Kluwer Health, July 2011.

Abbreviations: MAO, monoamine oxidase; NRT, nicotine replacement therapy; OTC, over-the-counter (non-prescription product); Rx, prescription product.

PREVENTION

The simple fact is that we cannot end the tobacco epidemic without focusing our efforts on young people. Nearly 100% of adults who smoke every day started smoking when they were age 26 years or younger, so prevention is the key to success. The tobacco industry spends almost \$10 billion a year to market its products, half of all movies for children younger than age 13 years contain scenes of tobacco use, and images and messages normalize tobacco use in magazines, on the Internet, and at retail stores frequented by youth. With a quarter of all high school seniors and a third of all young adults smoking, and with progress in reducing prevalence slowing dramatically, the time for action is now.¹

- Advertising and promotional activities by tobacco companies have been shown to cause the onset and continuation of smoking among adolescents and young adults.¹
- The evidence is sufficient to conclude that there is a causal relationship between depictions of smoking in the movies and the initiation of smoking among young people.¹
- The evidence is sufficient to conclude that mass media campaigns, comprehensive community programs, and comprehensive state-wide tobacco control programs can prevent the initiation of tobacco use and reduce its prevalence among youth.¹
- The evidence is sufficient to conclude that increases in cigarette prices reduce the initiation, prevalence, and intensity of smoking among youth and young adults.¹
- The evidence is sufficient to conclude that school-based programs with evidence of effectiveness, containing specific components, can produce at least short-term effects and reduce the prevalence of tobacco use among school-age youth.¹ One tobacco-free education program for kids from the American Academy of Family Physicians (AAFP) is *Tar Wars*: <http://www.tarwars.org/online/tarwars/home.html>.

PROGNOSIS

- Young individuals progress from smoking occasionally to smoking every day.
- Each day across the United States more than 3800 youths younger than 18 years of age start smoking. Of every 3 young smokers, only 1 will quit, and 1 of those remaining smokers will die from tobacco-related causes. Most of these young people never considered the long-term health consequences associated with tobacco use when they started smoking; and nicotine, a highly addictive drug, causes many to continue smoking well into adulthood, often with deadly consequences (**Figure 236-10**).¹
- Those with serious mental illnesses die, on average, 25 years earlier than the general population, with most deaths related to tobacco-related diseases such as heart disease, diabetes, and chronic lung disease.²

FOLLOW-UP

- All patients who receive a tobacco dependence intervention should be assessed for abstinence at the completion of treatment and

FIGURE 236-10 Smoking addiction is a killer. (Courtesy of Nerilicon, CagleCartoons.com, Mexico City, Mexico.)

during subsequent contacts.¹ Abstinent patients should have their quitting success acknowledged, and the clinician should offer to assist the patient with problems associated with quitting.² Patients who have relapsed should be assessed to determine whether they are willing to make another quit attempt. [SOR](#) 

PATIENT RESOURCES

- **1-800-QUIT NOW**—This free telephone quit line service refers callers to their own state's quit line via this national routing number. In some counties free nicotine patches are available to callers.
- The American Legacy Foundation's Became an EX Program—<http://www.becomeanex.org/>.

The EX Plan is a free quit smoking program that helps you re-learn life without cigarettes. Before you actually stop smoking, they'll show you how to deal with the very things that trip up so many people when they try to stop smoking. So you'll be more prepared to stop and stay off tobacco.

- Office on Smoking and Health at the Centers for Disease Control and Prevention. *Smoking & Tobacco Use*—<http://www.cdc.gov/tobacco>.

The Smoking and Tobacco Use website of the Centers for Disease Control and Prevention (CDC) provides tobacco use data and statistics; information about the health effects of smoking, smokeless tobacco products, and secondhand smoke; resources for tobacco cessation and youth smoking prevention; and products and materials that can help motivate behavior change. Visitors to the CDC website can find links to clinician and patient resources, such as a quit guideline.

PROVIDER RESOURCES

- *Treating Tobacco Use and Dependence 2008 Update*. Excellent clinical practice guideline. http://www.ahrq.gov/clinic/tobacco/treating_tobacco_use08.pdf
- American Academy of Family Physicians' Tobacco Cessation Program. <http://www.askandact.org>.

The American Academy of Family Physicians' (AAFP) tobacco cessation program, "Ask and Act," encourages family physicians to ASK their patients about tobacco use, then ACT to help them quit. Through the Ask and Act program, AAFP members have access to a variety of free resources to help patients quit using tobacco, such as a quit smoking prescription pad and a wallet card with quitline information.

- American Academy of Family Physicians. *Pharmacologic Product Guide: FDA-Approved Medications*—http://www.aafp.org/online/etc/medialib/aafp_org/documents/clinical/pub_health/askact/prescribguidelines.Par.0001.File.tmp/PRESCRIBINGGUIDE2010.pdf.

This is an excellent guide to pharmacologic intervention that summarizes precautions, dosing, adverse effects, advantages, disadvantages and costs for the 7 FDA-approved medications for treatment of tobacco addiction.

- Smoking Cessation Leadership Center. <http://smokingcessationleadership.ucsf.edu>.

The Smoking Cessation Leadership Center aims to increase smoking cessation rates and increase the number of health professionals

who help smokers quit. The site not only provides tobacco cessation resources for providers to pass on to patients, it also offers a variety of tools, materials, and training courses aimed toward improving the delivery of tobacco cessation intervention in clinical settings. 1-800-QUIT-NOW cards can be ordered online at this website, which provides telephone cessation resources for all 50 states in the United States.

237 ALCOHOLISM (ALCOHOL USE DISORDER)

Mark L. Willenbring, MD

PATIENT STORY

Theresa is a 39-year-old, white, single woman who presents with insomnia and depression. After exploring the presenting symptoms, her physician reviews some screening questions about potentially related problems. In response to a question about heavy drinking in the past year, Theresa responds that she is drinking about 2 bottles (10 drinks) of wine nightly. She acknowledges going over limits repeatedly and a persistent desire to quit or cut down, as well as continuing to drink in spite of hangovers and nausea in the morning. She denies withdrawal symptoms, driving while intoxicated, job or serious relationship problems, but admits that her social activities have decreased over the past year because she spends her evening drinking alone. No one else knows she is struggling with drinking. Her depression and insomnia started after her drinking increased about 2 years ago.

INTRODUCTION

Excessive drinking of alcohol is a common behavior encountered in primary care, yet few clinicians feel prepared to address it. Most clinicians are unclear about the best way to screen for heavy drinking and lack confidence in how to address it. Physicians often lack the knowledge and skill to screen and evaluate excessive drinking, let alone address it other than suggesting a referral to an addiction counselor or treatment program. Regrettably, few patients are appropriate for or accept referral to a counselor or program. Fortunately, research over the past 20 years has provided evidence-based, efficient ways to screen, evaluate, and treat heavy drinking in primary care.

SYNONYMS (TERMINOLOGY)

Heavy drinking refers to drinking in excess of low-risk guidelines (see below).

Alcohol dependence (alcoholism) is a disorder of compulsive drinking associated with impaired control over intake, such as repeatedly exceeding self-defined limits, a persistent desire to quit or cut down and difficulty doing so, and continued use despite adverse consequences.

The terms *alcohol use disorder*, *alcohol dependence*, and *alcoholism* can be used interchangeably.

EPIDEMIOLOGY

- In any given year, approximately 30% of U.S. adults 18 years of age and older exceed the National Institute on Alcohol Abuse and Alcoholism (NIAAA) low-risk drinking guidelines at least once (Figures 237-1 and 237-2).¹ The low-risk drinking limits for

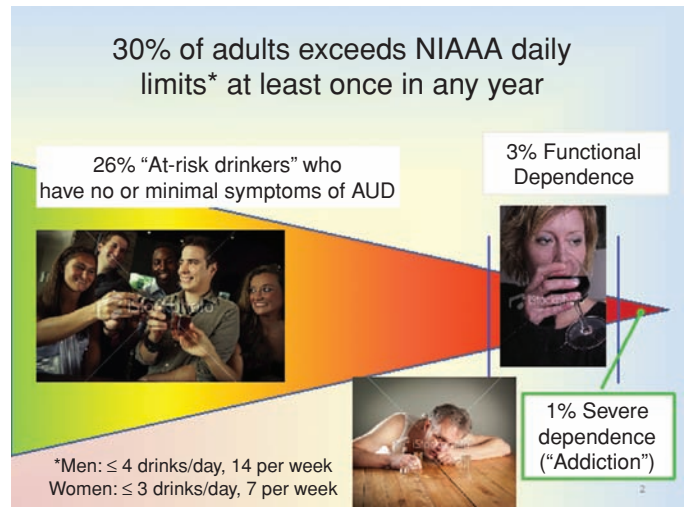

FIGURE 237-1 Spectrum of alcohol use disorder. (Courtesy of Mark L. Willenbring, MD.)

FIGURE 237-2 Past month use of alcohol among U.S. residents over age 12. Category definitions: *Current (past month) use*—at least 1 drink in the past 30 days; *binge use*—5 or more drinks on the same occasion (i.e., at the same time or within a couple of hours of each other) on at least 1 day in the past 30 days; *heavy use*—5 or more drinks on the same occasion on each of 5 or more days in the past 30 days.

healthy adult women is defined as drinking no more than 3 drinks in any day and 7 drinks in any week, and for men, no more than 4 drinks in any day and 14 drinks in any week.

- A drink refers to 12 oz of beer, 5 oz of wine or 1.5 oz of spirits, each of which contains about 14 g of absolute ethanol.¹ Within that group, the frequency varies from occasional to daily or near daily, and the amount of drinking varies from 5 to more than 20 drinks daily. Most excessive drinkers who exceed the limits (72%) do not meet diagnostic criteria for an alcohol use disorder and are considered at-risk drinkers.¹
- At-risk drinkers are analogous to asymptomatic patients with hyperlipidemia or hypertension: they do not currently have a disorder (other than the risk factor) but are at elevated risk for developing one if the risk factor is not decreased. Reduction in excessive drinking significantly reduces risk of developing an alcohol use disorder, liver disease, or social problems.²
- Approximately 4% of adults meet *Diagnostic and Statistical Manual of Mental Disorders, 4th Edition* (DSM-IV) criteria for alcohol dependence in any year.³ Three-quarters of them have functional alcohol dependence, which is characterized by a predominance of “internal symptoms” of impaired control such as going over limits and persistent desire to quit or cut down and a limited course. People with functional alcohol dependence have a single episode, lasting on average 3 to 4 years, usually with resolution of the episode and no recurrence. A quarter of those with dependence, 1% of the general population in any year, have recurrent alcohol dependence, demonstrating an average of 5 episodes over a period of years to decades.⁴
- Thus, there are 3 categories of heavy drinkers the primary care provider is apt to encounter (**Box 237-1**):
 1. At-risk drinkers (the predominant group);
 2. Functional alcohol dependence; and
 3. Recurrent, more severe alcohol dependence.

ETIOLOGY AND PATHOPHYSIOLOGY

Alcohol use disorder is a heritable disease: Approximately 50% of the risk is genetic, while environmental factors account for the remainder, the most clearly established factor being early childhood abuse or neglect.^{5,6} Multigenerational alcohol dependence often appears in the early to mid-teens, but functional alcohol dependence can begin at any age.⁷

RISK FACTORS

The most important risk factors are:

- Family history of alcohol dependence,⁸ and
- Early life stress in the form of early childhood abuse or neglect.⁹ Other risk factors include:
 - An early history of externalizing personality factors, such as:
 - Extroversion
 - Attention deficit disorder
 - Oppositional defiant disorder
 - Conduct disorder
- Antisocial and borderline personality disorders among adults¹⁰

BOX 237-1 Common Presentations of 3 Categories of Excessive Drinkers*

Diagnosis of Alcohol Use Disorder	
Category	Common Presentation
At-risk drinkers	None or driving while drinking only (no DWI)
Functional alcohol use disorder	<ul style="list-style-type: none"> • “Internal symptoms” of impaired control <ul style="list-style-type: none"> – Going over limits repeatedly – Desire to cut down/quit without success – Use despite “internal” problems associated with drinking (e.g., hangover, nausea) – Drinking and driving (no DWI) • Usually 2 to 4 criteria positive (out of 11)* • No legal, job, or serious interpersonal problems • Maximum drinks about 5 to 8 per drinking day • Single episode lasting 3 to 4 years on average, no recurrence
Severe recurrent alcohol use disorder	<ul style="list-style-type: none"> • “Internal” symptoms of impaired control (above) plus <ul style="list-style-type: none"> – Spending a lot of time drinking – Giving up non-drinking activities – Physical withdrawal and morning drinking – Serious medical complications (e.g. liver disease) • Usually >5 criteria positive • “External” symptoms of dysfunction <ul style="list-style-type: none"> – Social and family disruption – Problems with job, school, parenting – Legal problems (e.g. DWI) • Maximum drinks about 10 to 24 per drinking day • Recurrent episodes over years to decades (average of 5)

*The approach of proposed DSM-V diagnosis (combining DSM-IV abuse and dependence criteria is used here).¹⁵ (Courtesy of Mark Willenbring, MD.)

Onset of drinking before the age of 14 years markedly increases risk for later development of alcohol dependence, especially for adolescents with a positive family history.¹¹

DIAGNOSIS

CLINICAL FEATURES

- Contrary to common belief, heavy drinkers are very likely to answer questions about their drinking honestly, provided the questions are skillful. Asking about quantity and frequency (“On any single occasion during the past 3 months, have you had more than 5 drinks containing alcohol?”) is most likely to elicit an informative answer, whereas any question that suggests even the possibility of moral judgment (e.g., “How much do you drink?”) is less likely to yield helpful answers. **Box 237-2** for the specific screening question recommended by the NIAAA.
- Most heavy drinkers are not symptomatic. Thus, they do not have alcohol-related symptoms. They can only be detected through screening for quantity and frequency of drinking. Screening focused on symptoms of alcohol use disorder, such as the well-known CAGE (“Have you ever tried to cut down on your drinking? Have you ever felt annoyed by criticism of your drinking? Have you ever felt guilty about your drinking? Have you ever had a morning eye-opener?”), will not detect asymptomatic at-risk drinkers, and it

BOX 237-2 Screening question recommended by the National Institute on Alcohol Abuse and Alcoholism (NIAAA)

How many times in the past year have you had...

- 5 or more drinks in a day? (for men)
- 4 or more drinks in a day? (for women)

One standard drink is equivalent to 12 oz of beer, 5 oz of wine, or 1.5 oz of 80-proof spirits.

Source: <http://www.niaaa.nih.gov/guide>.

performs poorly compared to almost all other methods.¹² It is important to inquire about quantity and frequency of drinking in order to identify at-risk drinkers and patients with functional alcohol dependence. The AUDIT (Alcohol Use Disorders Identification Test) (**Figure 237-3**) is the gold standard for a written questionnaire; it only takes about 3 minutes to complete and is easy to score. A score of 8 or more for men or 4 or more for women suggests excessive drinking.¹

- Current diagnostic criteria are based on the DSM-IV.¹³ DSM-IV specifies 2 types of alcohol use disorder: abuse and dependence. However, since that manual was published, research on the epidemiology of alcohol use disorders and clustering of clinical signs and symptoms has failed to confirm the differentiation of these 2 disorders. Current research supports instead the presence of a single disorder that includes the criteria of both abuse and dependence under DSM-IV into a single dimensional diagnosis.¹⁴ The proposed criteria for the next edition, DSM-V, currently under consideration, have a single disorder, alcohol use disorder. The presence of any 2 of 11 criteria (**Box 237-3**) is enough to establish a diagnosis, where the number of criteria met are highly correlated with severity of the disorder.¹⁵ Although there may be some minor modifications, it is almost certain that in the final version, there will be a single diagnostic category. Note that serious medical, social or personal complications of heavy drinking, such as employment or school problems, serious family or marital disruptions or legal problems are not required for a diagnosis. DSM-IV alcohol dependence criteria are usually among the earliest to occur, while most abuse criteria such as serious interpersonal, vocational or legal problems only occur among a relatively small group of the most severely affected.¹⁶ Thus, in this chapter the terms *alcohol use disorder* (AUD) and *alcohol dependence* are used interchangeably.
- According to NIAAA, healthy adult men should not drink in excess of 4 standard U.S. drinks in any day, or 14 in any week, and adult women should not exceed 3 drinks in any day and 7 in any week.¹ Low-risk drinking limits may be less for certain groups, such as adults older than age 65 years, or in the presence of medical illnesses, such as liver disease. Women who are pregnant or are trying to become pregnant should be advised to abstain completely.
- Drinking in excess of these limits is considered unhealthy, placing heavy drinkers at elevated risk for developing AUD and associated complications such as liver disease.¹⁷ Approximately 30% of U.S. adults age 18 years and older drink in excess of low-risk limits at least once in any year. About 4 of 5 of them do not meet diagnostic criteria for a disorder, and are considered to be “at-risk” for developing one.¹ In other words, this group has an asymptomatic risk factor similar to hypertension or hyperlipidemia. At-risk drinkers are typically unaware that their drinking constitutes a health risk. This does not reflect “denial” but rather the lack of information available to the public about what constitutes high-risk drinking or how to measure consumption. For example, how many standard U.S. drinks are in a 7 oz. martini? (Depending on the specific way it is mixed, the answer is about 4.) It is much easier to obtain dietary information about food than information about alcohol content in a beverage.
- Patients with functional alcohol dependence are aware of struggling with their alcohol consumption, but lack serious life consequences at this time. Most are open to changing their drinking, but they

BOX 237-3 Alcohol Use Disorder

Proposed DSM-V (*Updated April 30, 2012*)

- A. A problematic pattern of alcohol use leading to clinically significant impairment or distress.
- B. Two (or more) of the following occurring within a 12-month period:
 1. Alcohol is often taken in larger amounts or over a longer period than was intended
 2. There is a persistent desire or unsuccessful effort to cut down or control alcohol use
 3. A great deal of time is spent in activities necessary to obtain alcohol, use the substance, or recover from its effects
 4. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home (e.g., repeated absences or poor work performance related to alcohol use; substance-related absences, suspensions, or expulsions from school; neglect of children or household)
 5. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
 6. Important social, occupational, or recreational activities are given up or reduced because of alcohol use
 7. Recurrent alcohol use in situations in which it is physically hazardous (e.g., driving an automobile or operating a machine when impaired by substance use)
 8. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance
 9. Tolerance, as defined by either or both of the following:
 - a. A need for markedly increased amounts of alcohol to achieve intoxication or desired effect
 - b. Markedly diminished effect with continued use of the same amount of the substance
 10. Withdrawal, as manifested by either of the following:
 - a. The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for Withdrawal)
 - b. The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms
 11. Craving or a strong desire or urge to use alcohol

AUDIT

PATIENT: Because alcohol use can affect your health and can interfere with certain medications and treatments, it is important that we ask some questions about your use of alcohol. Your answers will remain confidential, so please be honest.

For each question in the chart below, place an X in one box that best describes your answer.

NOTE: In the U.S., a single drink serving contains about 14 grams of ethanol or “pure” alcohol. Although the drinks below are different sizes, each one contains the same amount of pure alcohol and counts as a single drink:

Questions	0	1	2	3	4	
1. How often do you have a drink containing alcohol?	Never	Monthly or less	2 to 4 times a month	2 to 3 times a week	4 or more times a week	
2. How many drinks containing alcohol do you have on a typical day when you are drinking?	1 or 2	3 or 4	5 or 6	7 to 9	10 or more	
3. How often do you have 5 or more drinks on one occasion?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
5. How often during the last year have you failed to do what was normally expected of you because of drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
8. How often during the last year have you been unable to remember what happened the night before because of your drinking?	Never	Less than monthly	Monthly	Weekly	Daily or almost daily	
9. Have you or someone else been injured because of your drinking?	No		Yes, but not in the last year		Yes, during the last year	
10. Has a relative, friend, doctor, or other health care worker been concerned about your drinking or suggested you cut down?	No		Yes, but not in the last year		Yes, during the last year	
					Total	

Note: This questionnaire (the AUDIT) is reprinted with permission from the World Health Organization. To reflect drink serving sizes in the United States (14g of pure alcohol), the number of drinks in question 3 was changed from 6 to 5. A free AUDIT manual with guidelines for use in primary care settings is available online at www.who.org.

Excerpted from NIH Publication No. 07-3769 **National Institute on Alcohol and Alcoholism** www.niaaa.nih.gov/guide

FIGURE 237-3 The AUDIT questionnaire. Scores are added to determine the total. Positive screens are indicated by total scores ≥ 8 in men and ≥ 4 in women. Higher scores indicate more severe alcohol involvement. Scores >16 suggest the possibility of alcohol dependence.^{1,39}

may need to be identified through screening, rather than presenting with this problem.

- Patients with more severe, recurrent alcohol dependence often present with intoxication, withdrawal, or medical complications of heavy drinking, such as liver disease or pancreatitis. If these disorders are present, they demonstrate the expected physical manifestations. Like other patients with chronic, treatment-refractory illness, they have a chronic course, with periodic relapses or even with ongoing chronic illness.

TYPICAL DISTRIBUTION

- In a given year, 30% of the adult U.S. population engages in unhealthy drinking at least once (**Figure 237-1**). In an average primary care practice, approximately 10% to 15% of outpatients are heavy drinkers.

LABORATORY TESTING

- The most sensitive way to detect heavy drinking is to ask about the frequency of heavy drinking. Use of a written questionnaire such as the AUDIT can be helpful (**Figure 237-3**).¹⁸
- The most sensitive but least specific laboratory test is γ -glutamyltransferase (GGT). Carbohydrate-deficient transferrin provides similar sensitivity but better specificity but is not widely available.¹⁹
- Other transaminases such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are less sensitive, and require hepatic cell destruction before they are elevated. Thus, they are not very sensitive for detecting heavy drinking but they may be helpful in following patients who have elevated values at baseline.

IMAGING

- There are no imaging tests that detect heavy drinking itself. Abdominal ultrasound is often helpful in evaluating alcoholic liver disease.

DIFFERENTIAL DIAGNOSIS

- It is important to distinguish between AUD and asymptomatic at-risk drinking. AUD is characterized by preoccupation with and impaired control over drinking.

MANAGEMENT

Box 237-4: Clinical Prevention and Treatment of Alcohol Use Disorder.

NONPHARMACOLOGIC

- Brief counseling and advice to reduce drinking is effective for at-risk drinking, resulting in 15% to 20% reduction in drinking for at least 1 year.²
- Alcohol dependence requires either more intensive counseling and/or antirelapse medications. The relationship between intensity and setting (inpatient, residential, or outpatient) is complex. Most studies show no difference in 1-year outcomes based on intensity or

BOX 237-4 Clinical Prevention and Treatment of Alcohol Use Disorder

Category	Management
At-risk drinkers Goal: risk reduction	<ul style="list-style-type: none"> • Brief counseling to quit or cut down • Hand patients <i>Rethinking Drinking</i> booklet • Repeated counseling increases effectiveness
Functional alcohol use disorder Goal: long-term abstinence or low-risk drinking (e.g., recovery)	<ul style="list-style-type: none"> • Antirelapse medications <ul style="list-style-type: none"> – Naltrexone (oral, injection) – Topiramate (Topamax) – Disulfiram (Antabuse) • Brief behavioral support (medication management) • Recommend Alcoholics Anonymous • Offer referral to addiction specialist especially if fails to respond to primary care treatment
Severe recurrent alcohol use disorder Goals:	<ul style="list-style-type: none"> • Offer referral to addiction specialist • Recommend Alcoholics Anonymous • Medications <ul style="list-style-type: none"> – Treat withdrawal if needed – Antirelapse medications • Care coordination • Integrate medical, psychiatric, addiction treatment • Treatment for as long as needed; usually years to decades
<ul style="list-style-type: none"> • Reduce frequency, severity and length of relapses • Treat complications • Slow the rate of deterioration • Aim for full recovery but recognize it may not be achieved 	

setting.²⁰ For example, in a highly controlled, well-done study, 174 persons with alcoholism were randomly assigned to partial hospital treatment or extended inpatient rehabilitation after inpatient evaluation and/or detoxification. The outpatient group attended daily Monday through Friday therapy alongside the group that was assigned to 6 months of psychiatric inpatient hospitalization. The study found no additional benefit to extended hospitalization.²¹

- However, there are circumstances that make providing structured sober housing important: among people who are homeless, those who cannot stop drinking while living independently, and people with significant coexisting psychiatric illness.²⁰ The degree of housing structure required, however, is relatively independent of the intensity or type of treatment given. Some patients require a great deal of housing structure but very few treatment services, whereas others are stably housed but require intensive and prolonged treatment. Thus it makes sense to uncouple housing structure from treatment decisions, as there is no apparent benefit to having patients stay in a facility overnight while they are receiving treatment services.
- Increasingly, treatment for recurrent AUD (dependence) is being conceptualized as management of a chronic illness.²² A recent study found that continued care that included primary care management as well as continued access to specialty addiction care resulted in improved outcomes and reduced costs.²³
- Long-term regular medical follow up that simply attends to drinking and encourages abstinence is effective for reducing drinking among patients with medical complications such as liver cirrhosis or pancreatitis.²⁴

MEDICATIONS

- Several antirelapse medications are available for alcohol dependence. Their average efficacy is similar to that for selective serotonin reuptake inhibitor (SSRI) antidepressants in treating depression.^{25,26}
- Naltrexone 50 mg daily or as needed for each drinking occasion reduces relapse rates and quantity of drinking per occasion. It reduces craving for alcohol and the reward or “kick” an individual experiences when first beginning a drinking episode. This reduces the compulsive quality of drinking, making it easier to stop before a full relapse occurs. Its effectiveness is determined by genetic factors; it is most effective among northern Europeans and least likely to be effective among African Americans. In the author’s experience, naltrexone 25 to 50 mg as needed per drinking occasion may help at-risk drinkers reduce excessive alcohol use, especially in social situations. Approximately 10% of patients will experience nausea. Patients should be warned that usual doses of oral opioids such as hydrocodone will not work because of the opioid blockade, so naltrexone should be stopped at least 3 days prior to elective procedures. In emergencies the blockade can be overridden, but the therapeutic index is reduced. Although initially quite concerning, in practice this has not proved to be a significant problem. Naltrexone also is available in a long-acting injectable formulation that only requires monthly administration.
- Disulfiram 250 mg daily acts by blocking the breakdown of ethanol, resulting in increased levels of acetaldehyde, which causes an adverse flushing reaction. The disulfiram-ethanol reaction is thus dose related; a small amount of alcohol such as might exist in wine

vinegar, for example, might cause mild facial flushing, whereas drinking several glasses of wine or beer, or several ounces of distilled spirits, will cause a more severe reaction. Disulfiram-ethanol reactions may be very unpleasant but are unlikely to be harmful in the absence of preexisting ischemic heart disease. Reactions can occur up to several days after discontinuation, so patients should be warned. Some patients will not develop a disulfiram-ethanol reaction at the standard dose and require 500 mg daily. Disulfiram therapy is the most effective for maintaining abstinence, because any significant alcohol use will cause a reaction. It works best when administration is monitored by a family member, roommate, or friend. The most common side effect is a metallic taste. Less common are peripheral neuropathy, optical neuritis, and delirium or psychosis. A rare but serious idiosyncratic risk is that of fulminant hepatitis, often leading to liver failure and death.

- Topiramate is thought to work by normalizing the γ -aminobutyric acid (GABA)-glutamate imbalance that occurs with severe alcohol dependence. It both reduces desire to drink and the reward that occurs with drinking. Because of side effects, it is important to start at a low dose, for example, 25 mg before bedtime, and ramp up slowly over 4 to 8 weeks to a target dose of 200 to 800 mg daily. The most distressing side effect is cognitive dysfunction, best described as difficulty with word finding. Perioral paresthesias are common but reversible. Because of induction of renal tubular acidosis topiramate increases excretion of calcium, thus increasing the risk for renal calculi, especially in patients with a previous history.
- Acamprosate is licensed for alcohol dependence by the FDA but the last 3 large multisite trials demonstrated no effectiveness.^{27–29} It is expensive and must be taken 3 times a day. If it is effective at all, it would be in very severe dependence with a history of physical withdrawal.

COMPLEMENTARY AND ALTERNATIVE THERAPY

- No complementary/alternative therapies have proven efficacy in alcohol dependence.
- Unfortunately, some treatment programs continue to offer “nutritional therapy,” treatment guided by single-photon emission computed tomography (SPECT) scans, acupuncture and other unproven therapies, but there is no evidence of their effectiveness.
- 12-Step community support groups such as Alcoholics Anonymous (AA) help some patients with severe alcohol dependence. People who affiliate and stay with AA have better outcomes than those who do not.

REFER OR HOSPITALIZE

- Alcohol withdrawal is best managed in the hospital for patients with histories of alcohol withdrawal seizures or delirium, or who have medical conditions that might destabilize during withdrawal, such as ischemic heart disease or fragile diabetes.
- Alcohol withdrawal delirium requires hospitalization, usually in an intensive care unit.
- Most patients will not accept a referral to an addiction rehab program, but will accept treatment by their primary care physician. Patients who are naïve to rehab programs may benefit from referral. However, rehab programs tend to offer the same programming no matter how many times an individual has been exposed to it.

There is no reason to believe that repeated exposure to the same type of program improves outcomes. If an addiction medical specialist is available, referral for patients not responding to initial primary care management is indicated.

- Inpatient psychiatric hospitalization conferred no added benefit compared with outpatient treatment, but might inpatient treatment might be useful for patients who are unable to abstain for the 4 to 8 weeks necessary for outpatient treatment.³⁰ Sober housing coupled with an outpatient treatment program can also be beneficial for some.
- Antirelapse medication along with medical management is as effective as high-quality addiction counseling for more functional patients with alcohol dependence.³¹
- Patients with severe recurrent alcohol dependence with medical comorbidities fare best with long-term regular medical management, which includes discussion of alcohol consumption and its relationship to medical conditions, as well as encouragement to abstain. When sustained over 1 to 2 years, such medical management results in a substantial proportion of patients who are abstinent.³²
- The presence of severe psychiatric conditions such as psychosis, mania, or severe depression with suicidal ideation requires referral to a psychiatrist or hospital. Long-term comanagement by primary care physicians and psychiatrists is likely to be necessary.

PREVENTION

- Most heavy drinkers are asymptomatic, but are drinking at a rate that puts them at increased risk for developing alcohol addiction (dependence) and associated medical and social complications. These “at-risk” drinkers respond well to brief counseling by physicians, resulting in significant reductions in heavy drinking. This finding is based on extensive research, such that the U.S. Prevention Task Force has rated screening and brief counseling to be a “B” recommendation, which also have been determined to be cost-effective.³³ Because the prevalence of at-risk drinking is so high (26% of U.S. adults in any given year), the potential public health impact of broad implementation of screening and brief counseling is large.
- The NIAAA has published a guide to help physicians with screening, assessment and brief counseling techniques (**Figure 237-4**). There is also an online continuing medical education (CME) activity available. This online training uses 4 video case series, along with advanced interactive educational techniques, to improve physicians’ skills and knowledge (available at <http://www.niaaa.nih.gov/publications/clinical-guides-and-manuals/niaaa-clinicians-guide-online-training>). CME credit is available and it has been approved by the American Academy of Family Physicians.
- *Rethinking Drinking*, available as a booklet and online, is an educational tool for at-risk drinkers (available at <http://rethinkingdrinking.niaaa.nih.gov>). This publication takes the drinker through a process of increasing awareness of drinking, deciding whether to change and what the drinking goal is, and developing a plan to implement change. Using this publication substantially enhances the value while decreasing the time it takes to counsel a patient to reduce or stop drinking.

A

B

C

FIGURE 237-4 A. *Clinician's Guide* and (B) *Pocket Guide* versions are available from the National Institute on Alcohol Abuse and Alcoholism. These *Guides* provide physicians with the tools needed to screen for excessive alcohol use, diagnose alcohol use disorder, and provide the appropriate counseling and pharmacotherapy to their patients. A companion video case studies training program offers physicians the opportunity to see the *Guides'* principles put into action, and includes CME credits. Both are available at <http://www.niaaa.nih.gov/guide>. C. *Rethinking Drinking* is a booklet for excessive drinkers that physicians can hand out to patients who drink excessively. It greatly reduces the time required for counseling about excessive drinking. It is available from the National Institute on Alcohol Abuse and Alcoholism. A companion website has additional features (<http://rethinkingdrinking.niaaa.nih.gov>).

PROGNOSIS

- Most at-risk drinkers eventually reduce their drinking or abstain, and do not develop an AUD or other complications of heavy drinking.
- Nearly three-fourths of people who have an episode where they meet criteria for an AUD experience remission of the disorder (either through abstaining or reducing drinking to low-risk levels) after a few years. Once remitted, the AUD generally does not recur, and 20 years after onset, fewer than 10% still meet full diagnostic criteria for a disorder (Figure 237-5).⁴
- Those with recurrent or chronic dependence have an average of 5 episodes over a period of decades. However, many eventually do remit. Almost all patients who enter rehab programs have severe recurrent dependence.⁷ Rehab outcomes are very similar across different programs.³⁴ In the first year following an episode of rehab, roughly one-third of patients will be in stable recovery (approximately 25% will abstain and 10% will be in nonabstinent recovery, defined as engaging in no high-risk drinking and having no alcohol-related problems,) a third will not respond and will remain in stable nonrecovery, and the remainder will show variability (Figure 237-6).
- Patients with moderate-severe, recurrent dependence usually must make multiple quit attempts over several years before long-term abstinence is established.³⁵
- Recent research suggests that heavy drinking in mid-life tends to persist over time and may be resistant to available treatment approaches.³⁶ Consequently, repeated and ongoing efforts to support change are often required. It is helpful under these circumstances to think in terms of “quit attempts,” much like is used for smoking cessation.
- A minority of patients have chronic dependence or periodic relapses for many years, and as is true with all chronic illnesses, some will die of the disease and its medical complications, in spite of availability of all available current treatments and motivated effort by the patient. The science of behavior change is in its infancy, so much of what we do is non-specific and modestly effective.

FOLLOW-UP

- *At-risk drinkers:* Although a single brief counseling session has significant efficacy, the effect may be magnified by repeated counseling. For this reason, it is best to inquire about drinking quantity and frequency at each follow-up visit and to reinforce advice about low-risk drinking limits.
- *Patients with alcohol dependence:* Approach this group of patients with the same attitude you adopt for smoking cessation. Most people require multiple quit attempts before achieving lasting remission, so it is important to anticipate the possibility of recurrence, and to plan for it if it occurs. Let the patient know that you won't be angry or disappointed with them if recurrence occurs. In fact, if they have a relapse to heavy drinking, that is exactly when they should seek care; a relapse is similar to an asthma attack or an increase in chest pain from ischemic heart disease. Exacerbations or recurrences of chronic illnesses are common and can be managed.

FIGURE 237-5 Course of alcohol dependence over time. At time zero, 100% of subjects were dependent.³³ (Courtesy of Mark Willenbring, MD.)

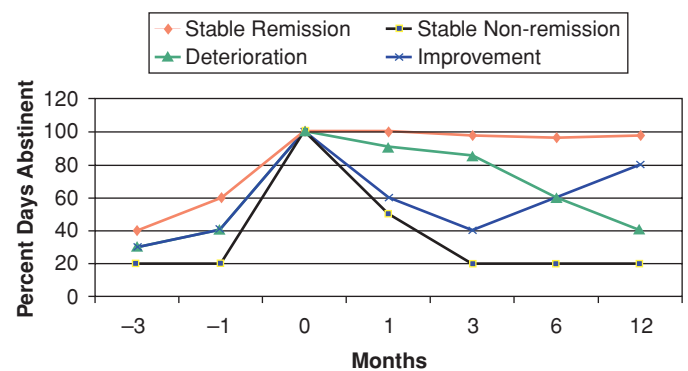

FIGURE 237-6 Course of alcohol dependence before and after treatment. Many patients reduce drinking significantly before entering treatment.³⁷ After treatment, about a third of patients will be in stable recovery for the following 12 months, a third will be in stable nonrecovery, and the remainder will fluctuate between recovery and nonrecovery.³⁸ (Courtesy of Mark Willenbring, MD.)

The goal is to seek care quickly if a recurrence occurs and to keep relapses infrequent, short and to reduce their severity. If withdrawal is a concern, it can generally be managed on an outpatient basis.³⁷ Reevaluate pharmacotherapy and behavioral approaches. Support learning from the recurrence: How did it happen? What could prevent the next one? Address guilt and shame and encourage patients to minimize time spent on this relapse and to look to the future and get right back on track.

- For patients with functional alcohol dependence consider referral to an addiction medicine or psychiatry specialist.
- For patients with complex chronic addiction, treat complications, recruit social and environmental resources (family, community, etc.) as indicated, and provide support.

PATIENT EDUCATION

- A patient handbook is available from the NIAAA. Titled *Rethinking Drinking* (**Figure 237-4**), it takes patients through a scientifically based process of education, evaluation of their drinking and decision-making regarding whether to change it. Free copies of the printed version are available from the Institute and it is also available on the Internet—<http://rethinkingdrinking.niaaa.nih.com>.
- General principles in approaching patients
 - Heavy drinking and AUDs are similar to other common complex diseases such as diabetes: they have about a 50:50 combination of genetic and environmental etiologies.
 - Alcohol dependence occurs when the brain changes after exposure to large doses of alcohol, causing an impairment of control over intake. In all but mild cases, this is irreversible and good control over drinking will always be problematic. Thus, abstinence is the best and easiest approach for most people.
 - Acknowledge that friends and family may take a long time to trust an individual in early recovery, as most have been disappointed numerous times in the past.
 - Emphasize that slips and relapses are common and encourage patients to keep trying in spite of them.

238 METHAMPHETAMINE

Michelle Rowe, DO
Andrew D. Schechtman, MD

PATIENT STORY

A 40-year-old woman with diabetes comes to the clinic with blood sugar in the 400s because she ran out of insulin a few weeks ago. She appears poorly groomed and has nicotine stains on her fingertips. Excoriated lesions (**Figure 238-1**) are noted on her forearms and face. She reports no itching at this moment, but when asked confirms that she regularly smokes methamphetamine. The diagnosis of her skin condition is meth mites. She acknowledges that she picks at her skin when she is high on meth. The physician asks her if she wants help to get off the meth so she can care for her health and well-being. She breaks down in tears and says that her craving for meth is very strong, but she is willing to try something because she knows the meth is ruining her body and life.

INTRODUCTION

Methamphetamine is a powerfully addictive stimulant that can be smoked, snorted, or injected. Methamphetamine can be produced by using common household products and pseudoephedrine. There is a worldwide epidemic of methamphetamine abuse and addiction.

SYNONYMS

Meth, crank, ice, and crystal.

EPIDEMIOLOGY

- Worldwide, compared to other drugs of abuse, only marijuana is used more often than amphetamine/methamphetamine.¹
- The lifetime prevalence (“ever-used”) rate for methamphetamine was 2.1% for 12th graders in the 2011 Monitoring the Future study, which surveys 50,000 students in 8th, 10th, and 12th grades in 420 schools nationwide annually. This has decreased from 1999, when the lifetime prevalence for methamphetamine use in 12th graders was 8.2%. For comparison, marijuana/hashish had a lifetime prevalence in 12th graders of 45.5% and 49.7% in 2011 and 1999, respectively.²
- Stimulants (methamphetamine and amphetamine) accounted for 9.6% of nationwide emergency department visits involving use of illicit drugs in 2009, with the highest incidence in those from 18 to 44 years old.³
- Methamphetamine use is associated with white or Native American race; residence in the west or south; having an ever-incarcerated father; marijuana, cocaine, intravenous drug use; and men who have sex with men (MSM).⁴

FIGURE 238-1 A 40-year-old woman with sores on her arm caused by picking at her skin while using methamphetamine. Also called meth mites, although there are no mites. (Courtesy of Andrew Schechtman, MD.)

- Analysis of methamphetamine found in workforce drug testing done nationwide in 2010 by Quest Diagnostics showed the highest rates of use in western and midwestern states, with relative sparing of eastern states. Highest prevalence (more than twice the national average) was found in Hawaii, Arkansas, Oklahoma, Nevada, California, Wyoming, Utah, and Arizona.⁵
- Methamphetamine is a Schedule II stimulant with legitimate medical uses, including the treatment of narcolepsy and attention deficit hyperactivity disorder.
- Methamphetamine is known on the street as meth, crank, ice (Figure 238-2), and crystal. It is abused by smoking, injecting, snorting, or oral ingestion. Smoking or injecting the drug gives an intense, short-lived “flash” or rush. Snorting or oral ingestion creates euphoria but no rush.
- Methamphetamine can be manufactured from inexpensive, readily available chemicals using recipes easily found on the Internet and in books (Figure 238-3).
- Common household and industrial chemicals used to make methamphetamine include pseudoephedrine and ephedrine (cold tablets), red phosphorus (matches/road flares), iodine (teat dip or flakes/crystal), methanol (gasoline additives), muriatic acid (used in swimming pools), anhydrous ammonia (farm fertilizer), sodium hydroxide (lye), sulfuric acid (drain cleaner), toluene (brake cleaner), and ether (engine starter).⁷
- The “meth laboratory,” the site of small-scale methamphetamine production (Figure 238-4), brings with it many hazards, including exposure to toxic chemicals for the meth cooks themselves, their children, and law enforcement, medical, and fire personnel entering the laboratory in the course of their duties. Explosions and fires at meth laboratories are common. Improper disposal of the toxic chemicals used in the laboratories frequently leads to environmental contamination.⁸
- Effects of methamphetamine, such as euphoria, increased libido, and impaired judgment, may lead to increased high-risk sexual behaviors, such as unprotected sexual intercourse and contact with multiple sexual partners. As a result, methamphetamine users are at increased risk of contracting sexually transmitted infections, including HIV.

ETIOLOGY AND PATHOPHYSIOLOGY

- Methamphetamine acts as a central nervous system stimulant by blocking presynaptic reuptake of dopamine, norepinephrine, and serotonin.
- Compared to amphetamines, methamphetamine has an increased ability to cross the blood–brain barrier and has a prolonged half-life (10 to 12 hours). This leads to faster-onset, more intense, and longer-lasting effects when compared to amphetamine.
- Intended effects of methamphetamine use include euphoria, increased energy, a heightened sense of alertness, and increased libido.
- Unintended effects include increased heart rate, blood pressure, and body temperature; headaches; nausea; anxiety; aggression; paranoia; visual and auditory hallucinations; insomnia; tremors; and cardiac arrhythmias.

FIGURE 238-2 Methamphetamine in its ice format. (Courtesy of DEA.)

FIGURE 238-3 One of many books by Uncle Fester that can be purchased on the Internet. The information to manufacture methamphetamine is readily available. (Reproduced with permission from Uncle Fester, www.unclefesterbooks.com.)

- With chronic abuse, neurologic manifestations include confusion, poor concentration, depression, paranoia, and psychosis. Weight loss and dental decay can occur. The face and body become atrophic and gaunt, making the chronic methamphetamine user appear older than their stated age.
- Methamphetamine users may experience formication, the hallucination that bugs are crawling under the skin. The skin excoriations resulting from picking at the imagined bugs are known as “meth mites” (Figures 238-1, 238-5, and 238-6).
- The rampant dental caries and gingivitis commonly seen in methamphetamine users is known as “meth mouth” (Figures 238-7 and 238-8). The causes of meth mouth are multiple. Vasoconstriction leads to decreased saliva production and dry mouth, which often result in consumption of large amounts of sugar-containing beverages. Methamphetamine users often neglect their oral hygiene when preoccupied with obtaining and using the drug. Methamphetamine-induced bruxism also damages the teeth. Neglect of early symptoms and lack of access to or failure to seek dental care often lead to unsalvageable teeth that can only be extracted.⁹⁻¹¹

DIAGNOSIS

ACUTE INTOXICATION

This can lead to tachycardia, hypertension, chest pain, hyperthermia, diaphoresis, mydriasis, agitation, irritability, hypervigilance, paranoia, hallucinations, and tremor.

CHRONIC USE

Chronic use of methamphetamine can cause violent behavior, anxiety, depression, confusion, insomnia, and psychotic symptoms (paranoia, auditory hallucinations, delusions, and formication).^{12,13}

WITHDRAWAL SYMPTOMS

Withdrawal symptoms include drug cravings, depressed mood, disturbed sleep patterns, increased appetite, and fatigue.

COMPLICATIONS

Complications arising from using methamphetamine include neurologic (seizures, stroke caused by intracerebral hemorrhage or vasospasm), cardiovascular (myocardial ischemia or infarction, dilated cardiomyopathy, and cardiac arrhythmias), hyperthermia (potentially fatal), rhabdomyolysis, consequences of injection drug abuse (skin infections and abscesses, endocarditis), and high-risk sexual behavior increasing risks of contracting sexually transmitted infections including hepatitis B, hepatitis C, and HIV.

LABORATORY STUDIES

- Urine drug screening is commonly done with immunoassays. These tests are highly cross-reactive and may give false-positive results for methamphetamine or amphetamine caused by the presence of other sympathomimetic amines such as pseudoephedrine or ephedrine. Unexpected positive results on a screening test can be confirmed

FIGURE 238-4 A methamphetamine laboratory with visible toxic and flammable substances.

FIGURE 238-5 A 19-year-old woman with sores on her arms from picking at her skin while using methamphetamine. Also called meth mites. (Courtesy of Richard P. Usatine, MD.)

with more specific tests such as gas chromatography/mass spectrometry (GC/MS) and stereospecific chromatography.¹⁴ One limitation of urine drug testing for methamphetamine is that the drug may only be detectable for up to 3 days after use. Hair testing is available and remains positive for up to 90 days after drug use.

- Methamphetamine users are at increased risk of sexually transmitted diseases and diseases transmitted through the use of shared needles. Consider screening for HIV, hepatitis B and C, and other sexually transmitted infections.
- For patients with signs and symptoms of acute intoxication, consider excluding complications of methamphetamine abuse by ordering creatinine phosphokinase (CK), complete blood count (CBC), and chem panel. If chest pain is present, cardiac enzymes and ECG are indicated.

DIFFERENTIAL DIAGNOSIS

ACUTE METHAMPHETAMINE INTOXICATION

- Intoxication with other substances causing sympathetic stimulation and/or altered mental status (cocaine, ecstasy, phencyclidine [PCP], theophylline, aspirin, monoamine oxidase inhibitors, serotonin syndrome).
- Psychiatric disorders (bipolar disorder, panic attack, and schizophrenia).
- Hyperthyroidism and thyroid storm (see Chapter 227, Graves Disease and Goiter).

METHAMPHETAMINE-INDUCED SKIN LESIONS (METH MITES)

- Scabies—Burrows may be present; located on wrists, fingers, genital region, and spares face; very pruritic. Family members may be infected too (see Chapter 143, Scabies).
- Atopic dermatitis—Persistent pruritus (pruritus from meth stops after acute intoxication clears). In most cases there is a long history of the dermatitis before the meth use had begun (see Chapter 145, Atopic Dermatitis).
- Contact dermatitis is pruritic but is generally localized to the area in which the contact allergen has touched the skin. A good history should allow this to be differentiated from meth mites (see Chapter 146, Contact Dermatitis).
- Neurodermatitis and prurigo nodularis—Persistent complaints of severe pruritus. In many ways, these are similar to meth mites in that the stimulus to scratch is from the brain not just the skin. Absence of meth use should be present in these self-inflicted dermatoses to distinguish them from meth mites (see Chapter 149, Self-Inflicted Dermatoses).

MANAGEMENT

- Acute methamphetamine intoxication is treated with supportive measures. Sedation with haloperidol, droperidol, or benzodiazepines (diazepam and lorazepam) can be used for agitated patients. Methamphetamine-induced cardiac ischemia is treated with

FIGURE 238-6 Postinflammatory hyperpigmentation in a young woman who has picked at her skin while addicted to methamphetamine. (Courtesy of Richard P. Usatine, MD.)

FIGURE 238-7 Methamphetamine mouth (meth mouth) in a 42-year-old woman with 20 years of methamphetamine use. The meth has completely destroyed her teeth. (Courtesy of Richard P. Usatine, MD.)

oxygen, nitrates, and β blockers. Seizures and rhabdomyolysis are treated in the standard fashion.¹⁵ SOR B

- There are no medications with proven efficacy for treatment of methamphetamine withdrawal. Mirtazapine and modafinil have shown some benefit in preliminary studies.¹⁶ SOR C

Treatment of methamphetamine dependence and addiction is challenging. Inpatient detoxification may be required initially, followed by a long-term program of behavioral interventions. SOR C

- Refer patients to 12-step programs, which are valuable and free. Crystal Meth Anonymous is a 12-step program modeled on the 12 steps of Alcoholics Anonymous and the White Book of Narcotics Anonymous. If Crystal Meth Anonymous meetings are not available, any 12-step program can be of help in recovery and maintaining sobriety. SOR B
- The Matrix model, a behavioral treatment method initially developed for treatment of cocaine addiction, has been used successfully to treat methamphetamine addiction. It consists of a 16-week program, including group and individual therapy, relapse prevention, family involvement, participation in a 12-step program or other spiritual group, and weekly drug testing.¹⁷ SOR C

In the context of outpatient behavioral treatment programs, providing small incentives for drug-free urine samples can help promote abstinence. One study found that 19% of incentivized patients achieved 12 weeks of continuous abstinence whereas only 5% of non-incentivized patients did so (number needed to treat [NNT] = 7.1) at a cost of only \$2.42 per day per participant.¹⁸ SOR B

- Although there currently are no FDA-approved medications to help treat methamphetamine dependence, several medications under study have shown favorable early results, including modafinil, bupropion, and naltrexone. SOR B “Replacement” therapy using low-dose stimulants, similar to the way methadone and nicotine are used for opioid and nicotine dependence, respectively, has also shown some benefit.¹⁹
- Methamphetamine-related skin excoriation should heal without treatment if the picking behavior stops. However, postinflammatory hyperpigmentation may never resolve (**Figure 238-6**). Antibiotic treatment with an antistaphylococcal agent, such as cephalexin or dicloxacillin, is indicated if the excoriations become infected. If methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected, choose an antibiotic that covers MRSA (see Chapter 116, Impetigo).
- Referral for dental care is indicated for patients with gingivitis and dental caries caused by chronic methamphetamine use. Recommend daily use of a soft-bristled toothbrush and dental floss for treatment and prevention of oral pathology. SOR A Rinsing with a chlorhexidine-containing mouthwash may be a reasonable alternative for patients who find it too painful to floss. SOR C (see Chapter 39, Gingivitis and Periodontal Disease and Chapter 45, Adult Dental Caries).

FIGURE 238-8 “Meth mouth” in a 17-year-old man actively using methamphetamine. (Courtesy of Michelle Rowe, MD.)

FOLLOW-UP

- Methamphetamine users who have recently quit are at high risk of relapse. Close follow-up is indicated to identify relapses and to reinstate treatment.

- Maintenance of abstinence can be aided by participation in an outpatient treatment program and 12-step programs.
- Methamphetamine-induced skin lesions should heal when the picking behavior ceases. Resolution is unlikely if methamphetamine abuse continues.

PATIENT EDUCATION

- Encourage patients to stop using methamphetamine. Offer referral to a treatment program in the community.
- Inform patients that methamphetamine use carries risks of heart attack, stroke, and death that can result from a single dose. There is no safe level of methamphetamine use.
- Counsel patients who have sex while using methamphetamine that this combination increases the likelihood of unsafe sexual practices and their risk of getting a sexually transmitted infection.
- Advise users who inject methamphetamine to use clean needles and to avoid sharing needles to decrease their risk of contracting hepatitis B, hepatitis C, and HIV.

239 COCAINE

Heidi Chumley, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 26-year-old man is brought into the emergency department in status epilepticus by his “friends,” who promptly flee the scene. His seizures spontaneously cease, and he is noted to have an altered mental status. IV access is obtained and he is stabilized. A urine toxicology screen is positive for cocaine and his creatinine phosphokinase is markedly elevated. He is admitted for cocaine-induced seizures and rhabdomyolysis. He survives the hospitalization and consents to a photograph of his eyes before discharge. **Figure 239-1** shows the bilateral subconjunctival hemorrhages that occurred during his seizures. The patient states that he understands the gravity of the situation and will enter a drug rehabilitation program when he leaves the hospital.

INTRODUCTION

Cocaine use is common, and 5% to 6% of users develop dependence within the first year of use. Acutely intoxicated patients have increased heart rates, blood pressures, temperatures, and, initially, respiratory rates; mood changes, involuntary movements; and dilated pupils. Chronic addiction can be treated with a comprehensive program, although only one-third of patients will become and remain abstinent.

SYNONYMS

Cocaine is also called blow, C, coke, crack, flake, and snow.

EPIDEMIOLOGY

- Based on the National Comorbidity Survey Replication (NCS-R) using interviews with a nationally representative sample of 9282 English-speaking respondents ages 18 years and older (conducted in 2001 to 2003), the cumulative incidence of cocaine use was 16%.¹
- Similar numbers were reported from the National Survey on Drug Use and Health in 2005:²
 - Of Americans ages 12 years and older, 13.8% reported lifetime cocaine use in 2005.²
 - A total of 33.7 million Americans ages 12 years and older reported lifetime use of cocaine, and 7.9 million reported using crack cocaine.²
 - An estimated 2.4 million Americans reported current use of cocaine (682,000 of whom reported using crack).²
 - Of the estimated 860,000 new users of cocaine in 2005, most were age 18 years or older, with the average age of first use being 20 years.²

FIGURE 239-1 Bilateral subconjunctival hemorrhages after severe cocaine-induced seizures in a young man. This patient also developed rhabdomyolysis and was hospitalized. (Courtesy of Beau Willison, MD.)

- The percentage of youth ages 12 to 17 years reporting lifetime use of cocaine was 2.3%, and among young adults ages 18 to 25 years the rate was 15.1%.²
- For both male and female cocaine users, the estimated risk for developing cocaine dependence, based on data from the NCS-R, was 5% to 6% within the first year after first use.³ Thereafter, the estimated risk decreased from the peak value, with a somewhat faster decline for females in the next 3 years after first use.
- Females may be more susceptible to crack/cocaine dependence; in a study of 152 individuals (37% female) in a residential substance-use treatment program, females evidenced greater use of crack/cocaine (current and lifetime heaviest) and were significantly more likely to show crack/cocaine dependence than males.⁴
- In one study, siblings of cocaine-dependent individuals had an elevated risk of developing cocaine dependence (relative risk [RR] = 1.71).⁵

ETIOLOGY AND PATHOPHYSIOLOGY

- Cocaine is a stimulant and local anesthetic that causes potent vasoconstriction.
- It produces its stimulant effects by causing increasing synaptic concentration of monoamine neurotransmitters (i.e., dopamine, norepinephrine, and serotonin).⁶
- Similar to other local anesthetics, cocaine blocks the generation and conduction of electrical impulses in excitable tissues (e.g., neurons and cardiac muscle) blocking the voltage-gated fast sodium channels in the cell membrane and abolishing the ability of the tissue to generate an action potential.⁷
- Effects are seen following oral, intranasal (as a powder [Figure 239-2]), IV, and inhalation administration (as crack cocaine [Figure 239-3], coca paste, and free-base).

RISK FACTORS

- Family history/genetic predisposition
- In a study of inner-city incarcerated male adolescents (23% of whom had used cocaine or crack in the month before arrest and 32% of whom had used cocaine at least once), current cocaine/crack users were more likely to have the following characteristics:⁸
 - Alcohol, marijuana, and intranasal heroin use.
 - Multiple previous arrests.
 - To be out of school.
 - To be psychologically distressed.
 - To have been sexually molested as a child.
 - To have substance-abusing parents.
 - To have frequent sex with girls, to be gay or bisexual, and to engage in anal intercourse.
- Among those who died from an accidental drug overdose in New York City, those dying from cocaine-only versus opiates were more likely to be male, black or Hispanic, have alcohol detected at autopsy, and to be of older age.⁹

FIGURE 239-2 Cocaine in a powder form used for snorting and injecting. (Courtesy of the Drug Enforcement Agency.)

FIGURE 239-3 Crack cocaine used for smoking. (Courtesy of the Drug Enforcement Agency.)

DIAGNOSIS

CLINICAL FEATURES

- Acute effects occur within 3 to 5 minutes with intranasal administration (8 to 10 seconds with free base) and last approximately 1 hour, after which there is an abrupt disappearance of the effects.⁶ When used IV or smoked as crack cocaine, the onset of action is immediate and the peak effect occurs 3 to 5 minutes later, lasting for 20 to 30 minutes.⁷
 - The acute effects include:^{6,7}
 - Elevated heart rate, increased blood pressure, and usually increased temperature.
 - Increased respiratory rate and/or dyspnea followed by decreased respiratory rate.
 - Mood changes including enhanced mood/euphoria, hyperactivity, irritability and anxiety, excessive talking, and long periods without eating or sleeping.
 - Involuntary movements (e.g., tremors, chorea, and dystonic reactions).
 - Additional findings on physical examination can include:
 - Dilated pupils, nystagmus, and/or retinal hemorrhages.
 - Nasal septum perforation (**Figure 239-4**), epistaxis, and/or cerebrospinal fluid (CSF) rhinorrhea.
 - Wheezing, rales, and/or pneumothorax.
 - Absent bowel sounds (mesenteric ischemia) and/or right upper quadrant tenderness (hepatic necrosis).
 - Skin tracks from intravenous use (**Figure 239-5**).
 - Multiple areas of atrophic skin scars are from skin popping—injecting cocaine directly into the skin without finding a vein for intravenous injections (**Figure 239-6**).
 - Acute effects may be altered by concomitant use of other drugs or alcohol.
- Adverse effects of cocaine use can include:⁶
 - Respiratory depression that may result in death.
 - Cardiac arrhythmias, chest pain, and myocardial infarction (MI).
 - Neurologic symptoms, including headache, tonic-clonic seizures, ischemic or hemorrhagic stroke, and subarachnoid hemorrhage.
 - Myalgias and rhabdomyolysis.
 - Severe pulmonary disease (e.g., alveolar hemorrhage and pulmonary edema) and hepatic necrosis caused by crack cocaine.
 - Exacerbation of existing hypertension, cardiac, and cerebrovascular disease.
 - Recurrent diabetic ketoacidosis.¹⁰
- Cutaneous vasculitis secondary to levamisole-adulterated cocaine has been reported many times in the literature.¹¹⁻¹⁵ This type of vasculitis presents with ear purpura (**Figure 239-7**), retiform (like a net) purpura (**Figure 239-8**) of the trunk or extremities, neutropenia, and positive tests for perinuclear antineutrophil cytoplasmic antibody (P-ANCA).¹¹ A 2010 U.S. report found that more than 77% of seized cocaine in the United States is contaminated with levamisole.¹³ This cutaneous vasculitis may also present on the nose or face (**Figure 239-9**).
- Chronic cocaine use is associated with decreased libido and impaired reproductive function.¹

FIGURE 239-4 Shining a light through a hole in the nasal septum caused by 10 years of snorting cocaine. (Courtesy of Richard P. Usatine, MD.)

FIGURE 239-5 An injection track along the vein of a young woman in recovery from IV cocaine use and addiction. (Courtesy of Richard P. Usatine, MD.)

- In men, cocaine can cause impotence and gynecomastia.
- In women, cocaine can cause galactorrhea, amenorrhea, and infertility.
- In pregnant women, crack cocaine is associated with an increase in placental abruption, miscarriage, and congenital malformation.
- Protracted use can cause paranoid ideation and visual and auditory hallucinations. Severe depression can follow recovery from cocaine intoxication (called “crashing”).¹
- Withdrawal from chronic cocaine use can cause depression, insomnia, and anorexia.

LABORATORY STUDIES

- Urine toxicology screen (using immunoassays) for commonly abused drugs (e.g., cocaine, marijuana, and opiates) is the gold standard.
 - Cocaine may be detected in the urine for 24 hours after use and the metabolite of cocaine, benzoylecgonine, may be detected as long as 60 hours after a single use.⁷
 - In chronic cocaine users, benzoylecgonine may be detected for up to 22 days.⁷
 - A rapid urine test, OnTrak Testcup-5, was reported in a manufacturer-supported study to be accurate and reproducible for marijuana, cocaine, and heroin.¹⁶
- Saliva and hair tests are also available but may not be as accurate for all drugs of interest.
- All injection-drug users should be screened for human immunodeficiency virus (HIV) (with consent) and hepatitis B and C.
- If there is a history of multiple sexual partners, unsafe sex and/or sex for drugs, cocaine users should be screened for sexually transmitted diseases (STDs). This might include *Chlamydia*, gonorrhea, hepatitis B and C, HIV (with consent), and syphilis (**Figure 239-10**).
- In an unconscious patient and in patients denying cocaine use, the following laboratory tests can be considered to rule out other diseases with similar symptoms:
 - Serum glucose, magnesium, and phosphorus.
 - Serum electrolytes.
- Laboratory tests that can be completed to detect or monitor acute complications of cocaine overdose include:
 - Arterial blood gas (respiratory acidosis or alkalosis).
 - Blood urea nitrogen (BUN) and/or creatinine (renal infarction).
 - Creatinine kinase (CK) (rhabdomyolysis) and isoenzyme of creatine kinase (CK-MB) (MI).
 - Liver function tests (liver necrosis).
 - Urine dipstick (rhabdomyolysis).

IMAGING AND OTHER TESTS

- Plain films of the abdomen (supine and upright) can be useful in the diagnosis of body packing or stuffing of cocaine (swallowing or inserting packets of cocaine into a body orifice), but false-negative results may occur. Serial abdominal roentgenograms may be useful in detecting the passage of drug packages.⁷
- A chest x-ray and head CT can be considered for respiratory and neurologic symptoms, respectively.

FIGURE 239-6 Multiple areas of atrophic skin scarring from skin popping cocaine. Note how the scars are depressed and relatively round. Some cocaine addicts inject the cocaine directly into the skin rather than look for a vein for intravenous injections. (Courtesy of Richard P. Usatine, MD.)

FIGURE 239-7 Cutaneous vasculitis of the ear caused by levamisole-adulterated cocaine. (Courtesy of Robert T. Gilson, MD.)

DIFFERENTIAL DIAGNOSIS

- Adrenal hyperplasia or adenoma—Produces excess cortisol, causing signs and symptoms of Cushing syndrome, including hypertension and emotional changes (ranging from irritability to severe depression and psychosis). Distinguishing features are increased body weight with adipose deposition in the upper face (“moon” facies) and interscapular area (“buffalo” hump), hirsutism, violaceous cutaneous striae, and proximal myopathy. A 24-hour urine test for free cortisol or overnight dexamethasone suppression test is recommended for diagnosis.
- Hyperthyroidism—In addition to tachycardia and nervousness/agitation, patients can report fatigue, weight loss, and heat intolerance. Exophthalmus and pretibial myxedema may be seen, and laboratory testing reveals a low or undetectable thyroid-stimulating hormone (TSH) and an elevated free thyroxine level (T_4) (see Chapter 227, Graves Disease and Goiter).
- Delirium—Defined as a state of confusion accompanied by agitation, hallucinations, tremor, and illusions, delirium can be caused by drug toxicity or withdrawal, seizure, head injury, systemic infections, metabolic disorders, or a chronic dementing condition. The history, physical examination, and laboratory tests (many noted above) can help to identify the etiology.
- Hypoglycemia—Low blood sugar most commonly caused by taking insulin or oral drugs used to treat diabetes mellitus. Symptoms include confusion, fatigue, seizures, and loss of consciousness. Autonomic responses to hypoglycemia include palpitations, sweating, tremor, and anxiety. Laboratory testing for serum glucose will document the condition, and symptoms resolve with administration of oral or IV glucose.
- Meningitis—Acute infection within the subarachnoid space presenting within hours or days with fever, headache, and stiff neck (more than 90% of patients); additional potential signs are change in mental status (e.g., confusion and decreased consciousness), seizures, increased intracranial pressure, and stroke. The appearance of a rash/petechiae can aid in the diagnosis (meningococemia). Diagnosis is made with examination of the CSF following lumbar puncture (LP).
- Encephalitis—Acute infection of the central nervous system that involves the brain parenchyma usually caused by viruses. The clinical features include fever, altered level of consciousness, and focal (e.g., aphasia, ataxia, hemiparesis, and involuntary movements) or diffuse (e.g., agitation, hallucinations, and personality change) symptoms. Diagnosis is established with examination of the CSF following LP.

MANAGEMENT

MANAGEMENT OF ACUTE OVERDOSE

- Acute overdose is a medical emergency best managed in the intensive care unit because of the hyperadrenergic state and seizures.
 - Hyperthermia and severe psychomotor agitation are the most immediately life-threatening complications of cocaine poisoning.⁷ Temperatures as high as 45.6°C (114°F) have

FIGURE 239-8 Cutaneous vasculitis in a retiform (net-like) pattern caused by the use of levamisole-adulterated cocaine. This is also called retiform purpura. (Courtesy of University of Texas Health Science Center San Antonio, Division of Dermatology.)

FIGURE 239-9 Cutaneous vasculitis of the nose secondary to the use of levamisole-adulterated cocaine. (Courtesy of Robert T. Gilson, MD.)

been recorded. Rapid physical cooling with sponging, fans, ice baths, and cooling blankets can be used and gastric or peritoneal lavage with iced saline is considered if persistent.

- IV diazepam up to 0.5 mg/kg given over 8 hours is used to control psychomotor agitation and seizures.
 - Hypertension may also respond to benzodiazepines. β -Blockers should not be used in the setting of cocaine toxicity (except to control ventricular arrhythmia, as below) because they may result in unopposed alpha effects of cocaine.⁷
 - Avoid the use of neuroleptic agents because they can interfere with heat dissipation and, perhaps, lower the seizure threshold.⁷
 - Avoid physical restraints if possible. Benzodiazepines are safe to use as a pharmacologic restraint.⁷
- Propranolol (0.5 to 1 mg IV) can be used to control ventricular arrhythmia.
 - Perform defibrillation in all patients with pulseless ventricular tachycardia.⁷
 - Consider electrical cardioversion in all unstable patients.⁷
 - Beta-blockers should not be used in cocaine-induced cardiac ischemia.¹⁷ Nitroglycerin may be used for cocaine-induced cardiac ischemia or infarct.⁷
 - Monitor for rhabdomyolysis and provide rapid fluid resuscitation as needed.⁷
 - Check a pregnancy test on women of childbearing years as 6% of emergency room patients may have an unrecognized pregnancy.⁷
- Administer activated charcoal to alert patients with oral ingestions of cocaine (i.e., body stuffers and body packers) to reduce absorption. Whole-bowel irrigation may be used to reduce transit time in these patients.⁷
- Medical providers should be prepared to manage multiple drug effects, especially heroin.

FIGURE 239-10 Secondary syphilis in a man who was involved in unsafe sex while addicted to cocaine. The papulonodular eruption is an unusual presentation of secondary syphilis that was diagnosed with a skin biopsy and confirmed with a rapid plasma reagin titer of 1:512. The specific treponemal blood test was also positive. (Courtesy of Richard P. Usatine, MD.)

MANAGEMENT OF CHRONIC ADDICTION

- Cognitive-behavioral therapy is effective in the treatment of cocaine-dependent outpatients.¹⁸
- There is no current evidence supporting the clinical use of carbamazepine, antidepressants, dopamine agonists, disulfiram, mazindol, phenytoin, nimodipine, lithium, and NeuRecover-SA in the treatment of cocaine dependence.¹⁹
- Antidepressant medication exerts a modest beneficial effect for patients with combined depressive and substance-use disorders, but should be used as part of a program to directly target the addiction.²⁰
- The cocaine vaccine elicits an immune response that binds cocaine, creating an immune complex that is too large to cross the blood-brain barrier. In early phase II trials, 57% of subjects remained abstinent at 6 months. The immunologic treatment of substance use disorders is an exciting new approach that needs further study.²¹

REFERRAL

- Referral to specialists may be needed to assist patients with upper respiratory tract (e.g., CSF rhinorrhea and nasal septum perforation) or ophthalmologic complications (e.g., central retinal artery occlusion).
- Following withdrawal from chronic cocaine use, patients may benefit from individual, group, and/or family therapy and peer assistance.⁶

PROGNOSIS

- Cocaine addiction is difficult to treat.
- Of patients enrolled in cocaine addiction programs, 42% do not complete treatment.²²
- One-third of patients treated for cocaine addiction remain abstinent.²² Some comprehensive therapy programs have demonstrated abstinence rates at 1 year of up to 58%.²³
 - Of 131 persons addicted to crack cocaine, 107 were able to be followed for 12-years: 43 (33%) were crack-free for at least 12 months, 22 (17%) continued to use, 13 (10%) were imprisoned, 2 (1.5%) were lost to follow-up, and 27 (20.5%) were deceased.²⁴

FOLLOW-UP

- Patients and their families may need ongoing support, home health-care, and physical and occupational therapy to address long-term neurologic and cardiovascular complications of cocaine including anoxic encephalopathy, stroke, intracerebral hemorrhage, congestive heart failure, and cardiomyopathy.
- Physicians should closely monitor and assist patients in managing depression, insomnia, and anorexia that may follow cessation of chronic cocaine use.⁶
- Among individuals leaving residential detoxification, chronic pain is a common problem and is associated independently with long-term substance use after detoxification; management of pain may improve long-term outcomes.²⁵

PATIENT EDUCATION

- Encourage patients to quit cocaine use and offer assistance.
- Recommend 12-step programs including cocaine anonymous.
- Patients should be made aware of the potential complications associated with use of cocaine, including its powerful psychologically addictive properties.
- Instruct patients about seeking help in the emergency department for any of the following:²⁶
 - A brisk nosebleed that does not stop after 10 minutes of direct pressure.
 - Facial pain or headache with a fever.
 - Severe chest pain, difficulty breathing, or shortness of breath.
 - If pregnant, vaginal bleeding or premature labor pains.
 - Significant swelling, pain, redness, and red lines leading from the injection site and accompanied by fever.
 - Severe abdominal pain, persistent vomiting, and vomiting blood.
 - If you think that one of your packets you have swallowed or stuffed in a body orifice (vagina and rectum) is leaking or has broken.
- Instruct IV drug users who continue to use not to reuse or share needles or syringes; cleaning the skin before injection can also decrease risk of infection. Harm reduction programs exist that help addicts obtain and maintain clean needles and syringes.

240 INJECTION-DRUG USE

Heidi Chumley, MD
Richard P. Usatine, MD

PATIENT STORY

A 23-year-old woman is seen for her intake physical in a residential treatment program for women recovering from substance abuse. She has not injected heroin for two days now, but her tracks are still visible (**Figure 240-1**). Her parents were both addicted to heroin, and she admits to having been born addicted to heroin herself. She began using heroin on her own in her early teens and has been on and off heroin since that time. She acknowledges a history of physical and sexual abuse as a child. She has had many suicide attempts and has cut herself with a knife across her arm many times. She has traded sex for money to buy heroin. Her 2 children are in foster care after having been removed by Child Protective Services. She is an attractive young woman looking for help and is thankful to have been admitted to this program. She does not know whether she has acquired hepatitis B, hepatitis C, or HIV, but wants to be tested.

INTRODUCTION

Injection-drug use affects millions of people across the world. Combinations of genetic, environmental, and behavioral factors influence risk of drug use and addiction. People who inject drugs often have other medical and psychiatric diagnoses, as well as social, legal, and vocational problems. Comprehensive management includes acute treatment and continuing care. Relapse is common, but involvement in a treatment program improves outcomes.

EPIDEMIOLOGY

- An estimated 16 million people inject drugs worldwide, based on data from 148 countries. The largest numbers of injectors are in China, the United States, and Russia.¹
- In the United States, injection-drug use among persons ages 15 to 29 years increased from 96 (1996) to 116 (2002) per 10,000 persons.²
- From 2000 to 2002, 1.5% of the U.S. population older than the age of 12 years reported injection-drug use at any time; 0.19% reported injection-drug use within the last year—440,000 persons.³
- Prevalence was highest in persons ages 35 to 49 years (3.5%); higher in men than women (2.0% vs. 1.0%); and higher in whites (1.7%) than African Americans (0.8%) or Hispanics (0.8%).³
- In 2002, the mean age of injection-drug users (IDUs) was 36 years compared to 21 years in 1979.³
- Needle sharing is common. In the previous 3 months, 46% of IDUs lent a person a used syringe⁴ and 54% injected with a used syringe.⁵
- There were 27,837–278,371 substance-abuse treatment admissions for injection-drug use (14.2% of all admissions reported

FIGURE 240-1 A 23-year-old woman with visible tracks on her arms from intravenous heroin use. She also has visible scars from self-mutilation with a knife. (Courtesy of Richard P. Usatine, MD.)

to Substance Abuse and Mental Health Services Administration's [SAMHSA] *Treatment Episode Data Set for 2009*.⁶

- The most commonly injected drug is heroin. Amphetamines, buprenorphine, benzodiazepines, cocaine, and barbiturates also are injected.⁷
- HIV prevalence among IDUs is estimated to be 20% to 40%.¹
- The 2009 Monitoring the Future Survey showed that 2.5% of 12th-grade boys in the United States were using anabolic steroids (**Figure 240-2**).⁸
- Anabolic steroid abuse among athletes may range between 1% and 6%.⁸
- Some adolescents abuse steroids as part of a pattern of high-risk behaviors. These adolescents also take risks such as drinking and driving, carrying a gun, driving a motorcycle without a helmet, and abusing other illicit drugs.⁸

ETIOLOGY AND PATHOPHYSIOLOGY

- Drug use disorders are thought to be a result of combinations of multiple factors, including genetic, environmental, and individual risk-conferring behaviors.⁹
- Drug use alters the brain's structure and function. These changes persist after drug use stops.¹⁰
- Most injecting drug users inject drugs intravenously, but subcutaneous injection (skin-popping) also is common.⁷
- Injected, snorted, or smoked heroin causes an almost immediate "rush" or brief period of euphoria that wears off very quickly, terminating in a "crash." The user then experiences an intense craving to use more heroin to stop the crash and bring back the euphoria. The cycle of euphoria, crash, and craving—repeated several times a day—leads to a cycle of addiction.
- A heroin overdose can lead to death from respiratory depression, coma, and pulmonary edema. Death from the direct effects of cocaine is usually associated with cardiac dysrhythmias and conduction disturbances, leading to myocardial infarction and stroke.⁷
- Anabolic steroids can lead to early heart attacks, strokes, liver tumors, kidney failure, and serious psychiatric problems. In addition, because steroids are often injected, users who share needles or use nonsterile techniques when they inject steroids are at risk of contracting dangerous infections, such as HIV/AIDS and hepatitis B and hepatitis C (**Figure 240-2**).⁸

RISK FACTORS

- Family history.

DIAGNOSIS

CLINICAL FEATURES

Heroin use produces the following clinical appearances:

- Pinpoint pupils and no response of pupils to light.
- A rush of pleasurable feelings.
- Cessation of physical pain.

FIGURE 240-2 A high school athlete used injectable anabolic steroids for muscle building and developed a large abscess in his buttocks. This photograph was taken 2 months after the original abscess was drained and the wound is healing by secondary intention. (Courtesy of William Rodney, MD.)

- Lethargy and drowsiness.
- Slurred speech.
- Shallow breathing.
- Sweating.
- Vomiting.
- A drop in body temperature.
- Sleepiness.
- Loss of appetite.

Cocaine (by injection) can produce the following signs, symptoms, and adverse effects:

- Dilated pupils.
- Hyperactivity.
- Euphoria.
- Irritability and anxiety.
- Excessive talking.
- Depression or excessive sleeping.
- Long periods without eating or sleeping.
- Weight loss.
- Dry mouth and nose.
- Paranoia.
- Cardiac—arrhythmias, chest pain, myocardial infarction (MI), and congestive heart failure (CHF).
- Strokes and seizures.
- Respiratory failure.

COMPLICATIONS OF INJECTING DRUG USE

- Local problems—Abscess (**Figures 240-2** and **240-3**; see Chapter 121, Abscess), cellulitis, septic thrombophlebitis, local induration, necrotizing fasciitis, gas gangrene, pyomyositis, mycotic aneurysm, compartmental syndromes, and foreign bodies (e.g., broken needle parts) in local areas.²
 - IDUs are at higher risk of getting methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections that the patient may think are spider bites (**Figure 240-4**).
 - Some IDUs give up trying to inject into their veins and put the cocaine directly into the skin. This causes local skin necrosis that produces round atrophic scars (**Figure 240-5**).
- IDUs are at risk for contracting systemic infections, including HIV and hepatitis B or hepatitis C.
 - Injecting drug users are at risk of endocarditis, osteomyelitis (**Figures 240-6** and **240-7**), and an abscess of the epidural region. These infections can lead to long hospitalizations for intravenous antibiotics. The endocarditis that occurs in IDUs involves the right-sided heart valves (see Chapter 50, Bacterial Endocarditis).² They are also at risk of septic emboli to the lungs, group A β -hemolytic streptococcal septicemia, septic arthritis, and candidal and other fungal infections.

LABORATORY TESTING

- All IDUs should be screened for HIV (with consent), hepatitis B, and hepatitis C.

FIGURE 240-3 A 32-year-old woman with type 1 diabetes developed large abscesses all over her body secondary to injection of cocaine and heroin. Her back shows the large scars remaining after the healing of these abscesses. (Courtesy of Richard P. Usatine, MD.)

FIGURE 240-4 A young woman with methicillin-resistant *Staphylococcus aureus* infection from injection-drug use. Track visible on hand with pustule from methicillin-resistant *Staphylococcus aureus*. (Courtesy of Richard P. Usatine, MD.)

- If there is a history of high-risk sexual behavior, screen for syphilis (rapid plasma reagin [RPR]), chlamydia and gonorrhea.
- Purified protein derivative (PPD) test to screen for tuberculosis (especially if the patient is homeless or HIV-positive).
- Urine screen for common drugs of abuse may reveal other drugs not admitted to in the history.
- ECG is warranted if there are any cardiac symptoms or if the physical examination reveals signs of cardiac disease.

DIFFERENTIAL DIAGNOSIS

- Injection-drug use and dependence may be hidden problems. The differential diagnosis will differ based on the presenting complaints.

MANAGEMENT

- Drug-abuse therapy is cost-effective. For example, 1 year of methadone maintenance therapy is approximately \$4700 compared to 1 year of imprisonment, which costs \$18,400.^{10,11}
- Every \$1 invested in addiction treatment saves \$12 in health, legal, and theft costs.¹⁰

NONPHARMACOLOGIC

- Recognize addiction as a chronic illness that requires a comprehensive approach during the treatment phase (e.g., residential/outpatient treatment) and continuing care (e.g., drug-abuse monitoring, booster sessions, and reevaluation of treatment needs).¹⁰
- Identify and address associated medical and psychiatric diagnoses, as well as social, legal, and work-related problems. Coexisting psychiatric illnesses are common.¹⁰
- For criminal justice-involved drug abusers and addicts, use this opportunity to engage individuals in treatment. Research supports the efficacy of combining criminal justice sanctions and drug-abuse treatment.¹⁰
- Test IDUs for HIV/AIDS, and hepatitis B and hepatitis C. Consider testing for tuberculosis and other infectious diseases as indicated.¹⁰
- Consider medically assisted detoxification to minimize withdrawal symptoms.
- Recommend an appropriate length of time for treatment. Most patients need at least 3 months to stop using drugs.¹⁰
- Encourage patients to engage in individual or group behavioral therapies and assist patients in finding programs that meet their individual needs.¹⁰
- Advise patients to join a self-help group, such as Narcotics Anonymous (NA) or Cocaine Anonymous (CA), which are based on the 12-step model. Most drug-addiction treatment programs encourage patients to participate in a self-help group during and after formal treatment.⁶

MEDICATIONS

- For opioid addiction, consider a methadone maintenance program.
 - Opioid replacement therapy reduces injecting drug use and thus reduces the mortality and morbidity associated with injecting

FIGURE 240-5 A young woman in residential treatment program with multiple scars from skin popping cocaine. She gave up trying to inject into her veins and put the cocaine directly into the skin. Note how the local skin necrosis caused round atrophic scars. (Courtesy of Richard P. Usatine, MD.)

FIGURE 240-6 A 24-year-old woman with an 8-year history of injection-drug use. She has a large deep linear scar from osteomyelitis of the ulnar bone and smaller round scars from skin popping. A track is also visible above the deep scar. (Courtesy of Richard P. Usatine, MD.)

drug use, including the transmission of HIV and hepatitis C virus (HCV).⁷

- Opioid replacement combined with counseling, medical and psychiatric care, employment assistance, and family services is superior to opioid replacement alone.¹⁰
- Buprenorphine, a partial opioid agonist, is also used for opioid detoxification and for opioid replacement therapy.^{7,10} In the United States, physicians who wish to prescribe buprenorphine must take a certification course.
- Naltrexone, a long-acting synthetic opioid antagonist, blocks opioid receptors, thereby preventing the effects of opioids. Treatment is initiated after patients have been opioid-free for several days to prevent a severe withdrawal.¹⁰
- Treating criminal justice-involved drug abusers and addicts—Drug abusers may come into contact with the criminal justice system earlier than with other health or social systems. Thus, the period of involvement with the criminal justice system may offer an opportunity to engage individuals in a treatment that can shorten a pattern of drug abuse and related crime. Research supports the efficacy of combining criminal justice sanctions and drug-abuse treatment.¹¹
- Drug-abuse treatment is less expensive than alternatives, such as not treating addicts or incarcerating them. The average cost for 1 full year of methadone maintenance treatment is approximately \$4700 per patient, whereas 1 full year of imprisonment costs approximately \$18,400 per person. According to several conservative estimates, every \$1 invested in addiction treatment programs yields up to \$7 in savings, much of which results from reduced drug-related crime and criminal justice costs.¹¹ Although methadone maintenance is not as desirable as full abstinence, the comparative costs are in favor of drug treatment over incarceration.
- Recovery from drug addiction has two key components: treatment and continuing care. The clinical practices that make up the treatment phase (e.g., residential/outpatient treatment) must be followed up by management of the disorder over time (e.g., drug-abuse monitoring, booster sessions, and reevaluation of treatment needs).¹¹
- Research shows that treatment must last, on average, at least 3 months to produce stable behavior change.¹¹ This accounts for the existence of 90-day residential treatment programs.
- A comprehensive assessment is the first step in the treatment process, and includes identifying individual strengths to facilitate treatment and recovery. In addition, drug abuse cannot be treated in isolation from related issues and potential threats, such as criminal behavior, mental health status, physical health, family functioning, employment status, homelessness, and HIV/AIDS.¹¹
- Treatments that utilize cognitive behavioral therapies, residential treatment, contingency management, and medications have demonstrated effectiveness in reducing drug abuse and criminal behavior.¹¹
- Medications are a key treatment component for drug abusers and can stabilize the brain and help return it to normal functioning. Methadone and buprenorphine are effective in helping individuals

FIGURE 240-7 The other arm of the woman in Figure 240-6 with deep scar from osteomyelitis secondary to injecting drugs that destroyed the bones in her left forearm. Her arm is deformed and poorly functional. (Courtesy of Richard P. Usatine, MD.)

addicted to heroin or other opiates reduce their drug abuse. Naltrexone is also an effective medication for some opiate-addicted patients and those with concurrent alcohol dependence.¹¹

- Family and friends can play critical roles in motivating individuals with drug problems to enter and stay in treatment. Family therapy is important, especially for adolescents. Involvement of a family member in an individual's treatment program can strengthen and extend the benefits of the program.¹¹
- Buprenorphine (Subutex or, in combination with naloxone, Suboxone) is demonstrated to be a safe and acceptable addiction treatment. Congress passed the Drug Addiction Treatment Act (DATA 2000), permitting qualified physicians to prescribe narcotic medications (Schedules III to V) for the treatment of opioid addiction. This legislation created a major paradigm shift by allowing access to opiate treatment in a medical setting rather than limiting it to specialized drug treatment clinics. Approximately 10,000 physicians have taken the training needed to prescribe these 2 medications, and nearly 7000 have registered as potential providers.
- Methadone and levo- α -acetyl methadol (LAAM) have more gradual onsets of action and longer half-lives than heroin. Patients stabilized on these medications do not experience the heroin rush. Both medications wear off much more slowly than heroin, so there is no sudden crash, and the brain and body are not exposed to the marked fluctuations seen with heroin use. Maintenance treatment with methadone or LAAM markedly reduces the desire for heroin.
- If an individual maintained on adequate, regular doses of methadone (once a day) or LAAM (several times per week) tries to take heroin, the euphoric effects of heroin will be significantly blocked. According to research, patients undergoing maintenance treatment do not suffer the medical abnormalities and behavioral destabilization that rapid fluctuations in drug levels cause in heroin addicts.

PREVENTION AND SCREENING

- The United States Preventive Services Task Force concluded that there is insufficient evidence to screen for illicit drug use in adolescents, adults, or pregnant women, but advises clinicians to be alert for sign and symptoms of drug use.¹²
- Accurate and reliable office screening instruments include CRAFFT (adolescent drug use/misuse), and the ASSIST, CAGE-AID, and DAST (adults with drug misuse).¹²

PROGNOSIS

- Most patients who enter and remain in treatment stop injecting drugs and see improvements in their work, relationships, and psychological functioning.¹⁰
- Forty percent to 60% of patients relapse.¹⁰
- Drug injectors who do not enter treatment are up to 6 times more likely to become infected with HIV than are injectors who enter

and remain in treatment. Drug users who enter and continue in treatment reduce activities that can spread disease, such as sharing injection equipment and engaging in unprotected sexual activity. Participation in treatment also presents opportunities for screening, counseling, and referral for additional services. The best drug-abuse treatment programs provide HIV counseling and offer HIV testing to their patients.¹⁰

FOLLOW-UP

- Follow-up is important for the treatment of IDUs. Addiction is a chronic (and relapsing) condition and requires long-term follow-up. Your intervention and caring attitude can help the patient to overcome addiction and to live a sober and drug-free life. Do not give up on patients who relapse because it often takes more than one attempt before long-term cessation can be achieved. The frequency and intensity of follow-up depend upon the substance, the addiction, and the patients and their complications.

PATIENT EDUCATION

- For patients who are not ready to stop their injecting drug use there are harm-reduction and counseling programs that can be helpful. Encourage patients to use clean and sterile needles and not to share their needles with anyone. Bleach can be used to clean and sterilize needles and prevent the spread of HIV and hepatitis.
- Refer continuing drug users to needle exchange programs that exist to help IDUs use clean needles and avoid infectious diseases. These programs can also be helpful if they give out condoms to encourage safe sex.
- Encourage patients to get help to become drug-free and abstinent. There is no safe level of injecting drug use.
- Explain to patients that addiction is a disease and not a failing of their moral character.
- Inform patients about the existing treatment programs in their community and offer them names and phone numbers so that they may get help.
- If your patient is not ready for help today, give the numbers and names for tomorrow.
- Speak about the value of 12-step programs including NA and CA because everyone can afford a 12-step program. There are 12-step programs in the community for everyone including nonsmokers and agnostics.

APPENDIX

Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1447–1450 for further information.

APPENDIX A INTERPRETING EVIDENCE-BASED MEDICINE

Mindy A. Smith, MD, MS

“Evidence-based medicine—is this something new?” asked my father, incredulously. “What were you practicing before?”

Like my father, our patients assume that we provide recommendations to them based on scientific evidence. The idea that there might not be relevant evidence or that we might not have access to that evidence has not even occurred to most of them. This is certainly not to imply that such evidence is the be-all and end-all of medical practice or that our patients would follow such recommendations blindly—rather, for me, it is a starting point from which to begin rational testing or outline a possible therapeutic plan.

The first time that I recall the term *evidence-based medicine* (EBM) being discussed was in the early 1990s.^{1,2} It seemed that we would need to develop skills in evaluating the published literature and determining its quality, validity, and relevance to the care of our patients. As a teacher and researcher, I was intrigued by the challenges of critically appraising articles and teaching this newfound skill to others. As a clinician, however, I was most interested in answering clinical questions and doing so in a compressed time frame. I need rapid access to tools or sources that provided summary answers to those questions tagged to information about the quantity and quality of the evidence and the consistency of information across studies.

There seemed to be many systems for rating literature but few that met the needs of the busy practitioner trying to make sense of individual clinical trials and the hundreds of both evidence-based and consensus-based guidelines that seemed to spring up overnight. In 2004, the editors of the U.S. family medicine and primary care journals and the Family Practice Inquiries Network published a paper on a unified taxonomy called *Strength of Recommendation* (SOR) Taxonomy that seemed to fit the bill (**Figure A-1**).³ This taxonomy made use of existing systems for judging study quality while incorporating the concept of patient-oriented (e.g., mortality, morbidity, symptom improvement) rather than disease-oriented (e.g., change in blood pressure, blood chemistry) outcomes as most relevant. A **SOR A** recommendation is one based on consistent, good-quality patient-oriented evidence; **SOR B** is a recommendation based on inconsistent or limited-quality patient-oriented evidence; and **SOR C** is a recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series (**Figure A-1** and **A-2**).

In this book, we made a commitment to search for patient-oriented evidence to support the information that we provide in each of the chapter sections (i.e., epidemiology, etiology and pathophysiology, risk factors, diagnosis, differential diagnosis, management, prevention, prognosis, and follow-up) and to provide a SOR rating for that evidence whenever possible. The bulleted format within these divisions would allow the practitioner to quickly find answers to their clinical questions while providing some direction about how confident we were that a recommendation had high-quality patient-oriented evidence to support it.

For example, a practitioner caring for a patient with severe chronic obstructive pulmonary disease (COPD) and frequent exacerbations who is already taking a combination long-acting β -agonist with an

inhaled glucocorticoid asks, “What other options are available to reduce exacerbations?” This information can be found in the Management section of Chapter 56: Chronic Obstructive Pulmonary Disease, under Medications. Although the Global Initiative for Chronic Obstructive Lung Disease does not recommend mucolytics for routine use, authors of a Cochrane review, based on strong evidence **SOR A**, concluded that these medications produce a small decrease in the frequency of exacerbations (0.5 fewer exacerbations/year) and in disability days.⁴ Tiotropium (a long-acting anticholinergic) also reduces exacerbations and improves symptoms, but a recent metaanalysis concluded that mortality was increased with use of this medication **SOR A**.⁵ Theophylline also reduces exacerbations **SOR B** but is associated with nausea. The physician armed with this information can discuss the options with this patient and explore potential benefits and risks. Particularly in difficult cases where there are multiple options, the clinician’s experience and the patient preferences are important aspects of shared decision making. One definition of EBM is “The integration of best research evidence with clinical expertise and patient values.”⁶

Several other concepts are used throughout the book that can assist practitioners in using evidence-based information and explaining that information to patients. Risk reductions from medical treatments are often presented in relative terms—the *relative risk reduction* (RRR) or the difference in the percentage of adverse outcomes between the intervention group and the control group divided by the percentage of adverse outcomes in the control group. These numbers are often large and use of them not only causes us to overestimate the importance of a treatment but misses its clinical relevance. A more meaningful term is the *absolute risk reduction* (ARR)—the risk difference between the two groups. This number can then be used to obtain a *number needed to treat* (NNT)—the number of patients that would need to be treated (over the same time as used in the treatment trial) to prevent 1 bad outcome or produce 1 good outcome. This is calculated as 100% divided by the ARR. NNT is more easily understood by us and our patients. See the NNT example in **Box A-1**.

In the above case, for example, the patient might ask how risky it could be to add tiotropium. As written in the chapter, the difference in death with use of this medication was 0.8% (2.4% vs. 1.6% on placebo) making the number needed to harm (NNH) over 1 year to be equal to 124 (for every 124 patients treated, 1 additional death might occur in 1 year).

Another term that is used in this book is the *likelihood ratio* (LR). This number, based on the sensitivity and specificity of a diagnostic

BOX A-1 NNT Example

If a new drug was released for the treatment of postherpetic neuralgia and a randomized controlled trial found that the 70% of the treated group reported significant pain control (based on the defined end point) and 20% of the placebo group reported significant pain control this would produce an absolute risk reduction (ARR) of 50%. In this case the NNT would be $100\%/50\% = 2$. On average, only 2 patients would need to be treated for 1 patient to receive the defined pain control benefit. If the ARR was only 10% (30% of the intervention group and 20% of the control group benefitted), then the $NNT = 10$ or 10 patients would need treatment on average for 1 to receive benefit.

Figure A-1

How recommendations are graded for strength, and underlying individual studies are rated for quality

In general, only key recommendations for readers require a grade of the "Strength of Recommendation." Recommendations should be based on the highest quality evidence available. For example, vitamin E was found in some cohort studies (level 2 study quality) to have a benefit for cardiovascular protection, but good-quality randomized trials (level 1) have not confirmed this effect. Therefore, it is preferable to base clinical recommendations in a manuscript on the level 1 studies.

Strength of recommendation	Definition		
A	Recommendation based on consistent and good-quality patient-oriented evidence.*		
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*		
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence,* or case series for studies of diagnosis, treatment, prevention, or screening		
Use the following scheme to determine whether a study measuring patient-oriented outcomes is of good or limited quality, and whether the results are consistent or inconsistent between studies.			
	Type of Study		
Study quality	Diagnosis	Treatment/prevention/screening	Prognosis
Level 1— good-quality patient-oriented evidence	Validated clinical decision rule SR/meta-analysis of high-quality studies High-quality diagnostic cohort study [†]	SR/meta-analysis of RCTs with consistent findings High-quality individual RCT [‡] All-or-none study [§]	SR/meta-analysis of good-quality cohort studies Prospective cohort study with good follow-up
Level 2— limited-quality patient-oriented evidence	Unvalidated clinical decision rule SR/meta-analysis of lower-quality studies or studies with inconsistent findings Lower-quality diagnostic cohort study or diagnostic case-control study [§]	SR/meta-analysis lower-quality clinical trials or of studies with inconsistent findings Lower-quality clinical trial [‡] or prospective cohort study Cohort study Case-control study	SR/meta-analysis of lower-quality cohort studies or with inconsistent results Retrospective cohort study with poor follow-up Case-control study Case series
Level 3— other evidence	Consensus guidelines, extrapolations from bench research, usual practice, opinion, other evidence disease-oriented evidence (intermediate or physiologic outcomes only), or case series for studies of diagnosis, treatment, prevention, or screening		
	Consistency across studies		
Consistent	Most studies found similar or at least coherent conclusions (coherence means that differences are explainable); or If high-quality and up-to-date systematic reviews or meta-analyses exist, they support the recommendation		
Inconsistent	Considerable variation among study findings and lack of coherence; or If high-quality and up-to-date systematic reviews or meta-analyses exist, they do not find consistent evidence in favor of the recommendation		
*Patient-oriented evidence measures outcomes that matter to patients: morbidity, mortality, symptom improvement, cost reduction, and quality of life. Disease-oriented evidence measures intermediate, physiologic, or surrogate end points that may or may not reflect improvements in patient outcomes (ie, blood pressure, blood chemistry, physiologic function, and pathologic findings).		‡ High-quality RCT: allocation concealed, blinding if possible, intention-to-treat analysis, adequate statistical power, adequate follow-up (greater than 80 percent).	
† High-quality diagnostic cohort study: cohort design, adequate size, adequate spectrum of patients, blinding, and a consistent, well-defined reference standard.		§ In an all-or-none study, the treatment causes a dramatic change in outcomes, such as antibiotics for meningitis or surgery for appendicitis, which precludes study in a controlled trial.	
		SR, systematic review; RCT, randomized controlled trial

FIGURE A-2 Assigning a Strength-of-Recommendation grade based on a body of evidence. (USPSTF = U.S. Preventive Services Task Force.) (With permission from Ebell MH, Siwek J, Weiss BD, et al. Simplifying the language of evidence to improve patient care: Strength of recommendation taxonomy (SORT). *J. Fam Pract* 2004;53(2):110–120. Dowden Health Media.)

test, is used to determine the probability of a patient with a positive test (LR+) having the disease or the probability of the patient with a negative test (LR-) not having the disease in question. The LR is defined as the likelihood that a given test result would be expected in a patient with the target disorder compared to the likelihood that that same result would be expected in a patient without the target disorder.⁶ The number obtained for the LR+ [Sensitivity/(100 – Specificity)] or the LR- [(100 – Sensitivity)/Specificity] can be multiplied by the pretest probability of disease to determine the posttest probability of disease. A nomogram (one can be found by visiting the website mentioned in reference 6) can be used to more easily work with these numbers to convert a pretest probability into a posttest probability. A LR+ over 10 is considered strong evidence to rule in disease while a LR- of less than 0.1 is strong evidence to rule out disease.

We both are privileged and cursed with practicing medicine in an information-rich environment. We have designed our *Color Atlas* to link evidence to clinical recommendations so that we can provide our patients the best science available. When the evidence is lacking, we make that clear and encourage you to engage in frank and honest discussions that lead to the shared responsibility for decisions. Our patients are justified in expecting science along with humanism—can we give them anything less?

APPENDIX B GUIDE FOR THE USE OF TOPICAL AND INTRALESIONAL CORTICOSTEROIDS

TABLE B-1 Corticosteroid Potency Chart

Generic Name	U.S. Trade Name and Strength
Class 1—Superpotent	
Betamethasone dipropionate*	Diprolene lotion/gel/ointment, 0.05%
Clobetasol propionate*	Temovate cream/emollient base cream/gel/ointment, 0.05%; Clobex ointment/lotion/shampoo/spray aerosol, 0.05%; Cormax ointment/solution 0.05%; Olux foam aerosol 0.05%
Diflorasone diacetate	Psorcon or ApexiCon ointment, 0.05%
Halobetasol propionate	Ultravate cream/ointment, 0.05%
Fluocinonide	Vanos cream 0.1%
Flurandrenolide	Cordran Tape 4 mcg/cm ²
Class 2—Potent	
Amcinonide	Cyclocort or Amcort ointment, 0.1%
Betamethasone dipropionate	Diprosone ointment/augmented cream 0.05%
Desoximetasone	Topicort cream/ointment, 0.25%; gel, 0.05%
Diflorasone diacetate	ApexiCon cream/ointment, 0.05%
Fluocinonide	Florone ointment, 0.05%; Psorcon cream/ointment, 0.05%
Halcinonide	Lidex cream/ointment/gel/solution, Fluone cream, 0.05%
Triamcinolone acetonide	Halog cream/ointment/cream/solution, 0.1% Kenalog ointment, 0.5%
Class 3—Upper Mid-Strength	
Amcinonide	Amcort cream//lotion 0.1%; Cyclocort cream 0.1%
Betamethasone dipropionate [†]	Diprosone cream or hydrophilic emollient, 0.05%
Betamethasone valerate [†]	Valisone or Betatrex ointment, 0.1%; Luxiq foam, 0.12%
Diflorasone diacetate [†]	Generic cream/ointment/lotion, 0.1%
Diflorasone diacetate	Maxiflor, Florone, Psorcon cream, 0.05%
Fluticasone propionate [†]	Generic cream/ointment, 0.05%
Fluocinonide [†]	Cutivate ointment 0.005%
Mometasone furoate [†]	Lidex-E cream, aqueous emollient, 0.05%
Triamcinolone acetonide	Elocon cream/ointment, 0.1% Kenalog ointment 0.5% Aristocort cream 0.05%, ointment, 0.1%
Class 4—Mid-Strength	
Clocortolone pivalate	Cloderm cream, 0.1%
Desoximetasone	Topicort LP cream, 0.05%
Fluocinolone acetonide [†]	Synalar-HP, Synalar ointment, 0.025%
Flurandrenolide	Cordran ointment, 0.05%
Hydrocortisone valerate	Westcort ointment, 0.2%
Mometasone furoate [†]	Elocon cream, lotion, solution 0.1% Momexin cream, 0.1%
Triamcinolone acetonide	Kenalog cream, ointment, spray 0.1% Kenonel cream 0.1%

(continued)

TABLE B-1 Corticosteroid Potency Chart (*Continued*)

Generic Name	U.S. Trade Name and Strength
Class 5—Lower Mid-Strength	
Betamethasone dipropionate	Diprosone lotion, 0.05%
Betamethasone valerate	Valisone, Beta-Val, Betatrex cream, 0.1%
Desonide	DesOwen Tridesilon ointment, 0.05%
	Desonate gel 0.05%
Fluocinolone acetonide	Synalar cream, 0.025%
Flurandrenolide	Cordran cream, lotion, 0.05%
Fluticasone propionate	Cutivate cream, lotion, solution, 0.05%
	Cortizone 10 lotion, spray, 0.1%
Hydrocortisone butyrate	Locoid cream, ointment, 0.1%
Hydrocortisone probutate	Pandel cream 0.1%
Hydrocortisone valerate	Westcort cream, 0.2%
Prednicarbate	Dermatop emollient cream, ointment, 0.1%
	Kenalog lotion, 0.1%, ointment 0.025%
Triamcinolone acetonide [‡]	
Class 6—Mild	
Alclometasone dipropionate [†]	Aclovate cream/ointment, 0.05%
Betamethasone valerate	Valisone or Beta-Val lotion, 0.1%
Desonide	DesOwen cream, lotion, 0.05%
	Tridesilon cream 0.05%
	LoKara lotion 0.05%
	Verdeso foam 0.05%
Fluocinolone acetonide	Synalar cream/solution, 0.01%; Capex shampoo, Derma-Smoothe oil, 0.01%
Triamcinolone acetonide	Aristocort cream, 0.1%
	Kenalog cream, lotion, 0.025%
Class 7—Least Potent	
Hydrocortisone [§]	Hytone, Cortate, Unicort, other nonprescription cream/lotion/foam 0.5% to 2.5%

*New Zealand Class 1, United Kingdom, Germany, and the Netherlands Class IV.

†New Zealand Class 2, United Kingdom, Germany, and the Netherlands Class III.

‡New Zealand Class 3, United Kingdom, Germany, and the Netherlands Class II.

§New Zealand Class 4, United Kingdom, Germany, and the Netherlands Class I.

TABLE B-2 Grams of Topical Medication Needed Based on Body Area*

Body Area	Grams of Medicine Needed for Daily Application for 1 Week
Face and neck	7.5
Trunk	30
One arm	7.5
One leg	15
Hands and feet	7.5
Whole body	90

*Multiply the amount by the number of times a day the medication is to be applied and the number of weeks of prescribed usage. Then choose the nearest higher volume available. For children divide the number by approximately 2 based on the child's size.

TABLE B-3 Common Side Effects of Topical Corticosteroids

Skin atrophy	Most common adverse effect Epidermal thinning may begin after only a few days Dermal thinning usually takes several weeks to develop Usually reversible within 2 months after stopping the corticosteroid
Telangiectasia	Most often occurs on the face, neck, and upper chest Tends to decrease when steroid discontinued, but may be irreversible
Striae	Usually occur around flexures (groin, axillary, and inner thigh areas) Usually permanent, but may fade with time
Purpura	Frequently occurs after minimal trauma Attributed to loss of perivascular supporting tissue in the dermis
Hypopigmentation	Reversible upon discontinuing the corticosteroid
Acneform eruptions	Particularly common on the face, especially with the "potent" and "very potent" corticosteroids Usually reversible
Fine hair growth	Reversible upon discontinuation of the corticosteroid
Infections	May worsen viral, bacterial, or fungal skin infections May cause tinea incognito
Hypothalamic– pituitary–adrenal axis suppression	Rare with topicals >30 g/week of "very potent" corticosteroids should be limited to 3 to 4 weeks Children (>10 g/week) and elderly are at higher risk because of thinner skin

TABLE B-4 Intralesional Steroids—Concentrations for Injection

Condition	Concentration of Triamcinolone Acetonide Solution (mg/mL)
Acne (Figure B-1)	2 to 2.5
Alopecia areata (Figure B-2)	5 to 10
Granuloma annulare	5 to 10
Psoriasis	5 to 10
Hypertrophic lichen planus	5 to 10
Prurigo nodularis	10
Hidradenitis suppurativa	10
Keloids and hypertrophic scars (Figure B-3)	10 to 40

Use a 27-gauge or 30-gauge needle when injecting intralesional steroids to minimize pain. Steroid dilutions can be made with sterile saline for injection. This is also less painful than diluting steroid with lidocaine. A Luer-Lok syringe is helpful to avoid the needle from popping off during the injection. For further information on performing intralesional injections see Usatine R, Pfenninger J, Stulberg D, Small R. *Dermatologic and Cosmetic Procedures in Office Practice*. Philadelphia, PA: Elsevier; 2012. This text and accompanying videos can also be purchased as an electronic application at <http://www.usatinemedia.com>.

FIGURE B-3 Injecting a hypertrophic scar with 10 mg/mL triamcinolone using a 27-gauge needle on a Luer-Lok syringe. (Courtesy of Richard P. Usatine, MD.)

APPENDIX C DERMOSCOPY

Ashfaq A. Marghoob, MD

Natalia Jaimes, MD

Richard P. Usatine, MD

Dermoscopy allows the clinician to visualize structures below the level of the stratum corneum. These structures are not routinely discernible without dermoscopy. The presence or absence of specific dermoscopic structures, their location and their distribution can assist the clinician in making a diagnosis or at least in narrowing the differential diagnosis.

The major goal of dermoscopy is to differentiate benign from malignant lesions on the skin so that one is less likely to miss a skin cancer (higher sensitivity) and less likely to perform unnecessary biopsies (higher specificity). Together, this will increase your diagnostic accuracy.

There are 3 major types of dermatoscopes:

1. Polarized
2. Nonpolarized
3. Hybrid, which combines a polarized mode with a nonpolarized mode in one dermatoscope.

Because some structures are better seen under polarized light and others best seen without polarization is helpful to purchase a hybrid dermatoscope. Dermatoscopes are currently manufactured by 3Gen, Welch Allyn, Canfield and Heine (**Figures C-1** and **C-2**). A number of dermatoscopes work well while attached to the iPhone for easy image capture and full screen images that can be shown to the patients.

FIGURE C-1 An assortment of polarized and hybrid dermatoscopes from 3Gen. (Courtesy of Richard P. Usatine, MD and 3Gen, San Juan Capistrano, CA.)

FIGURE C-2 Nonpolarized contact dermatoscopes from Heine and Welch-Allyn. (Courtesy of Heine, Herrsching, Germany, and Welch Allyn, Skaneateles Falls, NY.)

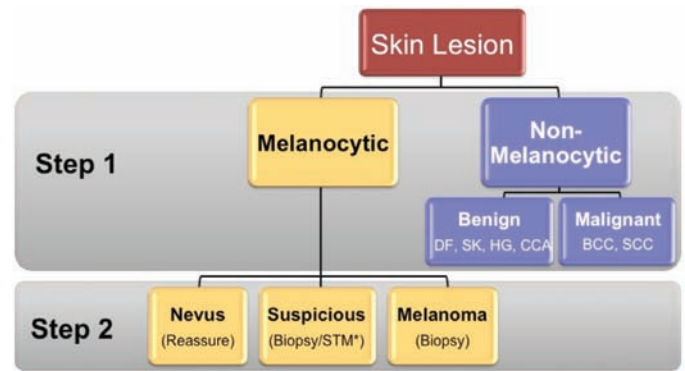

Dermoscopic diagnosis is based on the 2-step dermoscopy algorithm described in **Figure C-3**.

Step 1 requires the observer to decide whether the lesion in question is of melanocytic origin (contains melanocytes and therefore could be a melanoma). If the lesion is deemed to be a melanocytic lesion then the observer proceeds to step 2. In this phase of the evaluation, the observer needs to decide whether the lesion is a benign nevus or a melanoma. However, if during step 1 analysis the lesion does not display any features of a melanocytic lesion then the observer needs to decide if the lesion possesses any criteria for a basal cell carcinoma, seborrheic keratosis, hemangioma, or dermatofibroma. If the lesion does not display any structures common to the aforementioned lesions then the lesion is considered nondescript or featureless. The index of suspicion needs to remain high for all featureless lesions as amelanotic melanoma can present as a completely structureless lesion. These featureless lesions sometimes do reveal blood vessels and, if present, their morphology can often help in narrowing the differential diagnosis.

STEP 1 – LEVEL 1

A melanocytic lesion usually will display one of the following structures:

- Pigment network (**Figure C-4**).
- Negative network (**Figure C-5**).
- Streaks (**Figure C-6**).
- Homogeneous blue pigmentation (**Figure C-7**).
- Aggregated globules (**Figure C-8**).
- Pseudonetwork (facial skin) (**Figure C-9**).
- Parallel pigment pattern (acral lesions) (**Figure C-10**).
- There is one exception to including lesions with pigment network in the melanocytic category; that is, the dermatofibroma in which the pattern trumps the network (**Figure C-11**).

*STM: Short-term monitoring. Never monitor palpable lesions.

FIGURE C-3 Two-step diagnostic procedure requires separating all lesions into melanocytic or nonmelanocytic as step 1. BCC, Basal cell carcinoma; CCA, clear-cell acanthoma; DF, dermatofibroma; HG, hemangioma; SCC, squamous cell carcinoma; SK, seborrheic keratosis.

FIGURE C-4 Pigment network tells us this benign nevus is a melanocytic lesion in step 1 of the 2-step algorithm; that is, it contains melanocytes. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-5 Negative network inform us that this microinvasive melanoma is a melanocytic lesion. The negative network consists of dark, elongated and curved globular structures surrounded by relative hypopigmentation. (Copyright of Ashfaq Marghoob, MD.)

This lesion does not display any of the structures commonly seen in melanocytic lesions (i.e., network, streaks, globules). It also does not have any features of a basal cell carcinoma, seborrheic keratosis, dermatofibroma, or hemangioma. Thus, this is a featureless lesion. However, it does display many irregular tortuous blood vessels, which may be a sign of neoangiogenesis. The possibility of melanoma needs to be entertained for such featureless lesion.

FIGURE C-6 Streaks of the pseudopod type inform us that this is a melanocytic lesion. The 360-degree symmetry is typical in a Spitz nevus. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-7 Homogeneous blue pigmentation is a feature of a melanocytic lesion of the blue nevus type. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-8 Aggregated globules inform us that this benign nevus is melanocytic. (Courtesy of Ashfaq Marghoob, MD.)

FIGURE C-9 Pseudonetwork is the net-like pattern made by white adnexal openings on the face within any pigmented lesion. **A.** Pseudonetwork pattern is seen on the face in this congenital nevus that is melanocytic. **B.** Although this solar lentigo also has a pseudonetwork pattern created by white adnexal openings it is not melanocytic. It does have a typical moth-eaten border found in solar lentigines and seborrheic keratoses. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-10 Nevus on the sole of the foot showing parallel network pigment in the furrows (valleys) rather than the ridges. Note the white eccrine gland openings on the ridges which are wider than the furrows. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-11 Pattern trumps network in this dermatofibroma. Although this appears to have peripheral network, the central stellate scar makes this a dermatofibroma, which is not a melanocytic lesion. (Courtesy of Richard P. Usatine, MD.)

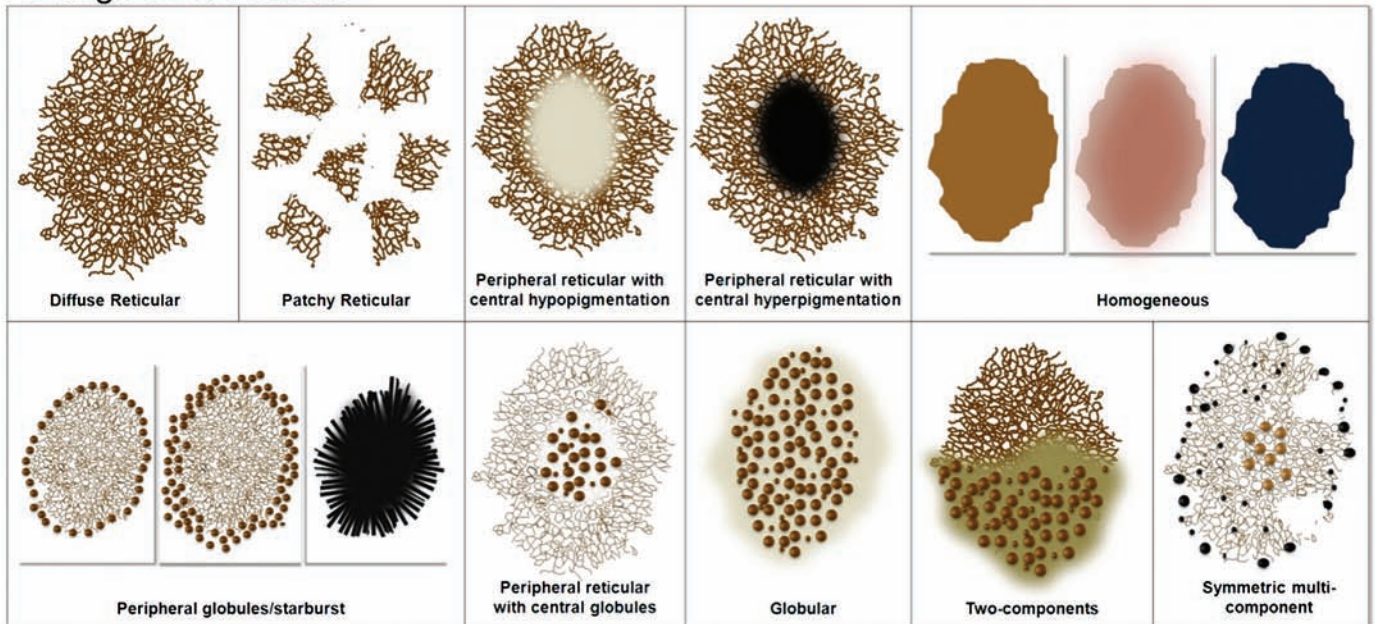

STEP 2

- If the lesion is deemed to be of melanocytic origin, then one needs to decide whether the lesion is a benign nevus or a melanoma.

Nevi tend to manifest one of the following 10 benign patterns (Figure C-12)

1. Diffuse reticular (Figure C-13)
2. Patchy reticular (Figure C-14)
3. Peripheral reticular with central hypopigmentation (Figure C-15)
4. Peripheral reticular with central hyperpigmentation (Figure C-16)
5. Homogeneous (Figure C-17)
6. Peripheral globules/starburst (Figure C-18)
7. Peripheral reticular with central globules (Figure C-19)
8. Globular (Figure C-20)
9. Two-component (Figure C-21)
10. Symmetric multicomponent (note this pattern should be interpreted with caution and a biopsy is probably warranted for dermoscopic novices) (Figure C-22)

Benign Nevi Patterns

Concept and design by Natalia Jaimes, MD and Ashfaq A. Marghoob, MD

Step 2: Nevus versus Melanoma

FIGURE C-12 Benign nevi tend to adhere to 1 of 10 recurrent patterns. Melanoma is a melanocytic lesion that deviates from the 10 benign patterns.

FIGURE C-13 Diffuse reticular pattern in a benign nevus. Note the regular line thickness and the fading of the lines at the periphery. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-16 Peripheral network with a central hyperpigmentation in this benign nevus. The central hyperpigmentation may also be called a typical blotch. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-14 Patchy reticular pattern in a benign nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-17 Homogeneous pattern with a brown coloration in a benign nevus. The color may be brown, pink, or blue. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-15 Peripheral reticular pattern with central hypopigmentation in a benign nevus. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-18 Peripheral globules that are symmetrically placed are visible in this benign nevus. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-19 Peripheral reticular pattern with central globules in this benign congenital nevus. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-21 Two-component pattern with globules on the right and a strictly reticular pattern on the left. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-20 Globular pattern in a benign nevus. Note this globules have a cobblestone pattern but other globules may be rounded. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-22 Symmetric multicomponent pattern. Although this turned out to be a benign nevus, only the most experienced dermoscopist could afford to call this benign without a biopsy. (Copyright of Ashfaq Marghoob, MD.)

In contrast, melanomas tend to deviate from the benign pattern described above. Furthermore, the structures in a melanoma are often distributed in an asymmetric fashion. Most melanomas will also reveal one or more of the melanoma specific structures (**Figure C-23**).

Melanoma Specific Structures	
	Atypical network
	Streaks (pseudopods and radial streaming)
	Negative pigment network
	Shiny white lines (Crystalline structures)
	Atypical dots and/or globules
	Off-centered blotch
	Peripheral tan structureless areas
	Blue-white veil overlying raised areas
	Regression structures • Blue-white veil overlying macular areas, scar-like areas and/or peppering
	Atypical vascular structures • Dotted vessels, serpentine vessels, polymorphous vessels, milky-red areas, red globules, corkscrew vessels

FIGURE C-23 Melanoma-specific structures.

MELANOMA-SPECIFIC STRUCTURES

1. Atypical network (**Figure C-24**)
2. Streaks (pseudopods and radial streaming) (**Figure C-25**)
3. Negative pigment network (**Figure C-26**)
4. Shiny white lines (crystalline structures) (**Figure C-27**)
5. Atypical dots and or globules (**Figure C-28**)
6. Off-center blotch (**Figure C-29**)
7. Peripheral tan structureless areas (**Figure C-30**)
8. Blue-white veil overlying raised areas (**Figure C-31**)
9. Regression structures (blue-white veil overlying macular areas, scar-like areas, and/or peppering) (**Figure C-32**)
10. Atypical vascular structures (dotted vessels, serpentine vessels, polymorphous vessels, milky red areas, red globules, corkscrew vessels) (**Figure C-33**)

Note that melanoma on the soles or palms may present with a parallel ridge pattern (**Figure C-34**).

On the face, with rhomboidal structures (**Figure C-35**).

FIGURE C-24 Atypical network can be seen in this suspicious melanocytic lesion. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-25 Pseudopods can be seen in this melanoma. Pseudopods are streaks with radial streaming, a melanoma-specific structure. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-26 Negative pigment network can be seen on the left side of this melanoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-27 Shiny white lines are visible in this melanoma. Shiny white lines are also called chrysalis or crystalline structures. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-28 Atypical dots and globules are seen in this melanoma. The dots and globules are peripheral and not symmetrically placed. A blue white veil is also visible. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-29 Off-centered blotch in a melanoma. Note the blue-white veil, atypical globules, atypical network, and the peripheral tan structureless areas. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-30 Peripheral tan structureless areas are visible on the bottom left portion of this melanoma (arrow). Note that there is also negative network visible. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-31 Blue-white veil overlying raised area in a melanoma. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-33 Atypical vascular structures can be seen in this amelanotic nodular melanoma. Dotted and serpentine vessels are visible. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-32 Regression structures visible in this melanoma-in-situ. The regression structures consist of blue-white veil overlying macular areas and "peppering." (Courtesy of Richard P. Usatine, MD.)

FIGURE C-34 Acrolentiginous melanoma on the foot with a parallel ridge pattern. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-35 Lentigo maligna on the face with rhomboidal structures. (Copyright of Ashfaq Marghoob, MD.)

STEP 2 FOR MELANOCYTIC LESIONS

Three possible pathways (Figure C-36):

1. The lesion adheres to one of the benign nevus patterns (Figures C-13 to C-22). Reassure the patient that the lesion is a benign nevus.
2. The lesion:
 - A. Adheres to one of the benign nevus patterns but also displays at least one of the melanoma specific structures.
 - B. Does not adhere to one of the benign nevus patterns and does not have any of the melanoma specific structures.

This is an indeterminate or suspicious lesion. The choices include: Perform a biopsy now or perform short-term mole monitoring with dermoscopic photographs and a 3-month followup. (Caveat: Do not monitor a raised lesion because a nodular melanoma can grow quickly with a worsened prognosis in a short time.)
3. The lesion deviates from the benign nevus patterns and has at least one melanoma specific structure (Figures C-24 to C-33).

Biopsy this lesion as a suspected melanoma (see Chapter 172, Melanoma).

STEP 1 FOR NONMELANOCYTIC TUMORS

If the lesion is not of melanocytic origin then one needs to look for structures seen in:

- Dermatofibromas
- Basal cell carcinomas
- Seborrheic keratoses
- Hemangiomas

DERMATOFIBROMA

- a. Peripheral delicate fine network (Figure C-37)
- b. Central scar-like area (Figure C-37)
- c. Blood vessels within the scar-like area (Figure C-38)
- d. Ring-like globular structures (Figure C-39)

Evaluating Melanocytic Lesions With Dermoscopy:

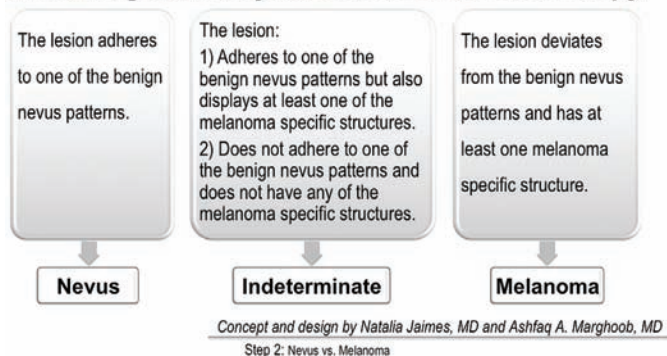

FIGURE C-36 Evaluating melanocytic lesions with dermoscopy.

FIGURE C-37 Peripheral delicate fine network with a central scar-like area are visible in this typical dermatofibroma. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-38 Blood vessels are visible in the scar-like area of the dermatofibroma. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-39 Ring like globular structures are visible in the central scar-like area of the dermatofibroma. (Courtesy of Ashfaq Marghoob, MD.)

BASAL CELL CARCINOMA

- a. Arborizing vessels (**Figure C-40**)
- b. Spoke-wheel-like structures/concentric structures (**Figure C-41**)
- c. Leaf-like areas (**Figure C-42**)
- d. Large blue-gray ovoid nest (**Figure C-41**)
- e. Multiple blue-gray globules (**Figure C-42**)
- f. Ulceration (**Figure C-43**)
- g. Shiny white structures (crystalline structures) (**Figure C-43**)

FIGURE C-40 Arborizing blood vessels like branching trees in a basal cell carcinoma. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-41 Spoke-wheel-like structures and isolated blue-gray ovoid nest on the left of this basal cell carcinoma. (Copyright of Ashfaq Marghoob, MD.)

BASAL CELL CARCINOMA

- a. Arborizing vessels (**Figure C-40**)
- b. Spoke-wheel-like structures/concentric structures (**Figure C-41**)
- c. Leaf-like areas (**Figure C-42**)
- d. Large blue-gray ovoid nest (**Figure C-41**)
- e. Multiple blue-gray globules (**Figure C-42**)
- f. Ulceration (**Figure C-43**)
- g. Shiny white structures (crystalline structures) (**Figure C-43**)

FIGURE C-42 A. Leaf-like structures in a pigmented basal cell carcinoma. B. Leaf-like structures and blue-gray ovoid nest in bottom left hand corner. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-43 Shiny white structures visible in this basal cell carcinoma. Also called chrySTALLINE and chrysalis structures. (Copyright of Ashfaq Marghoob, MD.)

SEBORRHEIC KERATOSIS

- a. Multiple (greater than 2) milia-like cysts (**Figure C-44**)
- b. Comedo-like openings (**Figure C-45**)
- c. Gyri and sulci (fat finger-like structures) (**Figure C-46**) and cerebriform (**Figure C-47**)
- d. Fingerprint-like structures (**Figure C-48**)
- e. Moth-eaten borders (**Figure C-48**)
- f. Additional features: sharp demarcation; negative wobble sign (the lesion slides).

FIGURE C-44 Seborrheic keratosis with milia-like cysts and comedo-like openings. (Copyright of Richard P. Usatine, MD.)

FIGURE C-45 Many comedone-like openings are visible in this seborrheic keratosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-46 Fat fingers are visible in this seborrheic keratosis. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-47 Cerebriform seborrheic keratosis with gyri and sulci. (Courtesy of Richard P. Usatine, MD.)

FIGURE C-48 Note the moth-eaten borders and fingerprint-like structures visible in this early seborrheic keratosis forming from any solar lentigo. (Copyright of Ashfaq Marghoob, MD.)

HEMANGIOMA

- a. Red lacunae (**Figure C-49**)
- b. Blue lacunae (**Figure C-50**)
- c. Black lacunae = angiokeratoma (**Figure C-51**)

FIGURE C-49 Hemangioma showing red lacunae (lakes or lagoons of sharply demarcated vascular tissue). (Courtesy of Richard P. Usatine, MD.)

FIGURE C-50 Hemangioma with red and blue lacunae. (Copyright of Ashfaq Marghoob, MD.)

FIGURE C-51 Angiokeratoma showing purple and black lacunae. (Copyright of Ashfaq Marghoob, MD.)

Note that dermoscopy can be helpful in detecting the scabies mite without having to scrape and use the microscope (**Figure C-52**; see Chapter 143, Scabies).

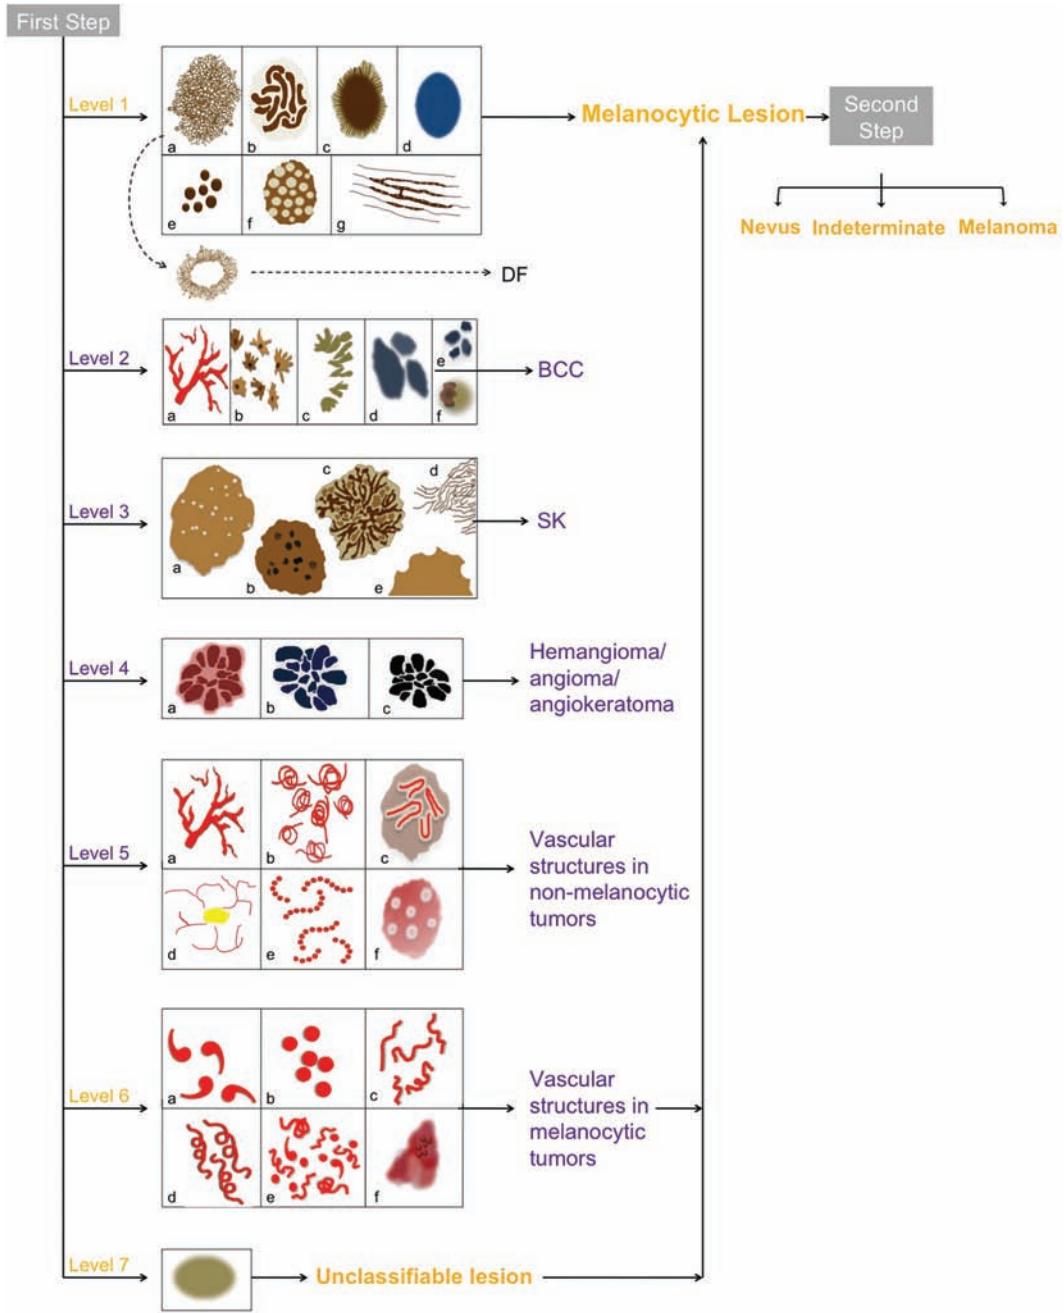

FIGURE C-52 Scabies mites (arrows) visible at the end of 2 intersecting burrows. The head and legs are most visible and resemble arrowheads pointing away from the burrows. (Courtesy of Richard P. Usatine, MD.)

VASCULAR STRUCTURES

Levels 5 and 6 (Figures C-53 and C-54) in step 1 involve evaluating vascular structures in nonmelanocytic and melanocytic tumors. For further information about this more advanced steps see the resources below.

Concept and design by Natalia Jaimes, MD and Ashfaq A. Marghoob, MD
 Step 1: Melanocytic vs. Non-melanocytic

FIGURE C-53 Seven levels are part of the 2-step algorithm. See Figure C-54 for an explanation of the letters and structures in this flow diagram.

Step 1: Melanocytic versus Non-melanocytic lesions						
Level 1: Melanocytic lesions	Level 2: Basal cell carcinoma (BCC)	Level 3: Seborrheic keratosis (SK)	Level 4: Hemangioma (HG)/ angioma/ angiokeratoma	Level 5: Blood vessels in non-melanocytic tumors*	Level 6: Blood vessels in melanocytic tumors*	Level 7: Unclassifiable lesions
a. Pigment network* b. Negative network c. Streaks d. Homogeneous blue pigmentation e. Aggregated globules f. Pseudonetwork (Facial skin) g. Parallel pigment pattern (Acral lesions) h. * Exception to pigment network: Dermatofibroma (DF)	a. Arborizing vessels b. Spoke wheel-like structures / concentric structures c. Leaf-like areas d. Large blue-gray ovoid nests e. Multiple blue-gray globules f. Ulceration g. Additional clues: Shiny white structures	a. Multiple (>2) milia-like cysts b. Comedo-like opening c. Gyri and sulci (Fat finger-like structures) d. Fingerprint-like structures e. Moth-eaten borders f. Additional features: sharp demarcation; negative wobble sign: the lesion slides	a. Red lacunae b. Blue lacunae c. Black lacunae	Morphology a. Arborizing vessels b. Glomerular vessels c. Hairpin vessels with white halo Arrangement d. Crown e. Serpiginous or string of pearls f. "Strawberry" pattern g. Focal clusters at the periphery Distribution • Focal • Diffuse • Central • Peripheral • Random * Usually seen in a. BCC b. Squamous cell carcinoma (SCC) c. SK/ Keratoacanthoma d. Sebaceous hyperplasia (SH) e. Clear cell acanthoma (CCA) f. Actinic keratosis	Morphology a. Comma vessels b. Dotted vessels c. Serpentine vessels (linear irregular) d. Corkscrew vessels e. Polymorphous vessels f. Milky-red area Distribution • Focal • Diffuse • Central • Peripheral • Random * Usually in: a. Intradermal nevi b – f .Melanoma	None of the structures from levels 1 to 6 are noted

Concept and design by Natalia Jaimes, MD and Ashfaq A. Marghoob, MD
 Step 1: Melanocytic vs. Non-melanocytic

- diagnosis of, 1270f–1273f, 1272–1273
 - differential diagnosis of
 - vs. GI blood loss, 1273
 - vs. infections, 1273
 - vs. inflammatory bowel disease, 1273
 - vs. iron-deficiency anemia, 1273
 - vs. irritable bowel disease, 1273
 - epidemiology of, 1270–1271, 1270f–1273f
 - etiology and pathophysiology of, 1270f–1273f, 1271–1272
 - follow-up of, 1274
 - global health problem of, 59–60
 - management of, 1274
 - patient education on, 1274
 - patient story of, 1270, 1270f
 - prevention of, 1274
 - prognosis with, 1274
 - risk factors for, 1272
 - water and sanitation in, 55–56, 55f, 56f
- Intimate partner violence (IPV), 95–100
- child witnesses of, 95
 - definition of, 95
 - diagnosis of, 95f, 96–97, 97f
 - epidemiology of, 95–96
 - follow-up of, 99
 - management of, 97–98, 97f, 98f
 - patient education on, 99–100
 - patient story of, 95, 95f
 - prognosis in, 99
 - risk factors for, 96
 - screening and prevention of, 98–99
- Intra-abdominal infections. *See also specific infections*
- vs. bacterial endocarditis, 290
- Intraarticular fractures, vs. knee soft tissue injuries, 621, 622f
- Intracranial bleeding, vs. child abuse, 85
- Intracranial injury
- from child abuse, 84, 85
 - vs. child abuse, 85

Intracranial pressure, increased
 etiology of, 153
 papilledema from, 151–154, 151f, 152f

Intradermal melanocytic nevus, 946, 946f, 947f

Intradermal nevi, 946, 946f, 947f, 949

Intrahepatic cholestasis of pregnancy
 epidemiology of, 463
 etiology and pathophysiology of, 464
 management of, 465
 patient story of, 462, 462f
 risk factors for, 464

Intrauterine device (IUD)
 copper-containing, 13t, 14–15
 levonorgestrel, 12, 12f, 13t, 14–15

Invasive squamous cell cancer, of cervix, 541–545, 541f–543f. *See also*
 Cervical cancer

Inverse psoriasis, 2, 3f. *See also* Psoriasis
 diagnosis of, 878f, 879, 880f
 differential diagnosis of
 vs. candidiasis, 778, 780f
 vs. tinea cruris, 796, 797f
 distribution of, 880f, 884, 885f
 management of, 880f, 893

Iodine, Lugol's, 530, 531, 532f

Iodine deficiency, 63–64, 64f
 vs. goitrous hypothyroidism, 1349

Iridocyclitis, 135

Iris, melanotic hamartomas of, in neurofibromatosis, 1387–1390, 1390f

Iritis, 135–137
 differential diagnosis of
 vs. acute-angle closure glaucoma, 137
 vs. conjunctivitis, 127, 137
 vs. corneal foreign body/abrasion, 123
 vs. corneal ulceration, 2
 vs. episcleritis, 2, 133
 vs. keratitis, 2
 vs. scleritis, 133, 136–137
 red eye in, 163–168, 164t, 167f
 traumatic, 135, 135f
 from zoster ophthalmicus, 718–722, 718f

Iron deficiency, 63

Iron-deficiency anemia, from hookworms, 1273

Irritable bowel disease, vs. intestinal worms and parasites, 1273

Irritant contact dermatitis, 834–841. *See also* Contact dermatitis

Irritant diaper dermatitis, 646–650, 647f. *See also* Diaper rash

Ischemic colitis, vs. ulcerative colitis, 409, 410f

Ischemic stroke, vs. subdural hematoma, 1377

Ischemic ulcer, of foot, 1255–1257, 1255f, 1256f, 1302, 1303f
 vs. dry gangrene, 1267
 vs. neuropathic ulcer, 1256, 1259

Isoniazid, reactions from, 1211–1222

J

Jaccoud arthropathy, 564f

Jacquemier sign, 464

Jacquet's diaper dermatitis, 648

Janeway lesions, 287–291, 289f. *See also* Endocarditis, bacterial

Joint sepsis, vs. olecranon bursitis, 598

Jones fracture, 611–614, 612f

Junctional nevi, 946f, 948

Juvenile nevi, 946, 946f. *See also* Nevus, benign

Juvenile polyp, 393–397. *See also* Colon polyps

Juvenile rheumatoid arthritis, vs. knee soft tissue injuries, 622

Juvenile transformation zone, persistent, 528f
 colposcopy and diagnosis of, 525, 525f, 526, 528f
 management of, 528

Juvenile xanthogranuloma, vs. hyphema, 161

K

Kala-azar, 67–69, 67f–69f. *See also* Leishmaniasis

Kaposi sarcoma, 1285–1288
 diagnosis of, 1285f–1287f, 1286–1287
 differential diagnosis of
 vs. bacillary angiomatosis, 1287, 1287f
 vs. dermatofibroma, 1287
 vs. hemangioma and angioma, 1287
 vs. hematoma, 1287
 vs. purpura, 1287
 epidemiology of, 1285, 1285f
 etiology and pathophysiology of, 1285–1286
 follow-up of, 1288
 fundamentals of, 1285
 management of, 1287–1288, 1287f
 patient education on, 1288
 patient story of, 1285, 1285f
 prognosis in, 1288
 risk factors for, 1286

Kawasaki disease
 diagnosis of, 209
 differential diagnosis of
 vs. hypersensitivity syndromes, 1054
 vs. scarlet fever, 209, 210, 210f

Kayser-Fleischer ring, 380, 382f

Keloids, 1224–1228
 diagnosis of, 1225, 1225f
 differential diagnosis of
 vs. acne keloidalis, 1225, 1226f
 vs. dermatofibromas, 1225
 vs. dermatofibrosarcoma protuberans, 1225
 vs. hypertrophic scars, 1225
 epidemiology of, 1224, 1224f
 etiology and pathophysiology of, 1224, 1224f
 fundamentals of, 1224
 management of, 1226–1228, 1226f, 1227f
 patient education on, 1228
 patient story of, 1224, 1224f
 in pregnancy, 463
 prevention of, 1228
 prognosis and follow-up for, 1228
 risk factors for, 1225

Keratitis
 differential diagnosis of
 vs. conjunctivitis, 128, 128f
 vs. corneal foreign body/abrasion, 124
 vs. scleritis and episcleritis, 133
 vs. uveitis and iritis, 137
 herpetic, 128, 128f
 vs. conjunctivitis, 128, 128f
 red eye in, 163–168, 164t, 166f
 from zoster ophthalmicus, 718–722, 718f

Keratoacanthoma, 977–980
 diagnosis of, 977f–979f, 978
 differential diagnosis of
 vs. actinic keratosis, 978

- Keratoacanthoma (*Continued*)
- vs. basal cell carcinoma, nodular, 995
 - vs. common warts, 751
 - vs. cutaneous horn, 978
 - vs. squamous cell carcinoma, 978, 1005, 1005f
- epidemiology of, 977
- etiology and pathophysiology of, 977–978

 with obesity, 1331, 1332f
 patient education on, 1327
 patient story of, 1322, 1322f, 1323f
 prevention and screening for, 1327
 prognosis in, 1327
 risk factors for, 1323
- Xerophthalmia, from vitamin A deficiency, 61–62, 62f
- Xerosis
 with atopic dermatitis, 827, 831f
 vs. X-linked ichthyosis, 1233
- Xerostomia, dental caries with, 263, 265
- X-linked ichthyosis, 1229–1234
 diagnosis of, 1230, 1232f, 1233f
 differential diagnosis of
 vs. acquired ichthyosis, 1233, 1234f
 vs. asteatotic eczema, 1233
 vs. ichthyosis vulgaris, 1233, 1234f
 vs. lamellar ichthyosis, 1233, 1235f

- vs. xerosis, 1233
- epidemiology of, 1229
- etiology and pathophysiology of, 1229
- follow-up of, 1234
- management of, 1233–1234
- patient education on, 1234

Y

Yeast infection, 499–503. *See also Candida vulvovaginitis*
Yeast onychomycosis, 1161
Yeast vaginitis, 499–503. *See also Candida vulvovaginitis*
Yolk sac, on first trimester ultrasound, 476, 476f

Z

Zinc deficiency, 62–63, 63f

- acrodermatitis enteropathica from, 648, 648f
- vs. seborrheic dermatitis, 873

Zoster. *See Herpes zoster*

Zoster ophthalmicus, 718–722

- diagnosis of, 718f–720f, 720
- differential diagnosis of
 - vs. abrasions, traumatic, 720
 - vs. conjunctivitis, 720
 - vs. glaucoma, 720
 - vs. pemphigus, 720
 - vs. trigeminal neuralgia, 720
- epidemiology of, 718
- etiology and pathophysiology of, 718–719, 718f–720f
- follow-up of, 722
- fundamentals of, 718
- management of, 721
- patient education on, 722
- patient story of, 718, 718f
- prevention of, 721
- prognosis in, 721–722
- risk factors for, 719

Note: In this index, the letters “f” and “t” denote figures and tables, respectively.

A

- Abscess and microabscess, 698–700, 698f–700f
 - acne conglobata, 652, 653f
 - breast abscess, 546–549, 546f, 548f, 553
 - breast cellulitis, 546, 546f
 - caries, early childhood, 258
 - cellulitis, 693–697, 693f, 696f
 - dermatitis herpetiformis, 1114, 1125–1126
 - endocarditis, bacterial, 287–291
 - Entamoeba histolytica*, 1270–1274
 - hemorrhoids, 414–418, 414f–416f
 - hidradenitis suppurativa, 516, 671–674, 672f, 674f, 1333f
 - injection-drug use, 1439–1444, 1440f, 1441f
 - lung cancer, 355–363
 - mycosis fungoides, 1042–1047
 - paronychia, 739, 1166–1169, 1166f–1168f
 - peritonsillar pharyngitis, 213–218, 214f
 - pneumonia, 303, 304f
 - pyoderma gangrenosum, 1028–1034
 - scarlet fever, 211
 - sinusitis, 197–202, 198f, 200f
 - tuboovarian abscess, 20
- Acetowhite changes, colposcopy
 - cervical cancer, 541–545, 541f
 - high-grade cervical lesions, 535–536, 535f, 537f
 - low-grade cervical lesions, 530–533, 530f, 531f
 - vulvar intraepithelial neoplasm, 520, 520f
- Alopecia
 - acne keloidalis nuchae, 665–669
 - alopecia areata, 1128–1131, 1128f–1132f, 1141
 - alopecia totalis, 1128, 1128f
 - alopecia universalis, 1128
 - androgenetic alopecia, 1141
 - dermatitis, seborrheic, 1141
 - discoid lupus erythematosus, 1070–1078, 1075f, 1076f
 - drug-induced alopecia, 1141
 - erythroderma, 915–921
 - folliculitis decalvans, 680–684, 682f
 - lichen planus, 901–908
 - mixed connective tissues disease, 1083
 - mycosis fungoides, 1042–1047, 1045f
 - postpartum, 464, 464f
 - sarcoidosis of scalp, 1141
 - scarring alopecia, 666, 667f, 1135, 1138–1143, 1138f–1142f
 - syphilis, secondary, 1141
 - telogen effluvium, 464, 464f, 1141
 - tinea, 772, 772f
 - tinea capitis, 772f, 782–786, 783f, 1141
 - traction alopecia, 1141
 - traction hair loss, 1133–1136, 1133f
 - trichotillomania, 1133–1136, 1134f–1136f, 1141
- Annular lesion
 - basal cell carcinoma, 990f
 - bullous fixed drug eruption, 1211–1222, 1213f
 - erythema annulare centrifugum, 1054, 1236–1239, 1236f–1238f
 - erythema chronicum migrans of Lyme disease, 824
 - erythema multiforme, 866
 - granuloma annulare, 789, 792f, 1022–1027, 1022f–1026f
 - lichen planus, 901–908
 - linear porokeratosis, 961

- Lyme disease, 1289–1296, 1289f–1291f
- pigmented purpuric dermatosis, Majocchi type, 1066, 1067f
- pityriasis rosea, 896–900, 897f, 900f
- psoriasis, 878–894, 883f
- reactive arthritis, 910–914, 910f, 911f
- sarcoidosis, 1035–1040, 1035f, 1039f
- tinea, 771f, 778, 780f
- tinea barbae, 785, 786f
- tinea capitis, 782–786, 784f
- tinea corporis, 771–776, 771f, 788–793, 788f–791f, 852, 888
- tinea cruris, 888
- tinea faciei, 771–776, 771f, 772
- urticaria, 863–869, 866f

Atrophy

- atrophic vaginitis, 485, 486, 489–492, 489f, 490f
- basal cell carcinoma, 989–997, 991f
- cervical atrophy, 527, 527f, 528
- cocaine abuse, 1431–1437, 1434f
- cortical/cerebral, normal pressure hydrocephalus, 1380–1382, 1380f
- corticosteroids, 1453t
- diabetic dermopathy, 1302f, 1314–1316, 1314f–1316f
- filiform papillae, geographic tongue, 232f, 233, 233f, 235f
- gastritis, chronic, 372, 374
- lichen planus, 901–908, 904f
- lichen sclerosus et atrophicus, 92, 92f, 491, 521, 522f
- lupus
 - chronic cutaneous lupus erythematosus, 1140, 1142f
 - systemic lupus erythematosus, 1070–1078, 1072f
- muscle, scleroderma, 1089–1095, 1091f
- mycosis fungoides, 1042–1047
- necrobiosis lipoidica, 1303f, 1315, 1317–1320, 1318f–1321f
- optic, hyphema, 162
- optic nerve, glaucoma, 139–142
- porphyria cutanea tarda, 1119–1121
- retina, age-related macular degeneration, 156, 157f
- skin tag, 922–924
- testicular, liver disease, 380
- tubular, polycystic kidneys, 436–439
- vaginal epithelium, 527, 527f, 528
- vulvar intraepithelial neoplasia, 520, 521f

B

- Bite, sexual assault, 105
 - Black dots
 - nevus
 - congenital nevus, 953–956, 953f–955f
 - nevus spilus, 946, 947f, 953–956, 954f
 - tinea capitis, 782–786, 783f
 - wart
 - common, 749–754
 - plantar, 766–769, 766f–768f
- ## Blanching
- angioma, 1287
 - drug reactions, cutaneous, 1211–1222
 - erythema toxicum neonatorum, 630–634
 - hemangioma, 1287
 - childhood, 636–640
 - measles, 723–726
 - Rocky Mountain spotted fever, 1066, 1068f

- scarlet fever, 208–212
vascular lesions, adult acquired, 1204, 1205f
- Bulla**, 1097–1103, 1097f–1103f
acropustulosis of infancy, 1102
acute febrile neutrophilic dermatosis, 1031, 1032f
arthropod reaction, 1100, 1102f
bacterial infections, 1100, 1102f
bullosis diabeticorum, 1097, 1097f, 1100, 1101f
bullous fixed drug eruption, 1214f, 1218f
bullous mastocytosis, 1102
bullous myringitis, 173, 175f
bullous pemphigoid, 1098, 1098f, 1099f, 1104–1107, 1104f–1108f
Candida, 1102
cellulitis, 693–697, 695f
chronic obstructive pulmonary disorder, 334–343, 339f
cicatrical pemphigoid, 1098, 1099f, 1103
coumadin necrosis, 1213f
cryotherapy, 1100, 1101f
dermatitis
allergic contact dermatitis, 1100, 1101f
contact dermatitis, 834–841, 834f, 835f, 839f, 1100, 1101f
dermatitis herpetiformis, 1098, 1103, 1125–1126
irritant contact dermatitis, 1100, 1101f
diaper rash, 646–650
drug eruptions, 1100, 1101f
drug reactions, cutaneous, 1211–1222, 1214f
eczema
hand, 843–849
nummular, 888
edema blisters, 1102
epidermolysis bullosa, 1121–1123, 1121f, 1123f

dermatitis
 atopic dermatitis, 826–833, 826f–833f
 contact dermatitis, 819f, 834f–839f, 840f
 dermatitis, perioral, 661, 664f
 seborrheic dermatitis, 820, 871–876, 871f, 872f, 874f, 875f, 1141
 stasis dermatitis, 1315
 dermatofibroma, 935–938, 937f
 dermatomyositis, 1079–1087, 1079f
 diabetic dermopathy, 1314–1316, 1314f–1316f
 diaper rash, 646–650, 646f, 648f
 eczema
 areola, 559, 559f
 asteatotic, 1233
 dyshidrotic, 801, 802f, 831, 839
 hand, 843–849, 845, 845f
 nummular, 851–854, 853f, 970, 972, 1024
 erythema annulare centrifugum, 791, 792f, 1024, 1236–1239, 1236f–1238f
 erythrasma, 689–692, 690f
 erythroderma, 915–921
 folliculitis decalvans, 1138f, 1140
 fungal infections, cutaneous, 824
 Grover disease, 683, 683f
 ichthyosis
 acquired, 831f, 1233, 1234f
 ichthyosis vulgaris, 1233, 1234f
 lamellar, 1233, 1235f
 X-linked, 1229–1234, 1232f, 1233f
 keratosis, 926–930, 927f
 lichen planopilaris, 1139f
 lichen planus, scalp, 901–906
 lichen simplex chronicus, 856–862, 858f, 859f
 lupus
 chronic cutaneous lupus erythematosus, 906
 discoid lupus erythematosus, 996, 1070–1078, 1074f, 1075f
 discoid lupus erythematosus, scarring alopecia, 1140, 1142f
 neonatal lupus, 634
 mycosis fungoides, 1042–1047, 1042f, 1043f
 onychomycosis, 1160–1164, 1160f–1162f
 Paget disease of breast, 557–560, 557f, 558f
 pemphigus foliaceus, 1109–1117, 1110f–1112f
 pigmented seborrheic keratosis, 937
 pityriasis rosea, 896–900, 896f–898f, 1024
 psoriasis, 791, 792f, 878–894, 878f–880f, 882f, 883f, 885f, 906
 plantar, 804f
 scalp, 785
 reactive arthritis, 910–914, 911f, 912f
 scabies, 70, 70f, 71, 71f, 644
 seborrhea, 785, 785f
 scalp, 785
 seborrheic keratosis, 1311
 tinea, 771–776, 771f, 774t
 tinea capitis, 782–786, 782f, 784f, 1141
 tinea corporis, 677, 789f, 852, 1238, 1238f
 tinea cruris, 795–798, 795f–797f
 tinea manus, 847
 tinea pedis, 799–804, 800f
 tinea versicolor, 805–808, 806f, 899
 transient neonatal pustular melanosis, 642–644
 xerosis, 1233

Scar

acne
 acne conglobata, 652, 653f
 acne keloidalis nuchae, 682f
 acne vulgaris, 651–657, 651f
 cicatricial bullous pemphigoid, 1106, 1106f
 cicatricial pemphigoid, 1114
 cocaine abuse, 1431–1437, 1434f
 conjunctival, in red eye, 168
 corneal, zoster ophthalmicus, 718–722, 718f
 dermatofibrosarcoma, 1225
 epidermolysis bullosa acquisita, 1098
 epidermolysis bullosa simplex, 1103f
 erythema induratum of Bazin, 1059
 folliculitis, 680–684, 681f, 682f
 granuloma gluteale infantum, 648
 herpes zoster, skin, 712–716, 712f
 hidradenitis suppurativa, 671–674, 672f–675f, 1333f
 hypertrophic scarring, 668f, 937
 injection-drug use, 1439–1444, 1439f, 1441f–1443f
 keloids, 1224–1228, 1224f–1227f
 lupus
 discoid lupus, 1181
 discoid lupus erythematosus, 1070–1078, 1074f–1076f, 1093
 systemic lupus erythematosus, 661, 1070–1078, 1072f, 1093
 porphyria cutanea tarda, 1100
 scarring alopecia, 666, 667f, 785, 1135, 1138–1143, 1138f–1142f
 scleroderma, 1089–1095, 1093f
 self-inflicted dermatoses, 856–862, 856f, 858f
 subretinal, age-related macular degeneration, 156, 157f
 vasculitis, 1062–1069
 Stone
 gallstones, 386–391, 386f, 388f–390f
 kidney stones, 425–428, 425f–427f
 polycystic kidneys, 437

T

Target lesion
 erythema multiforme, 468, 471f, 734, 866, 866f, 1049–1055, 1050f, 1052f, 1053f, 1124, 1282
 Stevens–Johnson syndrome, 1049–1055, 1050f
 Telangiectasia
 ataxia telangiectasia, 1389
 basal cell carcinoma, 115
 nodular, 933, 933f, 989–997, 994f
 Bloom syndrome, 1389
 corticosteroids, 1453t
 CREST syndrome, 1209
 dermatitis, seborrheic, 661
 dermatomyositis, 1079–1087, 1082f, 1083f
 discoid lupus erythematosus, 1070–1078
 erythema ab igne, 1198–1201
 hemangioma, childhood, 636–640, 636f–639f
 hereditary hemorrhagic telangiectasias, 1207–1210, 1207f
 hydrocystoma, 116f
 keratoacanthoma, 977–980, 977f–979f, 995
 necrobiosis lipoidica, 1303f, 1315, 1317–1320, 1317f–1320f
 nevus
 benign nevus, 945–951
 dermal nevus, 947f, 949, 995, 995f
 rosacea, 659–664, 660f–663f
 rosacea fulminans, 652

scleroderma, 1089–1095, 1091f, 1092f
 sebaceous hyperplasia, 931–934, 931f, 932f, 995, 996f
 squamous cell carcinoma, 999–1007, 1005f
 tuberous sclerosis, 1388

Tracks, skin
 cocaine abuse, 1431–1437, 1433f
 cutaneous larva migrans, 823–825, 823f, 824f
 heroin, IV, 1439, 1439f
 injection-drug use, 1439–1444, 1439f, 1441f, 1442f

Tracts, sinus
 acne conglobata, 652, 653f
 hidradenitis suppurativa, 671–674, 672f, 675f, 1333f

Trauma
 eye, 165, 166f, 167f
 corneal, 122–125, 122f–124f
 globe injury, 165, 167f
 hyphema, 159–162, 159f, 160f, 165, 167f
 subconjunctival hemorrhage, 164t, 165, 166f
 uveitis and iritis, 135–137, 135f, 165, 167f
 without hyphema, 160, 160f
 head
 normal pressure hydrocephalus, 1380–1382, 1380f, 1381f
 subdural hematoma, 1376–1379, 1376f–1378f
 intimate partner violence, 95–100, 95f–98f
 nail, 1146, 1146f–1148f, 1148t, 1149
 Beau lines, 1146, 1147f, 1148f
 leukonychia, 1145f, 1146, 1148t
 nail hypertrophy, 1145, 1146, 1146f
 onychogryphosis, 1145, 1146, 1146f
 onychoschizia, 1177, 1177f
 pseudo-Hutchinson's sign, 1153, 1154f
 subungual hematoma, 1175–1177, 1175f–1177f
 physical abuse, child, 82–87, 82f–86f
 sexual abuse, child, 89–93, 89f–92f, 89f–93f

Tumor and cancer
 actinic keratosis, 969–975, 969f–971f, 973f
 adenoid cystic carcinoma, 207, 207f
 angiosarcoma, 1203–1206
 basal cell carcinoma, nodular, 933, 933f
 bladder cancer, 448–452, 448f, 449f, 451t
 breast
 Bowen disease, 559
 breast cancer, 551–556, 551f–555f
 Burschke-Lowenstein, 762, 763f
 cervical cancer, colposcopy, 541–545, 541f–543f, 544t
 cervical intraepithelial neoplasia II/III, 535–539, 535f–538f
 colon cancer, 399–403, 399f, 402f, 403f
 cutaneous angiosarcoma, 1205f
 dermatofibrosarcoma protuberans, 936
 endocrine, acromegaly from, 1360–1364, 1360f–1362f
 glomus (glomangioma), 1167, 1203–1206, 1205f, 1209
 malignant fibrous histiocytoma, 936
 melanoma, 1008–1020, 1008f–1018f
 acral lentiginous, of foot, 1243–1244
 subungual, 1151–1154
 superficial spreading, of breast, 559, 559f
 mycosis fungoides, 1042–1047, 1043f, 1044f
 neurofibroma, 937
 neurofibromatosis, 1387–1390, 1387f–1390f
 oral cancer, 253–256, 253f–256f
 pigmented nail disorders, 1151–1154, 1152f–1154f

prostate cancer, 453–459, 453f–455f, 458f
 pseudosarcomatous dermatofibrosarcoma, 936
 renal cell carcinoma, 441–446, 441f, 442f, 444t
 squamous cell carcinoma, tobacco, 1401, 1402f
 syringoma, 933, 933f
 thyroid cancer, 1349, 1350f
 vascular type, pregnancy, 464, 465f
 xanthoma, 933, 1304f, 1322–1327

U

Ulcer

acute necrotizing ulcerative gingivitis, 236–238, 237f
 aphthous, 244–248, 244f, 245f
 aphthous stomatitis, 733
 basal cell carcinoma, 989–997, 992f–995f
 Behçet syndrome, 245f, 246, 246f, 739, 739f
 cancer, oral, 246

Strength of Recommendation (SOR)

Definition

A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1447–1450 for further information.
